Email: fschepis@unimore.it

Background and aims: Age is frequently considered a limiting factor for transjugular intrahepatic portosystemic shunt (TIPS). We aimed to assess the impact of age on post-TIPS outcomes, focusing on transplant-free survival (TFS) and overt hepatic encephalopathy (OHE) as co-primary endpoints, and rebleeding as a secondary endpoint, in patients undergoing pre-emptive or rescue TIPS for acute variceal bleeding.
Method: We analyzed the prospective multicenter EUROTIPS registry (18 centers, 2020–2024) including 370 patients who underwent pre-emptive (41%) or rescue (59%) TIPS and had ≥12 months follow-up. Mean age was 56 ± 12 years, with 21% aged ≥65 years. All stents were covered. External validation was performed in a retrospective multicenter Chinese cohort (5 centers, 2012–2024; n = 464; mean age 57 ± 11 years; 100% covered stents). Patients were stratified by age (<45, 45–54, 55–64, ≥65 years), MELD score, and Child–Pugh class. One-year TFS and OHE-free survival were estimated using the Kaplan-Meier method and compared by log-rank test.
Results: In the European cohort, 1-year TFS was 65.1% (95% CI 60.5–70.2) and 1-year OHE-free survival reached 57.9% (95% CI 52.6–63.7). Age was not associated with 1-year TFS, neither as a continuous variable (p = 0.566) nor across age classes (p = 0.294). MELD (<14 vs ≥14) and Child–Pugh class effectively stratified TFS (p < 0.001), with no additional prognostic value of age within risk strata. Similar results were observed in the Chinese cohort, despite major differences in etiology (57% viral-related vs 57% alcohol-related cirrhosis in EUROTIPS registry) and baseline liver disease severity (mean MELD score 12.0 ± 4.2 vs 15.8 ± 6.8 in EUROTIPS registry). Conversely, OHE was strongly age-dependent in both cohorts. One-year OHE-free survival declined from 77.8% in patients ≤45 years to 36.3% in those ≥65 years in the EUROTIPS cohort (p < 0.001), and from 89.8% to 61.7% in the Chinese cohort (p < 0.001). One-year rebleeding rates were low (8.8% EUROTIPS; 11% Chinese) and were almost exclusively associated with TIPS dysfunction.
Conclusion: Liver disease severity, rather than chronological age, determines 1-year TFS after TIPS for acute variceal bleeding. In contrast, post-TIPS OHE is strongly age-dependent and only marginally influenced by liver function. These data challenge age-based exclusion from TIPS. Risk stratification should prioritize liver disease severity for survival prediction, while age-specific strategies may optimize OHE prophylaxis.

THU-493-YI

Prognostic value of SSI-2D-shear wave elastography–derived indices for predicting hepatic decompensation

Christian Sebesta[1,2,3], Georg Kramer[1,2,3,4], Nina Dominik[1,2], Benedikt Hofer[1,2,3,4], Lorenz Balcar[1,2,3], Paul Thöne[1,2,3], Marlene Hintersteininger[1,2,3], Emilia Korn[1], Mathias Jachs[1,2,3], Lukas Hartl[1,2,3], Georg Semmler[1,2,3], Benedikt Simbrunner[1,2,3], Michael Trauner[1,3], Albert Friedrich Stättermayer[1,3], Mattias Mandorfer[1,2,3], Thomas Reiberger[1,2,3,4], David Bauer[1,5].

Email: christian.a.sebesta@meduniwien.ac.at

Background and aims: Accurate non-invasive prediction of hepatic decompensation in compensated advanced chronic liver disease (cACLD) remains an unmet clinical need. In this study, we evaluated the value of Supersonic Imagine 2D-shear wave elastography-based liver (SSI-LSM) and spleen (SSI-SSM) stiffness measurements or derived composite scores for risk stratification and prognostication for hepatic decompensation.
Method: We conducted a prospective study enrolling consecutive patients with cACLD undergoing HVPG measurement and same-day SSI-LSM and SSI-SSM. Patients with unreliable SSI-LSM (IQR/median >30%; n = 55) were excluded. Associations of SSI-LSM, SSI-SSM and combined elastography-based models with hepatic decompensation were analyzed using Fine–Gray models with liver transplantation and death as competing risks. Discriminative performance was assessed using time-dependent, competing-risk–aware C-statistics at 1 year (Y1) and by decision-curve analysis (DCA). Composite scores (SSI-LSPS: LSM-Spleen size-to-platelet ratio; SSI-ANTICIPATE: LSM, PLT; and SSI-LPS: LSM-platelet-SSM) were calculated according to their original publications.
Results: A total of 142 patients were included (median age 56 years; 76% male; median HVPG 11 mmHg; CSPH 57.7%; Y1 decompensation 9.2%). Median SSI-LSM and SSI-SSM were 24.6 (IQR 13.3–50.0) kPa and 50.4 (IQR 30.9–66.0) kPa; 52% had SSI-LSM >21 kPa and 65% SSI-SSM >40 kPa. In Fine–Gray models, each 1-kPa increase in SSI-LSM was associated with higher Y1 decompensation risk (sHR 1.02, 95% CI 1.01–1.03). Each IQR increase in SSI-LSPS (sHR 2.53, 95% CI 1.69–3.79), SSI-LPS (sHR 3.14, 95% CI 1.79–5.52), and SSI-ANTICIPATE (sHR 3.15, 95% CI 1.78–5.58) was also associated with decompensation (all p < 0.001). Time-dependent AUROCs at Y1 were 0.73 for SSI-LSM, 0.67 for SSI-SSM, and 0.83 for HVPG. Compared with SSI-LSM, discrimination was significantly improved by SSI-LPS (AUROC 0.77; p = 0.031) and SSI-ANTICIPATE (AUROC 0.77; p = 0.016) and numerically improved by SSI-LSPS (AUROC 0.81; p = 0.053). DCA showed the most consistent net benefit for SSI-LSPS, while SSI-ANTICIPATE performed best at intermediate risk thresholds.
Conclusion: Composite SSI-2D-SWE-derived scores seem to improve prognostication and risk discrimination beyond SSI-LSM alone for predicting first hepatic decompensation in cACLD patients. While our findings support the utility of non-invasive LSM/PLT-based composite scores for risk stratification, the value of additional SSM remains to be defined.

THU-494

Prognostic value of grading esophageal varices for decompensation and mortality in compensated and decompensated cirrhosis

Christian Sebesta[1,2,3], Georg Kramer[1,2,3,4], Benedikt Hofer[1,2,3,4], Paul Thöne[1,2,3], Marlene Hintersteininger[1,2,3], Lorenz Balcar[1,2,3], Mathias Jachs[1,2,3], Lukas Hartl[1,2,3], Jurij Maurer[1,5], David Bauer[1,6], Georg Semmler[1,2,3], Benedikt Simbrunner[1,2,3], Michael Trauner[1,3], Albert Friedrich Stättermayer[1,2], Mattias Mandorfer[1,2,3], Thomas Reiberger[1,2,3,4]. [1]*Division of Gastroenterology and Hepatology, Department of Medicine III, Medical University of Vienna, Vienna, Austria, Vienna, Austria;* [2]*Vienna Hepatic Hemodynamic Lab, Division of Gastroenterology and Hepatology, Department of Medicine III, Medical University of Vienna, Vienna, Austria, Vienna, Austria;* [3]*Clinical research group MOTION, Medical University of Vienna, Vienna, Austria, Vienna, Austria;* [4]*Christian-Doppler Laboratory for Portal Hypertension and Liver Fibrosis, Medical University of Vienna, Vienna, Austria, Vienna, Austria;* [5]*Klinikum Landstrasse, Vienna Healthcare Group, Vienna, Austria, Vienna, Austria;* [6]*Klinikum Ottakring, Vienna Healthcare Group, Vienna, Austria, Vienna, Austria*
Email: christian.a.sebesta@meduniwien.ac.at

Background and aims: Clinically significant portal hypertension (CSPH) is a key driver of decompensation and mortality in advanced chronic liver disease (ACLD). Esophageal varices (EV) represent a clinical manifestation of portal hypertension. Since EV grading for size is subject to interobserver variability, the prognostic implications of grading EV size in compensated (cACLD), and particularly in decompensated ACLD (dACLD) remains to be determined. We aimed to evaluate the prognostic value of EV presence and grading for the risk of hepatic decompensation in cACLD and liver-related death (LRD) in dACLD.
Method: Patients recruited in the prospective Vienna Cirrhosis study (VICIS) with available information on EV status were analyzed. EV were stratified as absent (no-EV), small <5 mm (S-EV) and large ≥5 mm (L-EV) varices. Cumulative incidence functions were used to estimate the incidence of hepatic decompensation and LRD, treating non–LRD and liver transplantation (LT) as competing events. Associations with hepatic decompensation and LRD were evaluated using Fine–Gray competing-risk regression, adjusting for age, sex, and MELD.
Results: A total of 516 patients were included (236 cACLD, 280 dACLD). In cACLD, hepatic venous pressure gradient (HVPG) increased with variceal status (median HVPG: no-EV 9 vs. S-EV 14 vs. L-EV 17 mmHg; $p < 0.001$), paralleled by higher 2-year (Y2) decompensation rates (14%, 24%, and 36%, respectively; Gray's $p = 0.008$). Presence of L-EV was linked to higher Y2 decompensation risk vs. no-EV (sHR 2.92 [1.44–5.89], $p = 0.003$), whereas S-EV were not (sHR 2.01 [0.89–4.53], $p = 0.092$). In dACLD patients, HVPG also increased with EV grade (16 vs. 19 vs. 19 mmHg; $p < 0.001$). Y2-LRD rates were 12%, 22%, and 17% for no-EV, S-EV, and L-EV, respectively (Gray's $p = 0.236$). dACLD patients with L-EV showed a higher Y2 LRD risk versus no-EV (sHR 2.67 [1.00–7.10], $p = 0.049$), whereas S-EV showed only a numerical trend (sHR 2.50 [0.99–6.30], $p = 0.051$). Overall, the presence of EV (vs. absent EV) was independently associated with worse outcomes in both cACLD (Y2 decompensation: sHR 2.49 [1.31–4.72], $p = 0.005$) and dACLD (Y2 LRD: sHR 2.58 [1.09–6.13], $p = 0.031$).
Conclusion: EV reflect the presence of CSPH, and HVPG increases with EV size in both cACLD and dACLD. In cACLD, EV grading showed prognostic relevance, with L-EV identifying patients at increased risk for decompensation versus absent EV, whereas in dACLD, L-EV remained significantly associated with higher LRD risk versus absent EV.

THU-495

Endo-TIPSitis in vascular liver diseases- a case series with mid-term follow-up

Ankita Singh[1], Akash Shukla[1], Yash Kallurwar[1]. [1]*Seth G S Medical College, Mumbai, India*
Email: drakashshukla@yahoo.com

Background and aims: Sustained bacteremia associated with stent infection or "Endo-TIPSitis" is a rare and life-threatening complication of TIPS. This case series describes TIPS-related infections in patients with vascular liver disease- the clinical course, diagnostic and therapeutic challenges, and outcomes.
Method: Single-center, prospective study of all patients with vascular liver diseases [Budd-Chiari syndrome (BCS) and portosinusoidal vascular disorder (PSVD)] who underwent TIPS between June 2019 to June 2025.
Results: A total of 156 TIPS procedures were performed in 123 patients during the study period. Early post-procedure sepsis (within 48 hours), defined by fever (≥38 °C) and tachycardia with or without hypotension, occurred in 21 patients (17%). Among these, 3 patients (14.3%) died during the index hospitalization, and 5 (23.8%) were subsequently diagnosed with endo-TIPSitis. Overall, 8 of 123 patients (6.5%) fulfilled criteria for endo-TIPSitis (7- BCS and 1-PSVD). The median MELD and Rotterdam scores of patients with endo-TIPSitis were 11 (range: 9–14) and 1.108 (range: 0.061–1.2), respectively. Fever in the immediate post-procedure phase was not observed in 3 (37.5%) patients. The median interval from intervention to fever onset was 42 days (range: 1–130 days), and stent thrombosis was present in all but one patient. Metastatic infectious foci in the form of septic pulmonary emboli and infarction was seen in 5 (62.5%) patients. Pseudomonas aeruginosa was the most frequently isolated pathogen, followed by Klebsiella pneumoniae; most isolates were carbapenem resistant, with acquisition of multidrug resistance documented in three patients over the treatment course. PET imaging demonstrated characteristic circumferential tracer uptake along the stent (mean SUV_{max} 7.43 on FDG-PET) and metabolically active thrombus within the stent. Median duration of antibiotic therapy was 67 days (range: 7–215 days), and median time to clinical remission was 40 days (range: 19–122 days). Overall mortality among patients with endo-TIPSitis was 50% (4/8); two patients remain on ongoing therapy, while two achieved sustained remission and remain afebrile 8 and 9 months after treatment discontinuation.
Conclusion: Endovascular stent infection or endo-TIPSitis is a serious complication of TIPS procedure, characterized by frequent stent thrombosis/dysfunction and acquisition of antibiotic resistance; requiring prolonged antibiotic therapy and long time to attain clinical remission; and associated with high mortality.

THU-496

Regular human albumin therapy in decompensated cirrhosis: Six-month clinical outcomes from a multicentre Australian cohort

Email: siddharth.sood1@nh.org.au

Background and aims: Long-term outpatient human albumin (HA) has shown benefits in randomized trials. However, trial populations exclude patients with the complexity seen in routine practice. Real-world data has been limited to a few European nations. We aimed to evaluate safety and clinical outcomes in the largest real-world cohort of HA outside Europe.
Method: Retrospective data was obtained from 11 centres in a larger cost comparison study through the Gastroenterological Society of Australia Liver Faculty Clinical Research Network. Patients with cirrhosis who had a baseline TIPPS, transplant or PVT were excluded. Patients were censored at 6 months, liver transplant or death. Standard statistical tests were applied.
Results: We included 134 patients initiating HA (median age 62.7 yrs, 43 female (32.1%), 17 (12.7%) with HCC < 12 months. Nearly all patients 125/134 (93.3%) had ascites. Alcohol-related liver disease (86, 64.2%) with half actively drinking, and steatotic liver disease (46, 34.3%) were predominant aetiologies. 2,298 infusions were performed with on average 40 g administered as 20% concentrated albumin each time (CSL Ltd, Australia), and a median 19 infusions/patient. There were 2 minor complications (0.09% complication rate) - nausea and a painful cannulation. Twenty-nine patients were censored before 6 months: 21 (15.7%) died a median of 118 days after commencing HA (17/21 liver-related), whilst 8 (5.97%) received a transplant; an additional 11 patients discontinued before 6 months. Recompensation was rare, whilst 7 patients were referred for TIPPS (5.22%). Among 105 patients not censored before 6 months, patients on diuretics decreased from 91.8% to 74.5% ($p = 0.0003$) and ascites severity improved ($p < 0.0001$). The proportion of patients requiring outpatient paracentesis decreased from 67.9% in the preceding 6 months, to 44.8% in the subsequent period ($p < 0.0001$). Serum albumin increased from a median of 30 to 35 ($p < 0.0001$), while MELD-Na showed a non-significant improvement from 19 to 17 ($p = 0.08$). Most patients 78/105 (74.3%) were planned to continue HA beyond 6 months.
Conclusion: In this real-world Australian cohort of patients receiving nearly 2,300 outpatient HA infusions, therapy was safe and associated with clinically meaningful improvements to ascites despite substantial baseline disease burden. HA presents a pragmatic strategy to lessen healthcare utilisation in routine practice and offers a palliative-type benefit for a large proportion of patients.

THU-497-YI
Contribution of myofibroblast activation and sinusoidal capillarization to portal hypertension

Thomas Sorz-Nechay[1,2,3], Benedikt Hofer[1,2,3], Philipp Königshofer[1,2,3], Alexis Treitler[3], Benedikt Simbrunner[1,2,3], Vlad Taru[1,3], Katharina Bonitz[1,2,3], Henriette Horstmeier[1], Kerstin Zinober[1,2,3], Katharina Regnat[1,2,3], Mattias Mandorfer[1], Barbara Neudert[4], Christopher Kaltenecker[4], Behrang Mozayani[4], Renate Kain[4], Michael Trauner[1], Philipp Schwabl[1,2,3], Thomas Reiberger[1,2,3]. *[1]Division of Gastroenterology and Hepatology, Department of Medicine III, Medical University of Vienna, Vienna, Austria; [2]Center for Molecular Medicine (CeMM) of the Austria Academy of Sciences, Vienna, Austria; [3]Christian Doppler Lab for Portal Hypertension and Liver Fibrosis, Medical University of Vienna, Vienna, Austria; [4]Department of Pathology, Medical University of Vienna, Vienna, Austria*
Email: thomas.sorz-nechay@meduniwien.ac.at

Background and aims: Portal hypertension (PH) is the risk factor for decompensation in cirrhosis. While fibrosis represents the main static component of PH, the specific contribution of other histological features of tissue remodeling and sinusoidal capillarization to PH remain incompletely defined. Next to collagen-proportionate area (CPA), we assessed alpha-smooth-muscle-actin (aSMA) and CD34 as myofibroblast activation and sinusoidal capillarization markers in human liver biopsies, respectively.
Method: Patients undergoing hepatic venous pressure gradient (HVPG) measurement and concurrent liver biopsy were included in this study. Tissue samples were stained using picrosirius-red/fast-green or immunohistochemistry and quantified morphometrically. Statistical analyses were performed via Mann-Whitney U test, Spearman's correlation (rho), and residual correlation analysis after covariate correction (i.e. partial correlation). Data are shown as medians (±IQR).
Results: Eighty-six patients (median age 56.7 years; 65.1% male) were included. Alcohol-related liver disease (25.6%) and MASLD (17.4%) were the most common etiologies. Median HVPG was 14 mmHg (±8 mmHg), with clinically significant PH in 75.6% and severe PH (HVPG≥16 mmHg) in 36.0%. Severe PH was associated with higher fibrosis burden (CPA: 24.9% [± 14.38%] vs. 14.3% [± 13.75%], $p = 0.002$), greater myofibroblast activation (aSMA: 4.72% [± 11.38%] vs. 2.05% [± 4.08%], $p = 0.027$), and increased sinusoidal capillarization (CD34: 3.76% [± 3.05%] vs. 2.27% [± 1.71%], $p < 0.001$). Among all markers, CD34 showed the strongest correlation with HVPG (rho = 0.428, $p < 0.001$), outperforming CPA (rho = 0.293, $p = 0.007$) and aSMA (rho = 0.206, $p = 0.059$). CD34 was also correlated with von Willebrand factor antigen (rho = 0.242, $p = 0.027$). In partial correlation analysis, CD34 (corrected for HVPG, aSMA and CPA) was strongly linked to sinusoidal remodeling via ELF ($r = 0.290$, $p = 0.016$), in addition to ALT ($r = -0.242$, $p = 0.032$) and platelet count ($r = -0.240$, $p = 0.032$). aSMA showed independent correlation (corrected for HVPG, CD34 and CPA) with the inflammation parameters C-reactive protein ($r = 0.348$, $p = 0.002$) and white blood cell count ($r = 0.274$, $p = 0.014$).
Conclusion: In patients with cirrhosis, histological features of fibrogenesis and vascular remodeling are differentially associated with PH. CD34, reflecting sinusoidal capillarization and hepatic vascular remodeling profoundly impacted on HVPG and represents a tissue surrogate for dynamic PH severity.

THU-498
Machine learning-based 8P model achieves high accuracy in predicting portal hypertension severity

Thomas Sorz-Nechay[1,2,3,4], Benedikt Hofer[1,2,3,4], Georg Kramer[1,3,4], Christian Sebesta[1,4], Paul Thöne[1,4], Marlene Hintersteininger[1,4], Lukas Hartl[1,4], Mathias Jachs[1,4], Lorenz Balcar[1,4], Philipp Schwabl[1,2,3,4], Albert Friedrich Stättermayer[1], Michael Trauner[1,4], Benedikt Simbrunner[1,2,3,4], Mattias Mandorfer[1,4], Thomas Reiberger[1,2,3,4]. *[1]Division of Gastroenterology and Hepatology, Department of Medicine III, Medical University of Vienna, Vienna, Austria; [2]Center for Molecular Medicine (CeMM) of the Austria Academy of Sciences, Vienna, Austria; [3]Christian Doppler Lab for Portal Hypertension and Liver Fibrosis, Medical University of Vienna, Vienna, Austria; [4]Clinical Research Group MOTION, Medical University of Vienna, Vienna, Austria*
Email: thomas.sorz-nechay@meduniwien.ac.at

Background and aims: Development of robust non-invasive tests to predict portal hypertension (PH) severity remains a major unmet need. Machine learning approaches may enable improved prediction of hepatic venous pressure gradient (HVPG) and clinically relevant PH stages.
Method: Patients with advanced chronic liver disease (ACLD) undergoing HVPG measurement were prospectively included. Exclusion criteria were: hepatocellular carcinoma, TIPS, occlusive portal vein thrombosis, liver transplantation. Random forest regression (RFR) and classification (RFC) models were trained to predict HVPG and severe PH (SPH; HVPG≥16mmHg) using blood-based

laboratory parameters. The cohort was randomly split into training (80%) and test (20%) sets. The initial RFR model was trained using 5-fold cross-validation with 10 imputations per fold. Feature importance was assessed by a permutation test, and 8-parameter (8P) RFR (8P-R) and RFC (8P-C) models were derived based on feature importance and wide clinical availability. Final models were evaluated on the test set after complete-case filtering. Performance was assessed using sensitivity, specificity, accuracy, Pearson's r (RFR), AUROC (RFC).

Results: A total of 1005 patients were included (training: n = 804; test: n = 201). Median age was 57.3 (IQR 15.4) years, 66.1% were male, main etiology was alcohol-related liver disease (47.6%). The median HVPG was 16 (IQR 10) mmHg, 508 (50.5%) had SPH. After missingness-filtering (>20%), 716 and 795 training cases remained for the full-feature RFR and for the 8P models, respectively. The full-feature RFR achieved a mean Pearson's r of 0.715 (IQR 0.046) across cross-validation folds. The most important features were bile acids, ammonia, antithrombin III activity, d-dimer and prothrombin time. The final 8P models included bile acids, prothrombin time, cholinesterase, ammonia, d-dimer, platelets, hematocrit, and gamma-glutamyl transferase. On the test set (n = 185 complete cases), the 8P-R model achieved high correlation with measured HVPG (r = 0.706, MAE = 3.41, p < 0.001), with better performance in compensated (r = 0.694) than decompensated ACLD (r = 0.525). Classification of SPH using predicted HVPG values of the 8P-R model showed high performance (sensitivity = 85.2%, specificity = 74.2%, accuracy = 79.5%). The 8P-C model had comparable performance (sensitivity = 85.2%, specificity = 75.3%, accuracy = 80.0%, AUROC = 0.84).

Conclusion: The novel blood parameter-based 8P-R and 8P-C models show high accuracy for non-invasive estimation of HVPG and prediction of SPH.

THU-499

Prognostic impact of clinically significant portal hypertension in hepatocellular carcinoma patients with concurrent metabolic dysfunction–associated steatotic liver disease undergoing surgical resection

Chien-Wei Su[1], Yi-Chen Lin[2], Chun-Ting Ho[1], Chia-Jung Ho[1], Tsai Shin-Yu[1], Yi-Hsiang Huang[3], Ming-Chih Hou[4], Jaw-Ching Wu[5].
[1]Division of General Medicine, Department of Medicine, Taipei Veterans General Hospital, School of Medicine, College of Medicine, National Yang Ming Chiao Tung University, Institute of Clinical Medicine, School of Medicine, National Yang Ming Chiao Tung University, Taipei, Taiwan; [2]Department of Medicine, Linkou Chang Gung Memorial Hospital, Taoyuan, Taiwan; [3]Department of Medical Research, Taipei Veterans General Hospital, Taipei, Taiwan; [4]Division of Gastroenterology and Hepatology, Department of Medicine, Taipei, Taiwan; [5]Institute of Clinical Medicine, School of Medicine, National Yang Ming Chiao Tung University, Taipei, Taiwan
Email: cwsu2@vghtpe.gov.tw

Background and aims: Clinically significant portal hypertension (CSPH) reflects impaired hepatic functional reserve and is associated with adverse hepatic events, such as ascites and variceal bleeding. Although the prognostic impact of CSPH in hepatocellular carcinoma (HCC) has been previously reported, data focusing on patients with concurrent metabolic dysfunction–associated steatotic liver disease (MASLD) remain limited. We aimed to assess the prognostic role of CSPH in HCC patients with concurrent MASLD undergoing curative surgical resection.

Method: A total of 477 patients with HCC and concurrent MASLD who underwent curative resection at Taipei Veterans General Hospital and had available pathological specimens and complete clinical data were included. Steatotic liver disease (SLD) was identified by the presence of more than 5% steatosis in the non-tumor liver tissues from surgical specimens, and MASLD was diagnosed as SLD accompanied by at least one cardiometabolic risk factor. CSPH was defined by the presence of esophageal or gastric varices, imaging evidence of splenomegaly, or a platelet count <100,000/μL. Patients were classified into CSPH (n = 65) and non-CSPH (n = 412) groups. Overall survival (OS) was compared using Kaplan–Meier analysis, and Cox proportional hazards models were applied to identify independent predictors of poor OS.

Results: Compared with patients without CSPH, those with CSPH had poorer hepatic functional reserve, including lower serum albumin levels, prolonged prothrombin time, lower platelet counts, and hemoglobin levels, and higher serum alpha-fetoprotein (AFP) levels. They also had higher positivity against hepatitis C virus, greater fibrosis severity, and higher inflammatory activity, but smaller tumor size and less vascular invasion. During a median follow-up of 55.0 months, 83 patients (17.4%) died, with a 5-year OS rate of 76.8%. Kaplan–Meier analysis demonstrated comparable survival outcomes between patients with and without CSPH (5-year OS: 76.7% vs. 76.8%, respectively). In multivariable Cox analysis, serum FIB-4 index, comorbid hypertension, serum albumin level, tumor number, serum AFP, and fibrosis stage were independently associated with poor OS, whereas CSPH was not.

Conclusion: HCC patients with concurrent MASLD and CSPH exhibited distinct clinical, biochemical, and histopathological characteristics compared with those without CSPH. However, the presence of CSPH did not determine long-term survival after curative resection in this patient population.

THU-500

Endoscopic ultrasound guided portal venous pressure predicts hepatic decompensation in patients with suspected portal hypertension: a multicenter study

Giuseppe Tarantino[1], Francesco Santopaolo[2], Lucia Salvi[1], Francesco Martini[1], Annalisa Alessandrini[1], Martina Dalla Bella[1], Clelia Cavallo[2], Lucia Giuli[2], Brigida Annicchiarico[2], Gianenrico Rizzatti[2], Giulia Tripodi[2], Alberto Larghi[2], Marco Marzioni[1], Isabel Carmona Soria[3], Victoria Alejandra Jiménez García[3], Maria Tous Romero[3], Manuel Rodriguez-Tellez[3], Angel Caunedo Alvarez[3], Rafael Romero Castro[3]. *[1]AOU delle Marche, Ancona, Italy; [2]Policlinico Universitario A. Gemelli, Rome, Italy; [3]Hospital Universitario Virgen Macarena, Seville, Spain*
Email: giuseppe.tarantino@ospedaliriuniti.marche.it

Background and aims: While Endoscopic Ultrasound (EUS-) guided Portal Pressure Gradient (PPG) correlates with portal hypertension (PH), the clinical utility of EUS- Portal Venous Pressure (PVP) remains unclear. This study is aimed to investigate the clinical and prognostic role of PVP in cohort of patients with compensated-advanced chronic liver disease (c-ACLD).

Method: Patients with c-ACLD of any etiology and suspected PH, underwent baseline EUS-PPG in this multicentric study. Clinical data, endoscopy, and elastography measurements, were retrospectively analyzed. During 3-month interval outpatient follow-ups, liver-related events (e.g., variceal bleeding, ascites, encephalopathy) were recorded.

Results: We investigated data of 178 consecutive patients. All underwent endo-hepatologic evaluation included EUS-PPG; 92 also underwent Hepatic Venous Pressure Gradient (HVPG) measurement. The mean age was 59.2 years, and 51.6% were males. Clinical findings included MELD score of 8.9 ± 2.9, liver stiffness (LSM) of 20.6 ± 18.2 kPa, spleen stiffness (SSM) of 56.6 ± 24 kPa, and platelet count of 123.2 ± 67.3 × 10^9/L. Cirrhosis was diagnosed in 73 patients (41%), and esophageal varices were detected in 92 (51.7%). HVPG mean value was 8.9 ± 5.3 mmHg. Etiologies included metabolic dysfunction-associated steatohepatitis (28.7.3%), porto-sinusoidal vascular disorder (PSVD, in 26.4%), alcohol-related disease (18.5%), autoimmune/cryptogenic liver disease (21.3%) and viral hepatitis (5.1%). PPG resulted to be 11.7 ± 7.4 mmHg (PVP 21.1 ± 8.4 minus Hepatic Venous Pressure 9.5 ± 5.6 mmHg). Significant correlations emerged between

PVP and both variceal size and SSM (Spearman's rho = 0.51; p < 0.001 and 0.57; p < 0.001; respectively). Over a median follow-up of 406.5 days, liver-related events occurred in 40 patients. Multivariate logistic regression, adjusted for platelet count, MELD, SSM and PPG, identified Fibrosis-4 index (OR 1.14; p = 0.03) and PVP (OR 1.14; p = 0.004) as independent predictors of decompensation. Kaplan-Meier analysis demonstrated that a PVP > 22 mmHg was significantly associated with an increased risk of clinical events (p < 0.001).
Conclusion: EUS-PVP emerges as a promising tool for assessing PH across different etiologies, including pre-sinusoidal disorders like PSVD. Furthermore, it appears effective in predicting the risk of hepatic decompensation. These findings warrant confirmation through further prospective validation.

Email: luistevilla@gmail.com

Background and aims: Chronic kidney disease (CKD) is frequent in patients undergoing TIPS for recurrent/ refractory ascites, but its impact on post-TIPS outcomes is poorly defined. We evaluated the association between CKD and 1-year outcomes after TIPS, focusing on CKD stage and MASH-related cirrhosis.
Method: Prospective analysis of patients included in the EuroTIPS cohort who underwent TIPS for ascites and had follow-up up to 1 year or until death. CKD was defined as baseline estimated glomerular filtration rate (eGFR) <60 mL/min/1.73 m^2 and further categorized by CKD stage. Persistent ascites (grade 2) at 1 year was assessed as a binary outcome among 1-year survivors and analyzed using Poisson regression to estimate adjusted risk ratios (aRR). One-year mortality was analyzed using Cox proportional hazards models. Multivariable analyses were adjusted for age, sex, bilirubin, INR, sodium, post-TIPS portal pressure gradient, and MASH etiology.
Results: Of 888 patients enrolled since January 2020, 653 patients with had one-year follow-up. 146 (22.4%) had CKD and 30.5% MASH-cirrhosis. CKD was more prevalent in patients with MASH-related cirrhosis than in non-MASH etiologies (39.0% vs. 15.0%, p < 0.01). One-year overall survival in the entire cohort was 78.8% and was significantly lower in patients with CKD compared with those without CKD (66.4% vs. 82.2%, p < 0.01). In multivariable Cox analysis (n = 631), CKD independently predicted 1-year mortality (aHR 2.26; 95%CI 1.54–3.31; p < 0.01). Among 1-year survivors, persistent ascites at 1 year occurred in 96 patients (19.4%). Ascites persistence was significantly more frequent in patients with CKD compared with those without CKD (50.5% vs. 12.7%, p < 0.01). In multivariable analysis, CKD remained strongly associated with persistent ascites at 1 year (aRR 3.35; 95%CI 2.37–4.74; p < 0.01). A clear stepwise increase in ascites persistence was observed across CKD stages (12.6% for eGFR ≥60, 38.5% for CKD 3a, 55.0% for CKD 3b, and 75.0% for CKD 4–5). In stratified analyses, the association between CKD and ascites persistence was stronger in patients with MASH-related cirrhosis (aRR 7.06; 95%CI 3.61–13.81) than in non-MASH etiologies (aRR 1.86; 95%CI 1.10–3.14), with a significant interaction between CKD and MASH etiology (p for interaction = 0.0038).
Conclusion: CKD independently predicts poorer ascites control and higher 1-year mortality after TIPS, with CKD stage enabling clinically relevant risk stratification, including a possible differential effect in MASH-related cirrhosis.

Email: paul.thoene@meduniwien.ac.at

Background and aims: Chronic hepatic venous pressure gradient (HVPG) response to non-selective beta-blocker (NSBB) therapy predicts outcome in patients with advanced chronic liver disease (ACLD) and clinically significant portal hypertension (CSPH). Non-invasive tests (NITs) for diagnosing HVPG response are currently lacking. This study investigated spleen stiffness measurement (SSM) via vibration-controlled transient elastography at 100 Hz for monitoring chronic HVPG response.

Method: Patients from eight European centers who underwent paired HVPG measurements before and after 5–365 days of NSBB therapy were included. SSM and liver stiffness measurement (LSM) were assessed on the same day as HVPG. HVPG response was defined as ≥10% reduction from baseline.

Results: One hundred and thirteen patients (median age: 59 [IQR: 52–62] years, 54% male, BMI 26 [23–30] kg/m^2; ALD/MetALD: 42.5%, MASLD: 27.4%, viral: 16.8%, others: 13.3%; prevalence of varices: 70.8%, decompensated: 38.9%; 87.6% received carvedilol, 12.4% propranolol) were included. Median baseline HVPG was 16 (13–20) mmHg, decreasing to 15 (11–19) mmHg on NSBB (−12% [−21 to 0%], p < 0.001 by Wilcoxon test). Sixty-three patients (55.8%) achieved HVPG response. Median SSM was 61 (48–84) kPa at baseline, decreasing to 58 (43–76) kPa at response measurement (relative changes: −9% [−23 to +8%], p = 0.001 by Wilcoxon test) in the overall cohort. Importantly, there was no difference in SSM dynamics in HVPG nonresponders (−8% [−17 to +8%]) and responders (−11% [−27 to +7%], Mann-Whitney-U-test: p = 0.352). LSM was 39 (22–63) kPa at baseline, while it had decreased to 32 (20–55) kPa at response measurement (relative changes: −6% [−24 to +6%], p = 0.005 by Wilcoxon test). No differences in LSM dynamics were observed between HVPG responders and nonresponders (Mann-Whitney-U-test: p = 0.315). Dynamics in HVPG and changes of SSM (Spearman's rho for absolute/relative changes: 0.016, p = 0.866/0.079, p = 0.405, respectively) and LSM (rho: −0.088, p = 0.362/<0.001, p = 0.996) did not correlate. Neither dynamics in SSM (AUC for absolute/relative changes: 0.522, p = 0.688/0.551, p = 0.355) nor LSM (AUC: 0.577, p = 0.168/0.557, p = 0.313) showed utility for detecting HVPG response non-invasively.

Conclusion: Chronic NSBB treatment was accompanied by decreases in SSM via VCTE at 100 Hz in ACLD patients with CSPH. However, these changes were unrelated to HVPG dynamics, rendering SSM unsuitable for diagnosing HVPG response on an individual patient level.

THU-506

Favourable outcomes in patients with advanced Fontan-associated liver disease following isolated heart transplant

Marius Vögelin[1], Daniel Cooper[1], Ava Poirier[1], Shani Nagler[1], Rafael Alonso-Gonzalez[2], Lucy Roche[2], Aliya Gulamhusein[1]. *[1]Toronto, Canada; [2]University Health Network, Toronto Adult Congenital Cardiac Clinic, Toronto, Canada*
Email: marius_voegelin@hotmail.com

Background and aims: In patients (pts) with a failing Fontan circulation, features of advanced Fontan-associated liver disease (FALD) are common whilst the indications for isolated HT (IHT) vs. combined heart-liver transplant (CHLT) remain unclear. We report our experience of liver outcomes in a cohort of pts with FALD undergoing IHT.

Method: Adult FALD pts who underwent HT between 1990–2024 at the University Health Network were reviewed. Descriptive statistics with proportions and medians with interquartile ranges (IQR) were used to describe clinical characteristics and outcomes of the cohort.

Results: Of 586 pts with Fontan circulation seen in the adult congenital heart disease program, 17 underwent IHT, and one patient had CHLT. For pts with IHT, median age at IHT was 35 years (yrs) (IQR 25.6–48.5), with a median Fontan exposure of 31 yrs (IQR 22.8–35.3). At IHT, 94% (n = 16) had features of portal hypertension including ascites (n = 14), esophageal varices (n = 4) and splenomegaly (n = 12). Benign liver nodules were present in 41% (n = 7). Median follow up after IHT was 4.6 yrs (IQR 1–8.3 yrs). During the follow-up period, no pts experienced hepatic decompensation or hepatocellular cancer. With 91.8 patient-yrs of follow-up, 4 pts died, 2 within the first year and 2 at 9 yrs post IHT. Of the early deaths, one occurred at 2 months (mos) from necrotizing pancreatitis, subsequent sepsis and multi-organ failure and the other at 19 mos from CMV colitis, associated colonic perforation and septic peritonitis. The 2 late deaths were of cardiac nature (sudden cardiac death and cardiogenic shock secondary to antibody-mediated rejection). No deaths were determined to be directly liver related. Ascites resolved or became clinically insignificant in 93% (n = 13) but persisted as severe in one case with pre-existing segmental portal vein thrombosis. Sequential liver stiffness measurements (LSM), taken a median of 11.8 and 16.3 mos pre- and post-IHT, respectively, improved in all patients for whom it was available (n = 5). Median pre IHT LSM was 35.8 kPa (IQR 34.8–47.2), and post IHT LSM was 9.3 kPa (IQR 6.7–17.1) with a median reduction in LSM of 28.1 kPa post IHT.

Conclusion: Optimal approach to selection of patients for IHT and CHLT remains undefined. Herein, we report favourable outcomes particularly with improved ascites and LSM in patients with advanced FALD undergoing IHT. Infectious risk in the immediate post-IHT period in those with advanced FALD warrants further study.

THU-507

An integrated single-cell and spatial transcriptomic atlas identifies pro-coagulant phenotypic remodeling of liver sinusoidal endothelial cells (LSECs) in porto-sinusoidal vascular disorder (PSVD)

Qirong Jiang[1], Haoxiang Zhu[2], Jinyu Wang[2], Jiming Zhang[2]. [1]*The First Affiliated Hospital of Fujian Medical University, Fujian, China;* [2]*Fudan University affiliated Huashan Hospital, Shanghai, China*
Email: jmzhang@fudan.edu.cn

Background and aims: The pathogenesis of porto-sinusoidal vascular disorder (PSVD) remains unclear. Using single-cell and spatial transcriptomics, we characterized hepatic endothelial heterogeneity in PSVD and identified liver sinusoidal endothelial cell (LSEC) phenotypic remodeling associated with portal hypertension.
Method: Liver tissue samples were obtained from 7 patients with PSVD, 3 patients with cirrhosis, and 2 patients with chronic hepatitis B as controls. Single-nucleus RNA sequencing was performed using the 10x Genomics platform to profile hepatic endothelial cells. Endothelial subpopulations were identified based on established marker genes using UMAP-based clustering. Spatial transcriptomics was used to validate lobular zonation and portal–sinusoidal distribution of LSEC subsets.
Results: A total of 12 endothelial cell subpopulations were identified, comprising 7 liver LSECs subsets, 3 vascular endothelial cell subsets, and 2 lymphatic endothelial cell subsets. In normal liver tissue, LSECs exhibited clear spatial zonation along the portal–central axis, including periportal, mid-lobular, and pericentral subsets, which was further validated by spatial transcriptomics. Compared with controls, LSEC composition was markedly altered in livers from patients with PSVD. Pro-fibrinolytic genes (PLAT, PLG) were significantly downregulated, whereas anti-fibrinolytic genes (SERPINE1, CPB2) were upregulated, indicating an impaired fibrinolytic state. In parallel, LSEC-specific markers associated with fenestration and endocytic function (LYVE1, STAB2, FCGR2B/CD32B) were reduced, consistent with loss of fenestrations and endothelial dysfunction. Expression of VEGFR2 was also decreased, suggesting attenuated VEGF signaling. UMAP analysis demonstrated enrichment of pro-microthrombotic LSEC subsets in PSVD. Spatial transcriptomic mapping further localized these pathological LSEC states predominantly to the portal–sinusoidal interface, supporting their contribution to increased intrahepatic microcirculatory resistance.
Conclusion: This integrated single-cell and spatial transcriptomic atlas identifies pro-coagulant phenotypic remodeling of LSECs as a defining feature of PSVD. These findings indicate that PSVD-associated portal hypertension arises from endothelial remodeling programs distinct from cirrhosis and establish LSECs as key contributors to non-cirrhotic portal hypertension.

THU-508

A novel non-invasive model to identify high risk varices in patients with HBV-related cirrhosis

Peishuang Xu[1], Mingchen Wang[1], Jiankang Song[1], Jinjun Chen[2], Haiyu Wang[3]. [1]*Hepatology Unit, Department of Infectious Diseases, Nanfang Hospital, Southern Medical University, Guangzhou, Guangdong, China;* [2]*Department of Infectious Diseases, Key Laboratory of Molecular Biology for Infectious Diseases (Ministry of Education), Institute for Viral Hepatitis, the Second Affiliated Hospital, Chongqing Medical University, Hepatology Unit, Department of Infectious Diseases, Nanfang Hospital, Southern Medical University, Guangzhou, Guangdong, China;* [3]*Department of Infectious Diseases, Nanfang Hospital, Southern Medical University, Guangzhou, Guangdong, China*
Email: 375612668@qq.com

Background and aims: Over the past decade, several non-invasive diagnostic models of high-risk varices (HRV) in patients with advanced chronic liver disease have been developed. However, these models can only be used to exclude HRV patients but cannot effectively rule in HRV patients. Early detection of HRV in cirrhosis is critical for prognostic improvement. This study aimed to develop and validate a reliable non-invasive diagnostic model capable of both safely ruling out and accurately ruling in HRV in patients with HBV-related cirrhosis.
Method: This prospective cross-sectional study enrolled 616 consecutive patients with compensated HBV-related cirrhosis from July 2021 to April 2024. Patients completed liver and spleen transient elastography (FibroScan®630, Echosens, France) and EGD. Variables selected through least absolute shrinkage and selection operator regression were subsequently analyzed by multivariable logistic regression to construct the model.
Results: Participants were randomly divided into training (n = 432) and validation (n = 184) cohorts (7:3 ratio). The model consisting of spleen stiffness measurement@100 Hz, platelets, spleen diameter, spleen thickness, and sex, named PASS model, performed robustly in training cohort (area under the receiver operating characteristic [AUROC] 0.94, area under the precision-recall curve [AUPRC] 0.81) and validation cohort (AUROC 0.92, AUPRC 0.78). Cut-off of 4.84 for ruling out and 78.28 for ruling in were best for discriminating HRV. In the training cohort, for ruling out HRV, PASS model spared 53.47% (231/432) unnecessary esophagogastroduodenoscopy (EGD) with a HRV missed rate of 1.11% (1/90), with the corresponding sensitivity, negative predictive value, and negative likelihood ratio were 98.89%, 99.57%, 0.02, respectively. For ruling in HRV, 92.50% (37/40) of positive patients were correctly classified (specificity 99.12%, positive predictive value 92.50%). These results were then confirmed in validation cohort.
Conclusion: The PASS score is an accurate, novel, and non-invasive HRV diagnostic criterion with dual cut-off values in patients with compensated HBV-related cirrhosis. It is based on five routine laboratory and clinical parameters. PASS can identify patients with an extremely low probability of HRV (HRV misclassification rate < 5%), allowing them to safely avoid EGD. At the same time, it can also accurately identify HRV patients (PPV > 92%), enabling the timely initiation of primary prevention treatment.

Recompensation of decompensated cirrhosis and long-term resolution of ascites in patients undergoing alfapump placement: experience from the multi-center POSEIDON study

Ethan Weinberg[1], Nadim Mahmud[1], Hugo Vargas[2], Jasmohan Bajaj[3], Mangesh Pagadala[4], Jeroen Capel[5], Gijs Klarenbeek[5], Patrick S. Kamath[6], Florence Wong[7], K. Rajender Reddy[1]. [1]*University of Pennsylvania, Philadelphia, PA, United States;* [2]*Mayo Clinic in Arizona, Phoenix, AZ, United States;* [3]*Virginia Commonwealth University, Richmond VA, Richmond, VA, United States;* [4]*Methodist Health System, Dallas, TX, United States;* [5]*Sequana Medical, Zurich, Switzerland;* [6]*Mayo Clinic, Rochester, MN, United States;* [7]*Toronto General Hospital, Toronto, Canada*
Email: ethan.weinberg@pennmedicine.upenn.edu

Background and aims: Recompensation of decompensated cirrhosis, characterized by resolution of ascites and hepatic encephalopathy, has been described in patients after cure or control of cirrhosis etiology. We hypothesized that long term regular ascites removal in those with refractory ascites would allow for better nutritional intake and recovery of liver function. We aimed to determine the rate of resolution of ascites and recompensation after long term management of ascites with an alfapump.
Method: The alfapump system consists of a subcutaneous device with a rechargeable battery that mobilizes ascites from the peritoneal cavity into the urinary bladder. The POSEIDON study was the pivotal North American study of the alfapump for recurrent ascites: 69

subjects at 15 centers had an alfapump implanted. In this post-hoc analysis, recompensation is defined as the average removal of less than 50 ml of ascites per day and without the need for large-volume paracentesis for at least 3 months until the last evaluation. Only those alive and with a functioning alfapump for at least 6 months were included.
Results: 48 subjects had a working alfapump 6 months after implant; 10 of whom experienced long-term recompensation. The median time to recompensation was 503 days (IQR 234 days). Six pumps were removed for recompensation; 4 subjects with recompensation chose to maintain the alfapump system *in situ*. Subjects who recompensated produced less daily ascites at the time of implant (577.6mL vs.845.1mL, $p < 0.001$) coupled with decreased ascites production over time. There were no baseline differences between the two groups in MELD-Na, etiology, sex, SF-36 scores, Ascites-Q scores, albumin, or duration of recurrent ascites (each $p > 0.05$). By month 6, subjects with recompensation had lower MELD-Na (11 vs. 15, $p = 0.004$), which persisted through months 12 and 24 (10 vs. 15, $p = 0.004$; 11 vs. 14, $p = 0.01$). By month 12, recompensation was associated with higher serum albumin (39.0 g/L vs. 32.5 g/L, $p = 0.03$). There were no differences at months 6, 12, or 24 between the two groups on Ascites-Q or pre-albumin.
Conclusion: Recompensation of decompensated cirrhosis is possible in long-term survivors after alfapump implantation. This may be a consequence of improved patient wellbeing and enhanced nutritional intake while there is ongoing control of the cirrhosis etiology. Signs of recompensation were lower ascites removal requirement at time of alfapump implant, decreasing ascites removal over time, decreasing MELD-Na, and increasing albumin.

THU-510

Integrating gut microbiota and clinical parameters to predict beta-blocker response and portal pressure in patients with cirrhosis

Peishan Wu[1,2], Yu-Cheng Lin[1], Yun-Cheng Hsieh[1,2], Shih-Yun Wu[1,2], Teh-Ia Huo[1,2], Bernd Schnabl[3], Han-Chieh Lin[1,2], Kuei-Chuan Lee[1,2], Ming-Chih Hou[1,2]. *[1]National Yang Ming Chiao Tung University Yangming Campus, Beitou District, Taiwan; [2]Taipei Veterans General Hospital, Beitou District, Taiwan; [3]University of California San Diego, La Jolla, United States*
Email: kclee2@vghtpe.gov.tw

Background and aims: Non-selective beta-blockers (NSBBs) are the key treatment for preventing variceal bleeding in cirrhosis. However, predictors of hemodynamic response remain limited. Growing evidence links portal hemodynamics with the gut microbiota, but their combined relevance to NSBB responsiveness remains poorly defined. We aimed to identify microbial and clinical features associated with portal pressure and hemodynamic response.
Method: Patients with cirrhosis and esophageal varices requiring NSBBs were enrolled. Hemodynamic parameters were measured before and after NSBBs. Stool samples were also obtained in cirrhotic patients and from healthy individuals as controls. Gut microbiota was analyzed using 16S rRNA sequencing. Predictions of HVPG and hemodynamic response were evaluated using machine–learning–based models.
Results: Between December 2019 and November 2024, 30 patients were enrolled, including 15 hemodynamic responders and 15 non-responders. Baseline demographic characteristics, liver disease severity, LSM, SSM, heart rate, mean arterial pressure, and HVPG were similar between groups. Responders had a significantly higher baseline cardiac output (CO) than non-responders (8.09 ± 2.51 vs. 6.03 ± 1.29 L/min, $p = 0.012$), which persisted after NSBB therapy (6.43 ± 1.28 vs. 4.90 ± 0.82 L/min, $p < 0.001$). NSBBs did not cause global gut microbial diversity or community structure alteration. However, responders showed higher relative abundances of *Enterococcus* spp. and *Escherichia–Shigella*, while non-responders were enriched in butyrate-producing and potential gut barrier-supporting taxa, including *Faecalibacterium prausnitzii, Agathobaculum desmolans*, and *Gordonibacter–Eggerthella.* In machine-learning analyses, post-treatment CO emerged as the only independent predictor of hemodynamic response. LSM demonstrated a weak but persistent association with HVPG, while SSM did not correlate with HVPG. Incorporation of *Weissella confusa* abundance improved HVPG estimation when combined with LSM.
Conclusion: NSBB therapy did not alter the overall composition of the gut microbiota; however, specific microbial profiles were associated with distinct hemodynamic responses. A higher cardiac output was associated with a favorable hemodynamic response to NSBBs, suggesting that assessment of cardiac function may help identify patients most likely to benefit from therapy. Liver stiffness and selected microbial features may provide additional information for estimating portal pressure.

THU-511

Effects of early placement of transjugular portosystemic shunts in patients with gastric fundal variceal bleeding: a multicenter cohort study

Jie Xue[1], Lijuan Chen[1], Chunqing Zhang[1], Guangchuan Wang[1]. *[1]Shandong Provincial Hospital, Jinan, China*
Email: riverwang@126.com

Background and aims: Some studies have shown that transjugular intrahepatic portosystemic shunt (TIPS) placement within 72 hours of admission improves survival in patients at high risk who present with acute variceal bleeding. However, regarding gastric fundal varices (isolated gastric varices type 1/gastroesophageal varices type 2), whether preemptive transjugular intrahepatic portosystemic shunt (P-TIPS) is a more optimal treatment method and which subgroup among them can benefit from P-TIPS remains controversial at present. This nationwide multicenter cohort study aimed to evaluate whether P-TIPS could improves survival incidence of gastric fundic variceal bleeding in patients with liver cirrhosis.
Method: In this retrospective cohort study, we collected data from patients with cirrhosis with gastric fundic variceal bleeding (within seven days after bleeding) who received P-TIPS or ECI treatment between June 2019 and June 2024 at ten medical centers. The primary endpoint was all-cause rebleeding and the secondary endpoints included overt hepatic encephalopathy (OHE) all-cause mortality and further decompensation.
Results: A total of 836 patients were included. Among them, 628 (75.1%) had gastroesophageal varices type 2 (GOV2), and 208 (24.8%) had isolated gastric varices type 1 (IGV1). The median follow-up period was 27.5 months. In the entire cohort, P-TIPS reduced rebleeding (52.51% versus 23.27%, $p < 0.001$) and further decompensation (85.62% versus 66.40%, $p < 0.001$) compared with ECI. However, no significant differences were found in mortality (30.45% versus 26.55%, $P = 0.090$). In patients with Child-Pugh B or C scores,P-TIPS reduced rebleeding (61.01% versus23.91%, $p < 0.001$) mortality (37.47% versus 30.24% $P = 0.026$) and further decompensation (95.77% versus 69.17%, $P < 0.001$). However, in patients with Child-Pugh A scores, P-TIPS did not reduce mortality (9.93% versus 18.38%, $P = 0.307$) or further decompensation (58.49% versus 60.40%, $P = 0.460$).
Conclusion: Compared with endoscopic cyanoacrylate injection, P-TIPS reduced rebleeding in all patients. More importantly, in the Child-Pugh B or C scores patient group, P-TIPS can reduce the incidence of further decompensation and improve survival rates. These findings suggest that in the Child-Pugh B or C scores group with gastric fundus varices, rather than Child-Pugh A scores, could benefit from P-TIPS.

THU-512

Controlled expansion stent-grafts in TIPS: a real-world analysis of in vivo diameter change and early hepatic encephalopathy

Zizhen Ye[1], Ruoting Men[1], Yi Shen[1], Ziqi Chen[2], Li Yang[1], Luo Xuefeng[1], Xiaoze Wang[1]. [1]*Department of Gastroenterology and Hepatology, Laboratory of Gastrointestinal Cancer and Liver Disease, West China Hospital, Sichuan University, Chengdu, China, Chengdu, China;* [2]*Department of Radiology, West China Hospital, Sichuan University, No.37, Guoxue Alley, Chengdu, 610041, China, Chengdu, China*
Email: 3027368878@qq.com

Background and aims: Post-TIPS hepatic encephalopathy (HE) remains a major limitation of portosystemic shunting, and stent diameter is a key modifiable determinant of HE risk. The VIATORR® Controlled Expansion (VCX) stent-graft was designed to allow tighter control of the functional lumen (8–10 mm) and potentially reduce HE by preventing passive self-expansion seen in conventional VIATORR TIPS stents (VTS). However, clinical data remain conflicting and information regarding the in vivo expansion behavior of VCX in real-world practice is limited. This study compared early HE after TIPS using VCX versus 8-mm VTS and quantitatively characterized VCX expansion and associated hemodynamic changes.
Method: This single-center retrospective cohort included consecutive cirrhotic patients undergoing TIPS between January 2024 and July 2025, receiving either an 8-mm VTS or VCX stent-graft. VCX stents were initially dilated to 8 mm and further dilated to 10 mm only if post-procedural portal pressure gradient (PPG) remained >12 mmHg or decreased <50% from baseline. The primary endpoint was new-onset OHE within 6 months. Stent diameter was quantitatively measured along the VCX controlled-expansion mid-segment on fluoroscopy at baseline and 3 months. PPG measurements were also obtained at both timepoints.
Results: Among 153 patients (43 VCX, 110 VTS), OHE occurred in 30 patients (19.6%). The VCX group showed a higher cumulative 6-month OHE incidence than the VTS group (HR = 2.34, 95% CI 1.05–5.20; log-rank $p = 0.032$). Among VCX patients, the mid-segment diameter increased from 8.0 mm to a mean of 8.65 mm (range 8.2–9.1 mm) at 3 months ($p < 0.001$). Post-TIPS PPG increased from 7.7 mmHg to 11.6 mmHg ($p < 0.001$). Stent expansion was not correlated with PPG increase (Spearman r = 0.038, p = 0.834).
Conclusion: VCX stent-grafts demonstrated consistent early in vivo expansion and are associated with a higher incidence of early OHE compared with 8-mm VTS. The observed PPG rise at 3 months underscores the unreliability of immediate intra-procedural PPG as a surrogate for long-term hemodynamic status. These findings support the need for refined VCX-specific dilation strategies—such as staged or intentionally smaller initial dilation—to optimize the balance between portal decompression and HE risk. Prospective studies are warranted to validate individualized diameter-modulation protocols.

THU-513

Spleen stiffness-based algorithms for predicting decompensation in treatment-naive HBV-HCC patients

Xiaofeng Zhang[1], Jinjun Chen[2], Xiao Cheng[1]. [1]*Southern Medical University, Guangzhou, China;* [2]*Department of Infectious Diseases, the Second Affiliated Hospital, Chongqing Medical University, Chongqing, China*
Email: 1282614092@qq.com

Background and aims: Survival in patients with hepatocellular carcinoma (HCC) is influenced not only by tumor burden but also by the degree of underlying liver dysfunction and portal hypertension. This study aimed to assess the predictive value of liver stiffness measurement (LSM) and spleen stiffness measurement (SSM) for hepatic decompensation and liver-related mortality in treatment-naive HCC patients, and to develop prognostic models incorporating LSM/SSM, tumor burden, and routine laboratory parameters.
Method: We prospectively enrolled compensated HBV-related HCC patients who underwent baseline SSM using a 100-Hz probe. Patients were followed for≥3 months or until death. The primary endpoint was hepatic decompensation.
Results: A total of 222 HCC patients were included (median follow-up 14.0 months). The cumulative 1-year and 2-year incidences of decompensation were 17.9% and 25.5%, respectively. Both LSM (subdistribution hazard ratio [sHR]: 1.03, 95% CI: 1.01–1.04) and SSM (sHR: 1.04, 95% CI: 1.02–1.05) were significant predictors of decompensation. A model incorporating LSM, total bilirubin (TBIL), albumin, and complete response to HCC treatment (Decom_model 1) achieved a C-index of 0.784 for predicting decompensation. Another model using SSM, TBIL, albumin, and complete response (Decom_model 2) achieved a C-index of 0.808. In comparison, the Albumin-Bilirubin (ALBI) grade (C-index: 0.687), Child-Pugh score (0.600), and Model for End-Stage Liver disease (MELD) score (0.650) showed lower predictive performance.
Conclusion: In treatment-naive HBV-HCC patients, both LSM and SSM are strong, independent predictors of hepatic decompensation. Prognostic models integrating either stiffness measurement with TBIL, albumin, and treatment response outperform conventional liver function scores (ALBI, Child-Pugh, MELD) in predicting decompensation risk. These findings support the incorporation of stiffness measurements, particularly SSM, into routine risk stratification to better guide the management of HCC patients.

Ultrasound localization microscopy for diagnosis of clinically significant portal hypertension: a prospective multicenter study

Wei Zhang[1], Chuan Liu[2], Xinde Gong[3], Yingchun Yuan[4], Renmei Wu[5], Jiahao Han[6], Xia Chen[7], Su Wu[8], Yanping Ma[1], Jieyang Jin[1], Jie Ren[1], Xiaolong Qi[2]. [1]*The Third Affiliated Hospital of Sun Yat-sen University, Guangzhou, China;* [2]*Liver Disease Center of Integrated Traditional Chinese and Western Medicine, Department of Radiology, Zhongda Hospital, Medical School, Southeast University, Nurturing Center of Jiangsu Province for State Laboratory of AI Imaging & Interventional Radiology (Southeast University), Basic Medicine Research and Innovation Center of Ministry of Education, Zhongda Hospital, Southeast University, State Key Laboratory of Digital Medical Engineering, Nanjing, China;* [3]*Department of Radiology, TaiHe Hospital (Affiliated Hospital of HuBei University of Medcine), Shiyan, China;* [4]*Department of Ultrasound, General Hospital of Ningxia Medical University, Ningxia, China;* [5]*Department of Ultrasound, Suining Central Hospital, Suining, Suining, China;* [6]*Department of Ultrasound, Zhongda Hospital Southeast University, Nanjing, China;* [7]*Department of Ultrasound, The First Affiliated Hospital of USTC, Division of Life Sciences and Medicine, University of Science and Technology of China, Hefei, China;* [8]*Department of Ultrasound, Xingtai People's Hospital, Xingtai, China*
Email: zhangw45@mail2.sysu.edu.cn

Background and aims: Currently, hepatic venous pressure gradient (HVPG) remains the gold standard for diagnosing clinically significant portal hypertension (CSPH), but its use is restricted by invasiveness and accessibility. This multicenter study aims to apply ultrasound localization microscopy (ULM) to visualize and quantify hepatic microvasculature in cirrhotic patients, evaluating its potential in non-invasive CSPH diagnosis.
Method: This study enrolled patients aged 17 to 80 with clinical diagnosis of cirrhosis who underwent HVPG measurement between October 2024 and December 2025 based on clinical needs. After informed consent, patients underwent ULM, with data acquisition in

the portal phase, followed by offline quantitative analysis of microvessel functional and morphological parameters. HVPG ≥ 10 mmHg was considered the gold standard for diagnosing CSPH. The Mann-Whitney U test was used to compare microvessel parameters between the CSPH and non-CSPH groups. Simple and multiple linear regression models evaluated independent predictors of HVPG. Receiver operating characteristic curve was used to assess the diagnostic performance of microvessel parameters in identifying CSPH.

Results: A total of 102 patients were enrolled, including 73 males, with an average age of 46 (range: 42–54) years. Among them, 53 had hepatitis B, 27 had alcoholic liver disease, and the remaining cases included hepatitis C, autoimmune liver disease, primary biliary cirrhosis, and metabolic dysfunction-associated steatotic liver disease. 77 patients were diagnosed with CSPH, and 25 were non-CSPH. Compared to the non-CSPH group, the CSPH group exhibited lower vessel density (VD) (0.5 ± 0.1 vs. 0.4 ± 0.01, p < 0.001), perfusion index (10.1 ± 2.9 vs. 8.0 ± 1.8, p < 0.001) and higher velocity variance (172.6 ± 39.5 vs. 205.5 ± 71.7, p < 0.001). VD was an independent predictor of HVPG (R^2 = 0.53). The diagnostic performance of VD for CSPH (AUC = 0.88, p < 0001) was higher than that of the CSPH risk score (AUC = 0.67, p = 0.07).

Conclusion: ULM-based microvessel parameters were proposed with good diagnostic consistency for HVPG measurement.

THU-515

Interventional embolization of spontaneous portosystemic shunts improves survival by reducing further decompensation in selected patients with decompensated cirrhosis: a retrospective matched analysis

Hongbin Zhu[1], Lijuan Chen[1], Guangchuan Wang[1], Chunqing Zhang[1]. *[1]Shandong Provincial Hospital Affiliated to Shandong First Medical University, jinan, China*
Email: riverwang@126.com

Background and aims: Spontaneous portosystemic shunts (SPSS) are observed in approximately 40% of patients with liver cirrhosis. Although traditionally regarded as a compensatory mechanism to alleviate portal hypertension, emerging evidence indicates that these shunts may mediate a "steal phenomenon," diverting portal blood flow away from the liver and thereby exacerbating hepatic dysfunction. This study aimed to assess whether interventional embolization of SPSS improves long-term survival and delays disease progression in patients with decompensated cirrhosis.

Method: In this single-center retrospective study, we included 201 patients with decompensated cirrhosis and radiologically confirmed SPSS who presented with variceal bleeding or refractory hepatic encephalopathy (HE) between 2016 and 2023. To mitigate potential baseline confounding, a 1:1 propensity score matching (PSM) analysis was performed, yielding 35 patients in the embolization group and 35 in the control group receiving standard treatment. The primary endpoint was 2-year overall survival; secondary endpoints included the occurrence of further decompensation events and longitudinal changes in liver function.

Results: Technical success was achieved in all embolization procedures. During the two-year follow-up, cumulative survival was significantly higher in the embolization group than in the control group (88.6% vs. 65.7%; P = 0.023). Patients who underwent embolization also had a lower incidence of recurrent decompensation events (P = 0.014). Longitudinal analysis using inverse probability of censoring weighting (IPCW) demonstrated that embolization promoted significant liver volume expansion and improved synthetic function, reflected by increased serum albumin, decreased bilirubin, and improved CTP scores. Subgroup analyses revealed that the survival benefit was particularly evident in patients with a baseline CTP score < 10 or in those whose initial clinical presentation was HE.

Conclusion: For carefully selected patients with decompensated cirrhosis and large SPSS, interventional embolization represents a safe and effective therapeutic strategy. By mitigating the portal steal phenomenon and reestablishing hepatopetal portal flow, the procedure promotes hepatic regeneration and significantly enhances 2-year survival. Early intervention—especially in patients with preserved hepatic functional reserve—is advocated to optimize long-term clinical outcomes.

THU-516

Sarcopenia predicts post-TIPS hepatic encephalopathy, and early hepatic encephalopathy predicts mortality: evidence from a multicentric cohort

Amine Zoughlami[1], Joseph Najjar[1], Benoit Billette[1], Philip Wong[1], Marc Deschenes[1], Giada Sebastiani[1], Tatiana Cabrera[2], Louis-Martin Boucher[2], David Valenti[2], Ali Bessissow[2], David Patch[3], Emmanuel Tsochatzis[3], Amine Benmassaoud[1]. *[1]Montréal, Canada; [2]McGill University Health Centre, Division of Interventional Radiology, Montreal, Canada; [3]Institute of Liver and Digestive Health, University College London, London, United Kingdom*
Email: amine.zoughlami@mail.mcgill.ca

Background and aims: Overt hepatic encephalopathy (OHE) is a common complication after transjugular intrahepatic portosystemic shunt (TIPS) insertion. Sarcopenia is a risk factor for OHE in cirrhosis, but its impact on post-TIPS OHE, particularly early OHE, and subsequent mortality, remains unclear. We aimed to identify predictors of post-TIPS OHE, and examine the interplay between sarcopenia, OHE and mortality.

Method: This was a multicentric, retrospective study of a prospectively maintained database of patients with cirrhosis who underwent TIPS insertion, from the McGill University Health Centre (Montreal, Canada), and the Royal Free Hospital (London, United Kingdom). Sarcopenia was defined using standard L3-skeletal muscle index cutoffs. Occurrence of overt HE (OHE) was collected, and early OHE was defined as occurring within 3 months of TIPS insertion. Logistic regression was used to identify predictors of OHE. Survival was assessed using Kaplan-Meier curves and Cox regression analyses.

Results: A total of 165 patients were included (mean age 56.9 ± 10.4 years, 59.4% male), and 100 (60.6%) were sarcopenic. Median MELD-Na was 12.0 (IQR 8.0), and median HVPG decrease was 7.0mmHg (IQR 8.0mmHg), and did not differ based on sarcopenia status. New or worsening post-TIPS OHE occurred in 57 patients (34.5%). Patients with sarcopenia were more likely to develop early OHE (29.7% vs 15.6%, p = 0.043), but no statistically significant difference was noted for overall OHE (42.9% vs 28.1%, p = 0.061). Sarcopenia independently predicted overall OHE (aOR 3.73, 95% CI 1.4–10.1) and early OHE (aOR 4.5, 95% CI 1.3–15.9). Early OHE was associated with increased mortality risk (56.8% vs 31.4%, p = 0.005) and shorter median survival (22.4 vs 58.7 months, log-rank p = 0.016). In Cox regression analysis, controlling for MELD-Na, female sex, stent diameter and decrease in HVPG gradient, early OHE was associated with mortality (aHR 2.35, 95% CI 1.2–4.6), however the association lost statistical significance with addition of age (aHR 1.71, 95% CI 0.8–3.5), suggesting partial confounding by age.

Conclusion: Pre-TIPS sarcopenia is a strong independent predictor of early OHE after TIPS. Early OHE is associated with markedly worse survival, although the relationship with mortality risk appears to be partially attributable to age. Further studies on the impact of pre-TIPS sarcopenia on early OHE and mortality are indicated, including the impact of nutritional optimization or post-TIPS HE prophylaxis.

Global pathways linking alcohol exposure, food systems, and alcohol-associated liver disease

James M. Paik[1], Annette Paik[1], Eliabe Abreu[1], Shira Zelber-Sagi[1,2], Manal F. Abdelmalek[1,3], Zobair M. Younossi[1]. [1]*The global NASH/MASH council, Washington DC, United States;* [2]*School of Public Health, Faculty of Social Welfare and Health Sciences, University of Haifa, Haifa, Israel;* [3]*MASLD Clinical Research Program at Mayo Clinic, Rochester, United States*
Email: zobair.younossi@cldq.org

Background and aims: Burden of alcohol-associated liver disease (ALD) varies widely across different countries, yet upstream structural factors remain insufficiently characterized. We examined how food systems, socioeconomic conditions, and healthcare capacity relate to ALD burden across socio-economic development levels for different countries.
Method: An ecological analysis of 187 countries was conducted using ALD estimates from the Global Burden of Disease Study (2023) and alcohol exposure indicators from World Health Organization (2020). ALD outcomes were defined as the combined prevalence and mortality from alcohol-related cirrhosis and liver cancer. Countries were categorized by Sociodemographic Index (SDI <0.64 vs ≥0.64). Structural equation models (SEM) evaluated associations among alcohol exposure, food environments indicators, and ALD outcomes. Results are presented as standardized coefficients (β).
Results: High-SDI countries (n = 115) had older populations (mean median age 36.3 vs 21.6 years) and stronger healthcare access and quality index (HAQ 70.5 vs. 28.2). They also demonstrated higher alcohol exposure, including higher per-capita intake (7.46 vs 3.41 L/year), higher intake among drinkers (27.0 vs 21.7 g/day), more heavy continuous drinking (8.9% vs. 6.6%), and heavy episodic drinking (23.8% vs 14.7%; all $p < 0.001$). Despite higher alcohol exposure, ALD mortality was lower in high-SDI countries (5.44 vs 6.69 per 100,000; $p = 0.002$), whereas ALD prevalence was similar between high and low SDI countries (6.29 vs 6.86 per 100,000; $p = 0.165$). In SEM analyses, higher SDI was associated with increased per-capita alcohol intake ($\beta = 0.36$ in high-SDI; $\beta = 0.29$ in low-SDI) and heavy continuous drinking ($\beta = 0.52$; $\beta = 0.20$), and higher animal-to-vegetable fat consumption ratio (food modernization indicator) ($\beta = 0.46$; $\beta = 0.31$). In high-SDI countries, heavy continuous drinking was associated with ALD prevalence ($\beta = 0.30$; $p = 0.002$), while high HAQ was associated with lower ALD mortality ($\beta = -0.20$; $p < 0.001$). In low-SDI countries, ALD prevalence was associated with dietary composition (animal-to-vegetable fat consumption ratio $\beta = 0.23$; $p = 0.03$), with no detectable association in these countries between HAQ and ALD mortality.
Conclusion: High-SDI countries exhibit stronger alcohol-related pathways moderated by greater health-system capacity, while low-SDI countries show associations involving dietary composition and limited healthcare capacity, contributing to worse ALD outcomes.

Clinical and humanistic burden of metabolic dysfunction-associated steatotic liver disease and metabolic dysfunction-associated steatohepatitis in the United States: a system dynamics model

Amreen Dinani[1], Elisabeth de Laguiche[2], Fotis Tefos[2], David W. Victor III[3], Fryderyk Wilczynski[4], Thomas Padgett[4]. [1]*Duke University School of Medicine, Durham, United States;* [2]*Novo Nordisk A/S, Søborg, Denmark;* [3]*Houston Methodist Hospital, Houston, United States;* [4]*Health Economics and Outcomes Research, Cardiff, United Kingdom*
Email: amreen.dinani@duke.edu

Background and aims: Metabolic dysfunction–associated steatotic liver disease (MASLD) can progress to metabolic dysfunction–associated steatohepatitis (MASH), characterized by inflammation, progressive liver damage and scarring. This study aimed to predict the system impact of MASLD/MASH prevalence on the clinical and humanistic burden based on current standard of care practices in the US.
Method: A US system dynamics model was developed to predict the prevalence and burden of MASLD/MASH and its complications, stratified by age and disease stage, from 2025 to 2060. The model was calibrated to National Health and Nutrition Examination Survey (NHANES)-derived data (2006–2020) and annual liver transplant incidence data from the Scientific Registry of Transplant Recipients (2012–2020) and validated by two clinical experts. Model outcomes included mortality, cardiovascular (CV) complications, liver transplants, hepatocellular carcinomas (HCCs), health-related quality of life (HRQoL), and lost productivity.
Results: Under current standard of care practices in the US, MASLD/MASH prevalence is projected to increase by 28%, from 104 million in 2025 to 133 million in 2060. Results suggest that people with MASH F2-F4 will drive the burden, with the greatest percentage increase occurring for F3 (126%) and F4 (116%). The annual incidence of liver transplants attributable to MASH cirrhosis is projected to increase by 131%, from 1,439 in 2025 to 3,317 liver transplants in 2060. Annual excess mortality is projected to increase from 0.95 million deaths associated with MASLD/MASH and its complications in 2025, to 1.3 million in 2060, an increase of 36%. This reflects worsening disease severity, with excess mortality for F4 increasing by 98%. Annual CV complications will rise by 28% by 2060, whereas HCC incidence will increase by 166%. The HRQoL burden from MASLD/MASH is projected to rise from 4.7 million years of perfect health lost in 2025 to 6.1 million in 2060. Absenteeism due to morbidity is projected to increase by 18%, reaching 615 million workdays in 2060, worth $158 billion. In 2060, MASH F4 is projected to represent approximately 0.7% of the population but account for 6.0% of excess deaths and 34.1% of HCCs.
Conclusion: Under current standard of care practices, the clinical and humanistic burden of MASLD/MASH is projected to rise substantially in the US, emphasizing the urgent need for earlier detection and intervention strategies.

Socio-demographic inequalities on the UK liver transplant waiting list over time: the impact of prognostic scores and candidate selection schemes

Ji Jade King[1,2], Rhiannon Taylor[2], David Wallace[3], Julia Verne[4], Emmanouil Tsochatzis[1,3], Douglas Thorburn[1,3]. [1]*University College London, Institute of Liver and Digestive Health, London, United Kingdom;* [2]*Nhs Blood & Transplant, Bristol, United Kingdom;* [3]*Royal Free Hospital, London, United Kingdom;* [4]*King's College Hospital, London, United Kingdom*
Email: jijadeking@gmail.com

Background and aims: Increasing international evidence suggest that liver transplant (LT) candidates may not have equal chances of transplantation based on socio-demographic characteristics, with female, non-White and socially deprived individuals experiencing disadvantage. We aimed to assess if such disparities exist in the UK, and if changes to prognostication scores (Child-Pugh to UKELD in

2008) and candidate selection schemes (centre-based clinician-driven to partially algorithmic in 2018) promoted equity. Recording of offer outcomes since 2018 allowed investigation of where disparities, if any, arise. Outcomes of both super-urgent (SU) and elective (EL) listing were assessed.
Method: Adults registered on the UK Transplant Registry for liver-only transplantation between 2004–2024 were included and grouped into Era1 (2004–2008), Era2 (2008–2018) and Era3 (2018–2024). Fine–Gray models assessed socio-demographic disparities in cumulative incidence of LT (LT CIF) at 7 days (SU) and 1 year (EL), accounting for death and removal as competing risks and adjusting for relevant clinical and demographic factors.
Results: 17,821 candidates were included. Socio-demographic characteristics did not significantly influence access to SU LT across eras. Disparities emerged in EL outcomes. While no differences were observed in Era1, female candidates had significantly lower EL LT CIF from Era2 onwards (sHR 0.91 [0.85–0.97]). Offer analyses in Era3 showed no sex difference in graft offers, but higher offer declines and lower EL LT CIF in women especially across centre-based pathways. Socioeconomic disadvantage emerged in Era2, with higher EL LT rates among the most affluent candidates (sHR 1.14 [1.04–1.25]), and higher waitlist mortality among the most deprived in Era3 (sHR 0.57 [0.41–0.80]). Ethnic disparities were modest due to small numbers: in Era2, Black candidates had marginally lower EL LT rates with similar mortality, while Asians showed higher waitlist mortality. Such differences were attenuated in Era3.
Conclusion: Access to SU LT in the UK has remained largely equitable. However, as EL candidate selection transitioned from clinician discretion to algorithm-driven systems, socio-demographic inequalities shifted. Sex inequity emerged after UKELD adoption and persists, arising at candidates' selection rather than algorithmic offering. Deprivation- and ethnicity-related disparities have narrowed but remain relevant, highlighting the need to revisit decision-making pathways to promote equitable transplant access.

Feasibility and outcomes of liver health checks in community alcohol services
Daniel Gutmann[1], Michael Griffiths[1], Susan Kemp[1], Erika Toth-Cserepes[1], Claire St John[1], Douglas Macdonald[1,2], Filomena Ferrentino[1], Rory Munday[3], Paul Trembling[3], Lourdes Cumlat[4], Deepak Suri[4], Evangelia Fatourou[4], Sana Rehman[5], Yuktha Gubbala[5], Mohamed Shariff[5], Thendral Mangala[6], Emmanuel Tsochatzis[1,7]. *[1]Sheila Sherlock Liver Unit, Royal Free Hospital, London, United Kingdom; [2]UCL Insitute for Liver and Digestive Health, Royal Free Hospital and UCL, London, United Kingdom; [3]Lister Hospital, Stevenage, United Kingdom; [4]The Whittington Hospital, London, United Kingdom; [5]Watford General Hospital, Watford, United Kingdom; [6]North Middlesex University Hospital, London, United Kingdom; [7]UCL Institute for Liver and Digestive Health, Royal Free Hospital and UCL, London, United Kingdom*
Email: daniel.gutmann@nhs.net

Background and aims: Alcohol-related liver disease (ALD) is a major cause of premature mortality. Many patients first present with cirrhosis or decompensation. In North Central London, Liver Health Check Clinics (LHCCs) were established within community alcohol services, utilising transient elastography (TE) to screen for significant fibrosis and cirrhosis. This enabled hepatology referral in those not otherwise engaged in healthcare. To date, case-finding programmes are not embedded in clinical practice despite guideline recommendations. We report the diagnostic yield of LHCCs and long-term clinical outcomes of all patients with elevated liver stiffness measurement (LSM).
Method: Between 15.08.2022 and 31.12.2024, 2,909 patients attending LHCCs were screened using TE. LSM was categorised as <8 kPa (likely no advanced fibrosis), 8–11.4 kPa (likely significant fibrosis), and ≥11.5 kPa (likely advanced fibrosis/ cirrhosis). Those with ≥11.5 kPa were referred to hepatology services at seven hospital sites with a non-invasive liver screen, liver ultrasound and prioritisation as per Baveno VI criteria for clinically significant portal hypertension (CSPH) (TE ≥25 kPa). Cirrhosis was defined using a standardised algorithm combining LSM, imaging, endoscopy and non-invasive biomarkers. Follow-up data included abstinence status, LSM change, decompensation events, admission, hepatocellular carcinoma (HCC) and mortality.
Results: Among 2,909 screened, 11.9% had LSM 8–11.4 kPa and 9.3% had LSM ≥11.5 kPa. Of the latter, 58.7% had cirrhosis, 63% met CSPH criteria. During follow up, 31 deaths occurred (concentrated in the cirrhosis group). 2/3 of CSPH patients had at least one admission while all decompensation events occurred in the cirrhosis group. Abstinence data suggested a non-significant trend towards greater LSM reduction with sustained abstinence. A substantial non-attendance rate of 39% for secondary care follow up underscored engagement challenges. Multivariate analysis linked higher age and greater Audit-C scores to higher odds of LSM ≥11.5 kPa; abstinence showed a non-significant trend towards larger LSM falls and higher odds of ≥20% LSM improvement, while higher baseline LSM and platelet count predicted greater LSM reductions among those with baseline ≥11.5 kPa.
Conclusion: Community TE screening identifies a substantial burden of undiagnosed advanced ALD. High short-term risks of admission and death support TE based case finding and integrated pathways linking alcohol services with hepatology care.

TOP-018-YI
Increased diagnosis and risk stratification for MASLD in primary care over the last 20 years: real-world evidence from over 11.7 million individuals in the UK
Huei-Tyng (Philippe) Huang[1], Michael Hewitt[1], Wenhao Li[1], Laura Temperley[1], Naveed Sattar[2], William Alazawi[1]. *[1]Barts Liver Centre and Barts Metabolism Network, Blizard Institute, Queen Mary University of London, London, United Kingdom; [2]School of Cardiovascular and Metabolic Health, BHF Glasgow Cardiovascular Research Centre, University of Glasgow, Glasgow, United Kingdom*
Email: h.t.huang@qmul.ac.uk

Background and aims: MASLD is a leading cause of chronic liver disease with rapidly growing prevalence. However, there is significant underdiagnosis in healthcare records, contributing to missed intervention opportunities and late presentation. Tools to stratify MASLD (e.g., Fib-4) exist but are underused. The last decade has seen awareness and educational efforts to promote detection and risk stratification in MASLD. Here we study the changes in prevalence, incidence of recorded MASLD, associated diseases, and availability of Fib-4 score in the UK primary care population.
Method: This real-world evidence study identified individuals with recorded MASLD diagnosis between 2003 and 2022 in the UK primary care Clinical Practice Research Datalink (CPRD). NAFLD codes were used as proxy for MASLD given near-complete overlap. Individuals with <1 year follow-up, age <18 years, or pre-existing autoimmune liver disease and viral hepatitis were excluded. We calculated point prevalence, incidence, comorbidities and availability of Fib-4 components. Controls were matched 1:4 on sex, age (±5 years), and general practice.
Results: Out of 11.7 million individuals active in CPRD in 2022, we identified 365,797 MASLD patients and 1,460,288 controls. In the last decade, recorded MASLD prevalence rose approximately 5-fold, from 0.52% in 2013 to 2.42% in 2023 ($p < 0.001$). Annual incidence doubled from 1.60 in 2012 to 3.31 in 2022 per 1000 person-years ($p < 0.001$). Compared to controls, MASLD patients (median age of 53, 51.8% male) had a higher prevalence of type 2 diabetes (21.0% vs 7.7%; $p < 0.001$) and hypertension (35.3% vs 18.7%; $p < 0.001$). The availability of components to calculate Fib-4 in MASLD group increased from 4.3% pre-2015 to 22.8% 2015 to 2022 ($p < 0.001$). The proportion of MASLD patients with high-risk Fib-4 scores modestly decreased from 7.6% to

6.4% (pre- vs post-2015). South Asians were over-represented in the MASLD group (11.0% vs 7.2%; p < 0.001) and had the lowest adjusted odds ratio of having Fib-4 components (0.67, 95% CI: 0.65–0.70; p < 0.001) available for calculation.
Conclusion: Recorded MASLD prevalence in UK primary care has increased 5-fold in the last decade, although there remains a large diagnostic gap. Fibrosis risk stratification has improved, commensurate with education efforts but overall implementation remains low. There is a potential care gap among South Asians, who are at high risk but less likely to have data collected for risk stratification.

Email: berenice.alard@genfit.com

Background and aims: Acute decompensation (AD) of liver cirrhosis encompasses various decompensating events. AD events are defined as the sudden onset or worsening of ascites, variceal bleeding (VB), or hepatic encephalopathy (HE), occurring alone or in combination. Using 10 years of real-world data from U.S. hospitals, we aimed to characterize patients (pts) admitted for AD and evaluate patterns of inpatient care according to AD event type and prior medical history.
Method: All hospitalizations (hosp) of pts with cirrhosis, recorded between April 2016 and February 2025 in the Komodo's Healthcare Map US real-world database, in which an AD event was documented on the day of admission, were included. For each hosp, the most specialized provider recorded during the entire hospital stay was extracted. The rate of consultations with a hepatologist and/or gastroenterologist (HG) and the proportion of pts requiring intensive care unit (ICU) admission were determined. Hosp were grouped based on either etiology of pts or type of AD recorded on the first day of hosp to assess potential differences in hospital care and impact on clinical outcomes.
Results: A total of 2,454,386 hosp in 1,024,096 pts (59% male; mean age at admission 60 y) were analyzed. Median hosp duration was 5 d; 4% required ICU admission (median ICU stay: 4 d). Of all pts, 42% had only one admission, 17% had ≥5, and 0.7% had ≥20 hosp. Rehospitalization rates increased progressively: 51% after the first hosp, 56.5% after the second, 61.3% after the third, and 65% after the fourth. The most common type of AD was ascites (74%), followed by HE (35%) and VB (17.5%). Internal medicine was the primary specialty in 33% of hosp, HG in only 20% of cases overall. Among admissions for a unique type of AD event, VB admissions had the highest HG involvement (26.5%) and ICU use (5%), with a 28-days mortality of 6% in ICU vs 3% in hosp without ICU admission, followed by ascites (17%; ICU 3% and a 28-days mortality of 13% in ICU vs 7%) and HE (15%; ICU 3.4% and a 28-days mortality of 13% in ICU vs 6%). Among pts with the same types of AD events at admission and no additional AD event during hosp, those seen by a HG on the first day had a lower 28-day mortality (−2.3% in absolute average) compared to those who were seen later by a HG during hosp.
Conclusion: Most pts hospitalized for AD were not seen by a HG on the first day of hosp, or were never seen during their stay, highlighting a critical opportunity to improve hospital care and clinical outcomes for these pts.

THU–003

Evolving impact of alcohol and abdominal adiposity on liver mortality in Finland over four decades: implications for public health interventions

Fredrik Åberg[1,2], Jaakko Reinikainen[2], Aki Havulinna[3], Annamari Lundqvist[2]. *[1]Helsinki University Hospital and University of Helsinki, Helsingfors, Finland; [2]Finnish Institute for Health and Welfare, Helsinki, Finland; [3]Department of Computing, University of Turku, Turku, Finland*
Email: fredrik.aberg@helsinki.fi

Background and aims: Liver-related mortality has been rising in Finland until recently, but the extent to which these trends are explained by changes in major risk factors – alcohol use, adiposity, diabetes, and smoking – remains unclear. By comparing individual-level data from nationally representative health surveys conducted at regular intervals over 36 years with population-level mortality trends, we analyzed the independent and combined contributions of these risk factors to liver-related mortality.
Method: Finnish health surveys conducted roughly every 5 years between 1987 and 2023 included 38,659 men and women aged 35–64 years. Predicted liver mortality was estimated using a cause-specific competing-risk regression model fitted to multiply imputed survey data with registry-linked follow-up, including sex-specific interaction terms. Population-weighted predictions were then applied to each survey year to estimate mortality based on risk factor changes relative to 1987. Observed mortality was obtained from the National Causes of Death Register, and observed and predicted age-standardized trends were compared as percentage changes from the 1987 baseline.
Results: Observed age-standardized liver-related mortality in Finland increased by 46% in men and 66% in women from 1987 to 2023, peaking in 2007 (111%, both sexes). Of the age-standardized liver mortality, 85%/75% (men/women) was recorded as alcohol-related liver disease, 3%/8% as other liver diseases, and 12%/17% as liver cancer (alcohol-related or not). Predicted liver mortality based on average alcohol use, waist-to-hip ratio, diabetes, and smoking closely mirrored observed national trends in both sexes. Alcohol use remained the strongest single contributor to liver mortality throughout the study period, while increases in waist-to-hip ratio

increasingly explained recent temporal variation. In men, observed mortality during the most recent years declined more slowly than predicted, suggesting that increasing abdominal adiposity may have offset part of the mortality reduction expected from declining alcohol consumption. Changes in smoking and diabetes contributed minimally to temporal trends.
Conclusion: Changes in the main risk factors – particularly alcohol use, and more recently, abdominal adiposity – largely explain temporal variation in liver-related mortality at the population level. This highlights the need for coordinated public health strategies addressing both alcohol use and obesity.

THU-004
Rising liver fibrosis rates due to MASLD identified amongst young adults in a general population birth cohort
Kushala Abeysekera[1], Ann Archer[1], Jon Heron[1], Matthew Hickman[1]. [1]*University of Bristol, Bristol Medical School, Bristol, United Kingdom*
Email: k.abeysekera@bristol.ac.uk

Background and aims: Steatotic liver disease is the leading cause of liver-related morbidity across Europe. Understanding its asymptomatic disease course and subclinical burden in the general population is vital to intervene with targeted therapies before major adverse liver outcomes (MALOs) occur. A cross-sectional analysis performed on the Avon Longitudinal Study of Parents and Children (ALSPAC) general population birth cohort when participants were 24 years identified 1 in 40 had fibrosis based on transient elastography (TE). The aim of this study was to re-evaluate the prevalence of SLD in the same cohort, now 30 years, using TE and controlled attenuated parameter (CAP).
Method: 3599 participants had TE assessment during a Focus@30 clinic. Liver stiffness measurements (LSM) with interquartile range/median ratio (IQR/M) greater than 30% were excluded when analysing fibrosis. Data was collated on anthropometric measurements including body mass index (BMI), waist circumference-to-height ratio (WCHt) as well as alcohol use, smoking and socioeconomic status. Statistical analysis was performed using Stata MP 18.0.
Results: Mean participant age was 29.8 years (SD 0.6). 4.2% of participants met criteria for alcohol use disorder; 20.5% had obesity (mean BMI 26.5; SD 5.9). 320 LSMs were excluded with an IQR/M > 30%. 3279 participants had a valid LSM. 130 (3.9%) had a LSM ≥8 kPa, of which 30 (0.9%) had a LSM ≥12 kPa. This had increased from 88 (2.4%) of participants with a LSM ≥8 kPa and 8 with a LSM ≥12 kPa aged 24 years. Based on a CAP≥275 dB/m, 19.5% (n = 674/3453) of participants had steatosis compared to 11.1% (n = 420/3767) 6 years prior. 19.3% of participants met criteria for MASLD, 7.9% for MetALD and 1.1% for ALD. 2356 participants had had TE at both 24 and 30 years. 82 participants who had no fibrosis at 24 years had a LSM ≥8 kPa at 30 years. Increased adiposity based on WCHt ratio, was the most strongly associated variable with elevated LSM at 30 years, despite adjustment for sex, socioeconomic status, alcohol use and smoking (aOR 2.54 [95%CI 1.94–3.32]; p < 0.0001). A smaller effect estimate was observed with BMI (aOR 1.15 [95%CI 1.10–1.19]; p < 0.0001).
Conclusion: In this UK general population birth cohort, the number of asymptomatic participants with suspect SLD fibrosis has increased almost 50% between 24 to 30 years. The aetiology attributed to this rise was MASLD rather than MetALD or ALD. WCHt ratio may provide more value than BMI in identifying those at greater fibrosis risk amongst young adults.

THU-005
Cirrhosis burden dynamics in the Asia-Pacific region from 1990 to 2023 and forecasting to 2050: findings from the global burden of disease study 2023
Aimitaji Abulaiti[1]. [1]*First Affiliated Hospital of Xinjiang Medical University, Urumqi, China*
Email: aimitaji1215@sina.com

Background and aims: Cirrhosis represents a critical public health concern throughout the Asia-Pacific. To guide future regional health strategies, this study evaluated the trends and underlying drivers of the disease burden spanning the period from 1990 to 2023.
Method: Leveraging data from the Global Burden of Disease Study 2023, we examined metrics including incidence, prevalence, mortality, and disability-adjusted life years (DALYs), stratified by age, gender, and Socio-demographic Index (SDI). The study utilized estimated annual percentage changes (EAPCs) to assess trends, the slope index of inequality (SII) to measure disparities, and decomposition analysis to identify key drivers. Additionally, frontier analysis was applied to evaluate efficiency, alongside burden projections extending to 2050.
Results: Between 1990 and 2023, the number of prevalent cases increased by 57%, reaching 624.7 million (95% UI 584.4–671.8), while total fatalities grew by 7% to 354,279 (309,789–401,481). Men experienced a significantly higher mortality burden (246,656 deaths) compared to women (107,623 deaths). In contrast, age-standardized rates exhibited a marked decline, with incidence decreasing by an EAPC of −0.56%, mortality by −2.53%, and DALYs by −2.33%. The majority of deaths were concentrated in India (188,370) and China (121,033), whereas the Solomon Islands reported the highest standardized mortality rate (37.4 per 100,000). Notably, incidence rates among individuals aged 95 and older surged by 657%. Decomposition analysis revealed that demographic shifts—specifically population growth and aging—were the primary factors counteracting epidemiological improvements. Absolute inequality narrowed, as indicated by a shift in the DALYs SII from −426.9 to −308.1, and efficiency gaps regarding mortality decreased universally. Projections for 2050 suggest that despite falling standardized rates, the absolute number of deaths will rise to 391,317.
Conclusion: While epidemiological indicators have shown improvement, the absolute burden of cirrhosis is escalating due to rapid population aging and growth, with India and China being particularly affected. To address the anticipated rise in disease burden, future policies must prioritize the allocation of integrated care resources tailored to an aging demographic.

THU-006
Digital technology policy is associated with liver disease mortality: a multinational ecological study
Somaya Albhaisi[1], Jennifer Dodge[1], Brian Lee[1]. [1]*University of Southern California, Los Angeles, United States*
Email: somaya.albhaisi@med.usc.edu

Background and aims: The GovTech Maturity Index (GTMI) is a World Bank-validated metric of government digital technology use and population-level access to digital public services. Its relationship with liver disease mortality is a knowledge gap that can inform governmental policies.
Method: We conducted a multinational ecological study using 2020 data to assess the association of liver disease mortality with GTMI. Covariates were captured from the World Bank, including Gross Domestic Product per capita, Human Development Index, and Healthcare Access and Quality Index. GTMI was categorized as Low (0–0.24), Medium (0.25–0.49), High (0.50–0.74), or Very High (0.75–1.00). The primary outcome was liver-related mortality from the Global Burden of Disease study, expressed as age-standardized mortality rates (ASMRs) for 14 liver disease etiologies. Multivariable linear regression assessed associations between ASMRs and GTMI, adjusted for the aforementioned country-level covariates.
Results: Among 198 countries, 33 were classified as Low, 63 as Medium, 59 as High, and 43 as Very High GTMI categories. The population-weighted mean overall liver ASMR was 23.14 per 100,000. In multivariable analysis, each ordinal increase in GTMI category was associated with a decrease in overall liver ASMR of 4.83/100,000 (95% confidence interval [CI]: −7.55 to −2.11, p-trend = 0.001), with ASMR 43.02 vs. 16.21/100,000 for Low vs. Very High

GTMI. This association was primarily attributable to the Public Service Delivery subcomponent of GTMI ($p < 0.05$). Higher GTMI was associated with lower mortality from hepatitis B-related liver diseases, but not consistently with other etiologies. For hepatitis B, each ordinal GTMI increase was associated with fewer deaths from cirrhosis (−1.48/100,000; 95% CI: −2.43 to −0.52; $p = 0.003$) and hepatitis B–related liver cancer (−0.85/100,000; 95% CI: −1.28 to −0.41; $p < 0.001$). For other etiologies, results were heterogeneous. A higher GTMI score was associated with fewer deaths from metabolic dysfunction-associated steatohepatitis-related liver cancer (Coefficient: −0.59/100,000; $p = 0.013$) but with more deaths from acute hepatitis A (Coefficient: 0.77/100,000; $p = 0.001$).
Conclusion: Advanced digital government maturity is associated with lower liver-related mortality, particularly from hepatitis B, possibly due to improved digital public service delivery. Investments in digital technology on a governmental level may represent a policy lever to improve population-level liver health outcomes.

THU-007
Impact of United States food and drug administration drug approvals on public and scientific dialogue on metabolic dysfunction-associated steatotic liver disease: a multi-platform digital analysis
Somaya Albhaisi[1], Norah Terrault[1]. [1]*University of Southern California, Los Angeles, United States*
Email: somaya.albhaisi@med.usc.edu

Background and aims: The US Food and Drug Administration (FDA) approvals of Resmetirom in March 2024 and Semaglutide in August 2025 for metabolic dysfunction-associated steatotic liver disease (MASLD) are landmark events. However, their impact on public disease dialogue, patient community discourse, and scientific research publications has not been measured. This study aimed to quantify the impact of these approvals across multiple digital platforms.
Method: We conducted a longitudinal digital analysis from January 2023 to October 2025 across three data sources: Google Trends search volume indices; Reddit discussions; and PubMed publications. Analytical methods included interrupted time series analysis, valence aware dictionary and sentiment reasoner (VADER) sentiment analysis, non-negative matrix factorization topic modelling, network analysis, and rigorous statistical validation.
Results: Semaglutide approval drove the most substantial increase in public search interest, with an immediate + 17.1 point level change for MASLD searches ($p < 0.001$) and a very strong correlation between MASLD and Semaglutide search volumes ($r = 0.93$). Resmetirom approval did not cause an immediate level change in MASLD searches but initiated a significant positive post-approval weekly trend (slope + 0.032 points per week, $p < 0.001$). On Reddit, Semaglutide approval triggered an increase (+ 82.3%) in discussion volume, largely focused on personal experiences and weight loss, while Resmetirom approval was associated with a decrease (−30.8%). Community sentiment, measured using VADER compound scores ranging from -1 (most negative) to +1 (most positive), remained stable after both approvals ($p > 0.05$). Network analysis showed Reddit communities responded collectively to FDA approvals but were weakly correlated with public searches ($r = 0.344$ for MASLD). In scientific literature, Resmetirom approval created a new research domain (0 publications before vs. 132 after), whereas Semaglutide approval significantly accelerated an existing research trajectory (157 pre- vs. 54 post-approval publications; odds ratio = 3.557, $p < 0.001$).
Conclusion: FDA approvals differentially modulated the MASLD digital ecosystem. Semaglutide drove larger increases in public search interest and patient community engagement, while Resmetirom catalyzed de novo scientific field formation. Public dialogue around MASLD appears closely tied to weight-loss pharmacotherapy popularity, underscoring the need for integrated public health messaging.

THU-008
Socioeconomic barriers to initiation of second-line therapy in primary biliary cholangitis patients with incomplete response to ursodeoxycholic acid
Lital Aliasi-Sinai[1], Christopher Kim[1], Liliana Vittini Hernandez[1], Francina Collado[1], Xiaotao Zhang[1], Douglas T Dieterich[1], Anna Mageras[1], Frances Lee[1]. [1]*Icahn School of Medicine, New York, United States*
Email: lital.aliasi-sinai@mountsinai.org

Background and aims: Second-line treatment for primary biliary cholangitis (PBC), including seladelpar, elafibranor, off-label fenofibrate, and obeticholic acid (OCA, withdrawn from market) should be offered when there is intolerance or incomplete response to ursodeoxycholic acid (UDCA). We sought to characterize the use of second-line (2L) therapies and identify demographic factors associated with second-line therapy initiation.
Method: This single center retrospective observational study from 2000 to 2025 identified adults with PBC ICD-10 code, ALP >200, and active UDCA prescription verified by chart review. Patients on UDCA for at least 12 months with ALP >200 were considered eligible for 2L therapy. Primary outcome was prescription of 2L therapy; secondary outcomes included reasons for lack of 2L therapy initiation. Covariates included age, sex, race, preferred language, marital status, and insurance type. Univariable and multivariable analyses were performed using R.
Results: Among 356 patients with PBC with ALP >200, 331 (93.0%) were receiving UDCA and 296 (89.4%) met criteria for treatment escalation. In this cohort, the mean age was 64.3 years, 88.5% were female, 50.3% were White, 11.5% Hispanic/Latino and 8.1% Black. 11.1% were uninsured. 81 (27.4%) received 2L therapy, and 215 (72.6%) did not, of whom 99 (46.0%) had no documented discussion of escalation. OCA was the most frequently prescribed 2L therapy (12.1%), followed by seladelpar (10.0%), fenofibrate (5.4%), and elafibranor (2.7%). While 35.3% of Hispanic patients and 31.5% of White patients received 2L therapy, 0% of Black patients received 2L therapy, though there was no significance in documented offering of 2L therapy (OR 2.08, 95% CI 0.85–6.27, $p = 0.11$). In univariable analysis, older age, and uninsured status were associated with lower likelihood of escalation to 2L therapy (OR 0.97, 95% CI 0.95–0.99, $p = 0.008$; OR 0.05, 95% CI 0.003–0.24, $p = 0.004$). In multivariable analysis, only uninsured status was associated with lack of initiation of 2L therapy (OR 0.08, 95% CI 0.004–0.40, $p = 0.02$).
Conclusion: Despite meeting treatment criteria, 72.6% of eligible patients have not received 2L PBC therapy, and over half of these patients lack documented discussion or offering of 2L therapy. Race and insurance status influence treatment escalation. Future studies should investigate system and patient-level barriers to treatment escalation and assess if addressing these gaps improves downstream clinical outcomes.

THU-009
Cirrhosis in France: is there disparities to address to improve prognosis?

Background and aims: Although the main risk factors for cirrhosis (Cir) are well known, diagnosis remains frequently delayed and associated with poor prognosis. In France, comprehensive population-based data on Cir epidemiology, care pathways, and outcomes are scarce. We aimed to describe the epidemiology of incident Cir and identify medical and social disparities associated with prognosis.
Method: Using the 2% representative sample of the French National Health Data System (SNDS), we identified incident cases of Cir between 2015 and 2021 based on diagnostic codes, procedures, or Cir-specific treatments. Demographic characteristics, risk factors, comorbidities, complications, care pathways, and outcomes were collected. Social deprivation was assessed using the FDep index of the municipality of residence. Overall survival (OS) was analyzed using Kaplan-Meier and multivariable Cox models.
Results: 9,967 incident Cir cases were identified: 65% were men and 63% were aged ≥60 years. Alcohol misuse was detected over follow-up in 49%, diabetes in 25% and obesity in 22%. Known risk factor and cause of Cir were identified prior to diagnosis in 47% and 19.0% of cases, respectively. Cir was alcohol-related in 46%, only metabolic in 21%, viral in 2%, and of unknown causes (UC) in 25%. Over time, viral and alcohol-related Cir declined, while metabolic Cir increased significantly. During follow-up, 80% experienced at least one Cir-related complication: hepatic failure (40%) and ascite (29%) were most frequent. Primary liver cancer (PLC) occurred in 14%. Two-year OS was 56%. Poorer OS was independently associated with Cir-related complications, concomitant PLC, higher Charlson score at liver disease diagnosis, UC of Cir, and residence in more deprived towns (FDep Q4–Q5). In contrast, benefiting from long-term disease coverage (LTDC) for Cir and social solidarity health coverage were associated with improved survival. Cir was mostly diagnosed in hospitalization (87%) and through death in 6%, especially in women. Exclusive outpatient management (3%) was associated with better prognosis.
Conclusion: If cirrhosis epidemiology in France is shifting toward metabolic causes, diagnosis remains late, hospital-based, and associated with high short-term mortality. Socioeconomic, gender and etiological disparities substantially affect prognosis, but access to LTDC and social solidarity–based health coverage may improve outcome. Strategies promoting earlier ambulatory diagnosis and targeted, equity-based strategies are urgently needed.

Unmet needs in palliative care for terminal liver diseases: analysis of a german physician survey

Lena Bartke[1], Jeanette Wehnes[1], Dirk Adolph[2], Marcin Krawczyk[3], Hartmut Schmidt[3], Nicole Selbach[1], Ali Canbay[1], Jan Best[3]. *[1]University Hospital Knappschaftskrankenhaus Bochum, Bochum, Germany; [2]Ruhr University Bochum (RUB), Bochum, Germany; [3]University Hospital Essen, Essen, Germany*
Email: jan.best@uk-essen.de

Background and aims: The burden of liver cirrhosis is increasing (*Luo et al. J Health Popul Nutr. 2025*). Given the limited availability of donor organs and long waiting times, many patients with end-stage liver disease (ESLD) are no longer eligible for liver transplantation (LT) and could therefore benefit from early integration of palliative care (PC). This study surveyed the attitudes of treating physicians at German LT- centers toward PC.
Method: Over a five-month period, transplant physicians at 22 German LT-centers were surveyed using a validated online questionnaire based on 10-point Likert scale. A total of 38 dedicated questions assessed attitudes toward PC, perceived needs, availability, and barriers to integration of PC.
Results: Of the 321 physicians contacted, 62 (19.3%) completed the questionnaire. Among the responders 62.9% were male, mainly senior physicians and internists. PC consultation teams were used weekly by 41.9% and monthly by 30.6% of physicians. Respondents reported significant impairment of quality of life and moderate-to-high burden from somatic and psychosocial symptoms, and they rated the benefits of PC integration as substantial. Barriers to PC integration were perceived mainly at the interface between patients, families and care planning, while physician- and structure-related obstacles were rated significantly lower ($F(7,724) = 24.20$, $p < 0.001$, $\eta^2 = .284$). While 16.1% of respondents felt that end-of-life discussions took place at the right time, 1.6% considered them to be too early and 82.3% too late.
Conclusion: Despite broad acceptance of PC at German LT centers, respondents identified numerous barriers to early integration. Earlier, patient-centered discussions might enable better PC integration. Patient-reported data are warranted to identify relevant PC needs.

Email: 101013436@seu.edu.cn

Background and aims: Cardiovascular disease is the major driver of mortality in individuals with metabolic dysfunction-associated steatotic liver disease (MASLD) or type 2 diabetes (T2D). Current clinical practice guidelines emphasize lifestyle management as the cornerstone for treatment of T2D and MASLD. This study assessed the influence of the American Heart Association's Life's Essential 8 (LE8) metrics on the onset and progression of MASLD and T2D comorbidity.
Method: Data were obtained from a nationwide community-based survey in China, NHANES and UK Biobank. LE8 scores were quantified using a combination of behavioral and clinical metrics obtained through physical examinations and structured questionnaires. Multinomial logistic regression was used to assess the association between LE8 scores and four health states —healthy (reference), MASLD only, T2D only, and comorbid MASLD-T2D. Multi-state models and restricted cubic splines (RCS) were employed to analyze how LE8 scores influence eight health transitions, ranging from disease-free baseline to MASLD, T2D, comorbidity, and mortality.
Results: Across three cohorts (N = 246,723), higher LE8 scores were consistently associated with reduced risks of MASLD, T2D, and their comorbidity (all $P < 0.001$). Prospective multi-state modeling in the UK Biobank further demonstrated that high (vs. low) CVH scores markedly reduced the risk of incident MASLD (HR: 0.27; 95% CI: 0.18–0.39) and T2D (HR: 0.10; 95% CI: 0.09–0.12). Among individuals with a single disease, high CVH scores significantly hindered progression to comorbidity. Notably, each 10-point LE8 increment was associated with a 24% and 11% lower risk of mortality from MASLD and T2D onset, respectively. Both behavioral and biological domains conferred significant protection, with RCS analysis revealing non-linear dose-response relationships between LE8 scores and health transitions(all $P_{non\text{-}linear} < 0.05$).
Conclusion: LE8 scores are robust predictors of MASLD and T2D risk and clinical trajectories. Optimal cardiovascular health offers substantial protection across the entire disease continuum—from initial onset to comorbidity and mortality—underscoring the clinical utility of the LE8 framework in the integrated prevention and management of metabolic-associated disorders.

MASLD in the WHO Africa region: prevalence and development of a simple score to detect advanced fibrosis in dysmetabolic patients

Isabelle Bough[1], Bakary Dibba[2], Anna Sessa[3], Ousman Bah[2], Joel Dave[1], Dirk Blom[4], Mashiko Setshedi[4], Kitabu Jammeh[2], Rumaysa Ahmed[5], Karen Foreest[2], Erwan Vo Quang[2], Neliswa Gogela[1], Brendan Janse Van Rensburg[1], Ben Mullish[5], Isabelle Garcia[5], Dalessandro Umberto[2], Caity Cattell[4], Gibril Ndow[2], Wendy Spearman[4], Yusuke Shimakawa[6], Mark Sonderup[4], Maud Lemoine[5,7,8]. *[1]University of Cape Town, Division of Endocrinology, Department of Medicine, Cape Town, South Africa; [2]MRCG@LSHTM, Fajara, Gambia; [3]APHP Henri Mondor Hospital, Creteil, France; [4]University of Cape Town, Division of Hepatology, Department of Medicine, Cape Town, South Africa; [5]Imperial College London, Department of Metabolism, Digestion and Reproduction, London, United Kingdom; [6]Pasteur Institute, Paris, France; [7]MRC Gambia, Fajara, Gambia; [8]MRCG@the London School of Hygiene and Tropical Medicine, Fajara, Gambia*
Email: lemoine.maud@gmail.com

Background and aims: MASLD remains underdiagnosed and understudied in the WHO Africa Region despite a growing burden of obesity and diabetes. In a cohort study of patients with metabolic dysfunction in The Gambia and South Africa, we evaluated the prevalence, severity and clinical correlates with MASLD and developed a simple score to detect advanced liver fibrosis in this population.
Method: Consecutive patients with high blood pressure (HBP), obesity (body mass index (BMI)≥30 kg/m2) or type 2 diabetes mellitus (T2DM) were enrolled in the Metlive study in Gambia (training cohort) and South Africa (validation cohort) and underwent comprehensive assessment including a Fibroscan-CAP scan. MASLD was defined as CAP≥248 dB/m (or hyperechoic liver on ultrasound if invalid CAP), advanced liver fibrosis (ALF) as LSM≥8 kPa, and cirrhosis as LSM≥12 kPa. A simple score was derived by dichotomizing chosen variables using receiver operating characteristic-derived cut-offs. In the validation cohort diagnostic performance was assessed by calculating sensitivity, specificity, positive and negative predictive values (PPV, NPV).

Results: Between 5 November and 17 December 2025, 315 consecutive participants were enrolled in Gambia (76% female, median age 55 (45–64) years, 33% obesity, 61% T2DM, 56% HBP, 46% steatosis). Between 9 September and 9 December 2025, 151 consecutive patients were enrolled in South Africa, 24 were excluded due to alcohol intake (10%) or missing data, leaving 127 participants analyzed (58% female, median age 53 years, 54% obesity, 21% T2DM, 79% HBP, 67% steatosis). In The Gambia, 43% (n = 130) had MASLD and 8.3% (n = 26) ALF including seven (2.2%) cirrhosis, whilst in South Africa, MASLD was observed in 65% with 24.5% having ALF including 10% (n = 12) with cirrhosis. In the training cohort, BMI, Waist/Hip circumference ratio (WHR), and GGT level were independent factors of MASLD, while GGT level and Platelet count were the only factors associated with ALF. A simple score based on at least 2 of the following parameters, BMI ≥26 kg/m^2, WHR ≥0.92 and GGT ≥41 IU/L, had a high sensitibity (89%) and NPV (93%) to detect ALF, higher than FIB-4, but a low specificity (50%).
Conclusion: MASLD and advanced liver fibrosis are frequently observed in dysmetabolic patients in The Gambia and South Africa. The use of a simple score based on BMI, Waist and Hip circumferences and GGT level could help the identification of patients with advanced liver fibrosis in Africa where access to Fibroscan-CAP remains limited.

Background and aims: The European care landscape for metabolic dysfunction-associated steatotic liver disease (MASLD) is evolving rapidly, and further introduction of care innovations, such as care pathways, screening platforms, and decision tools, is anticipated. The primary aim of this study is to map current approaches to care for MASLD and to gain health system insights to inform implementation of initiatives aimed at improving MASLD care.
Method: We conducted a cross-sectional, mixed-methods, comparative analysis. We distributed an explorative survey amongst healthcare providers (May–October 2025), and assessed national guidelines, policy papers, and other relevant documents. Data collection and analysis were informed by a theoretical framework encompassing five distinct healthcare dimensions. This allowed us to assess receptivity and susceptibility to adoption of new models of care, defined as the extent to which a health system is able to accommodate the implementation of an innovation.
Results: Across ten European countries, the survey was completed by 36 respondents (36% primary care setting, 19% non-academic hospital setting, and 39% university hospital setting) and 50 documents were analyzed. Alignment was observed across countries and levels of care regarding current standard practices of care, with targeted screening and lifestyle interventions most commonly mentioned. Patients still enter care for MASLD predominantly upon incidental findings. Formal referral structures were largely absent and MASLD was rarely embedded in care for diabetes or obesity. Accessibility and availability of MASLD care services was suboptimal, mainly relating to care organization, allocation of diagnostic resources, and reimbursement policies. MASLD guidelines were available in 7 countries, but specific primary care guidance remains scarce. Available guidelines primarily differed in terms of non-invasive test use, follow-up, and use of pharmacotherapy.
Conclusion: The European care landscape for MASLD is largely comparable across countries yet care for MASLD lacks structural embedding in national healthcare systems and all examined healthcare systems showed opportunities to strengthen receptivity and susceptibility to care innovations. Upcoming innovations and models of care for MASLD need tailoring to local healthcare contexts prior to implementation in order to facilitate effective and efficient adoption, thereby recognizing that each country maintains a distinct health system architecture.

THU-014

Evaluating the impact of implementing criteria for initial fibrosis assessment in people at risk of MASLD: a national level analysis using the health survey for England

Ryan Buchanan[1], Sophie Robin[1], Chris D Byrne[1], Kate Glyn-Owen[1]. [1]*University of Southampton, Southampton, United Kingdom*
Email: k.glyn-owen@soton.ac.uk

Background and aims: International guidelines propose a multi-step diagnostic strategy to identify those with Metabolic Dysfunction-Associated Steatotic Liver Disease (MASLD) and advanced fibrosis. We have evaluated the impact of this approach in a representative sample of the English population.
Method: The Health Survey for England (HSE) is an annual survey designed to be representative of the population living in private households in England. The 2016 dataset includes AST and ALT, allowing Fib4 to be calculated. 7746 non-pregnant adults were surveyed in 2016, of whom 3787 had a blood test. Descriptive statistics explored characteristics of the population stratified by eligibility for initial fibrosis assessment (as defined by recent guidelines) and Fib-4. Exploratory analyses were conducted to optimise criteria for initial fibrosis assessment, including adding an

age cut-off, using body mass index instead of waist circumference, and using adjusted alanine aminotransferase (ALT) thresholds. Survey weightings were used in all analyses, to ensure results were generalisable to the population of England.

Results: 55% of adults met criteria for initial fibrosis assessment (type 2 diabetes, abdominal obesity and ≥1 cardiometabolic risk factor, increased ALT). 2.9% of those meeting the criteria had a Fib-4 ≥2.67 but only 66% of those with a high Fib-4 met the initial criteria for a test. Modelled in a population of 240,000 (representing one tertiary hepatology centre): 132,000 people meet the criteria for a Fib-4 test. Of these, 20,328 require further investigation and 3,828 a direct referral to hepatology. Adding an age cut off ≥45 years and using increased ALT according to commonly used standard clinical thresholds reduced the proportion of the population needing initial fibrosis assessment to 35% (from 55%) and improved the negative predictive value of the initial criteria.

Conclusion: The implementation of international MASLD guidance for diagnosing liver fibrosis in England would mean that more than half of the adult population are eligible for initial fibrosis assessment. This would have a substantial impact on hepatology service resources. Pragmatic additional criteria, such as the use of an age 'cut-off' for testing should be considered if implementing international guidelines at scale.

Email: zobair.younossi@cldq.org

Background and aims: MASLD affects women and men differently, and stigma, both perceived and self-stigma, may contribute to gender-specific patterns of care avoidance. This study aimed to

assess gender-specific patterns of stigma and their associations with care avoidance in MASLD.
Method: A cross-sectional, international survey was developed and administered in 2023 by the Global MASH/NASH Council (GNC) among adults with a confirmed diagnosis of MASLD. The survey collected sociodemographic and clinical data, assessed perceived stigma (presence or absence across several domains and overall), and measured self-stigma using the validated Self-Stigma Scale–Short Form, generating domain-specific and total scores. Severe self-stigma was defined as a total score above the 75th percentile, stratified by sex. Care avoidance in primary care or secondary care (gastroenterology, hepatology, and endocrinology) was also reported. Mixed-effects logistic regression models were conducted separately for women and men, adjusting for relevant cofactors and including geographic region as a random effect, to evaluate associations between perceived stigma, self-stigma, and care avoidance.
Results: Among 1,313 respondents with MASLD [51% male; 50% aged ≥55 years; 28% Europe, 26% USA/Canada, 23% East Asia, and 16% MENA; 73% with ≥1 and 43% with ≥2 chronic conditions), care avoidance was more frequent among men (23.6% vs. 18.9%, $p = 0.04$), occurring predominantly in primary care settings. Women reported higher self-stigma domain scores (all $p < 0.0001$) and more discrimination-related perceived stigma (27.8% vs. 19.1%). In adjusted analyses, both perceived stigma [OR (95% CI) = 1.84 (1.07–3.18)] and severe self-stigma [1.84 (1.19–2.85)] were associated with care avoidance in men, whereas only perceived stigma [2.29 (1.25–4.22)] was associated with care avoidance in women. No other factors were associated with care avoidance. In women, perceived stigma was predicted by younger age, multimorbidity, and a history of medical weight loss ($p < 0.05$), while no predictors were identified in men ($p > 0.05$). Indicators of lower socioeconomic status and advanced fibrosis predicted severe self-stigma in both genders ($p < 0.05$).
Conclusion: Stigma is a key driver of care avoidance in MASLD, with distinct gender-specific patterns. Although women report higher levels of self-stigma and discrimination-related perceived stigma, the association between severe self-stigma and care avoidance is stronger among men.

THU-019

Sexual function in chronic liver disease: a case-control study

Yooyun Chung[1], Mussarat Rahim[2], Refah Ahmed[3], Rachel Rosales[4], Bezalel Comia[1], Ilkay Ergenc[1], Mark Mcphail[1], Michael Heneghan[1].
[1]King's College Hospital, London, United Kingdom; [2]St George's Hospital, London, SW17 0QT, UK, United Kingdom; [3]Doctorate of Clinical Psychology, University of Hertfordshire, AL10 9AB, UK, United Kingdom; [4]Princess Royal University Hospital, London, BR6 8ND, UK, United Kingdom
Email: yooyun.chung@nhs.net

Background and aims: Chronic liver disease (CLD) and liver transplantation (LT) are associated with sexual dysfunction (SD), neuropsychiatric symptoms and impaired quality of life (QoL). However, data on SD in patients with CLD/LT remain limited. This study aimed to determine the prevalence of SD in patients with CLD/LT and to assess its relationship with cognitive impairment, QoL and mental health.
Method: In this cross-sectional study, adults with CLD/LT and healthy volunteers (HV) were recruited at King's College Hospital. CLD included patients with cirrhosis and non-cirrhosis. Sexual function was assessed using the international index of erectile function (IIEF) in men and the female sexual function index (FSFI) and Sexual Satisfaction Scale for Women (SSSW) in women. Cognitive function was evaluated using the Montreal Cognitive Assessment (MOCA). Anxiety and depression were assessed with the Hospital Anxiety and Depression Scale (HADS) and QoL using the Clinical Outcomes in Routine Evaluation (CORE) questionnaire and Chronic Liver Disease Questionnaire (CLDQ). Outcomes were analysed by sex, disease stage and cognitive impairment status.
Results: Two hundred women (100 CLD/LT, 100 HV) and 105 men (51 CLD/LT, 54 HV) were recruited with no age differences between patient and HV groups. Among patients with CLD/ LT, SD was highly prevalent, affecting 67% of women (FSFI defined) and 57% of men (IIEF defined). Both women and men with CLD/LT demonstrated significantly poorer sexual function scores compared with HV ($p = 0.013$ FSFI defined, $p = 0.029$ SSSW, $p = 0.046$ IIEF). In women with CLD/ LT, depression and anxiety were associated with SD, reflected by lower FSFI scores ($p = 0.015$), a higher prevalence of SD ($p < 0.001$) and poorer SSSW scores ($p = 0.019$) compared with HV. This was not observed in men. Cognitive dysfunction was not associated with SD in either sex. However, in men with CLD/ LT, cognitive impairment was associated with poorer QoL and higher levels of anxiety and depression. Women with CLD/LT reported poorer liver disease specific QoL than men ($p < 0.001$) and patients with cirrhosis experienced worse QoL than those without cirrhosis ($p < 0.001$).
Conclusion: Approximately two third of patients with CLD/LT experience SD. Marked sex differences exist in relationships between SD, mental health, cognitive impairment and QoL. This highlights the need for sex-specific targeted interventions to address SD and associated psychosocial burden in patients with CLD/ LT.

An interpretable artificial intelligence framework for cardiovascular risk prediction in metabolic dysfunction-associated steatotic liver disease: LiverCARD

Antonio Cirella[1], Pierangela Bruno[2], Valerio Caputo[1], Alessandro Quarta[2], Edoardo de Rose[2], Valeria d'Arpino[1], Silvano Junior Santini[1], Gianluigi Greco[2], Germano Scevola[3], Marco Vinci[3], Pierpaolo Palumbo[4], Ernesto di Cesare[4], Antonella Guzzo[2], Francesco Calimeri[2], Clara Balsano[1].
[1]Department of Clinical Medicine, Life, Health & Environmental Sciences-MESVA, University of L'Aquila, Italy, L'aquila, Italy; [2]Department of Mathematics and Computer Science, University of Calabria, Rende, Italy, Rende, Italy; [3]Ospedale Sandro Pertini Roma, UOC Radiology, Italy, Roma, Italy; [4]Department of Applied Clinical Sciences and Biotechnology-DISCAB, University of L'Aquila, Italy, L'aquila, Italy
Email: cirella.nt@gmail.com

Background and aims: Metabolic dysfunction-associated steatotic liver disease(MASLD) affects approximately 30% of the global population and represents a major public health challenge. Cardiovascular disease is the leading cause of mortality in this population. However, cardiovascular risk (CVR) assessment in MASLD remains suboptimal, as traditional risk scores do not incorporate liver-related parameters or advanced imaging biomarkers. The aim of this study was to develop LiverCARD, an artificial intelligence (AI)-based framework designed to improve CVR prediction in patients with MASLD by integrating routinely collected clinical data with imaging features extracted from coronary computed tomography angiography(cCTA) images.
Method: In this retrospective multicentre study, 164 patients from two Italian hospitals were evaluated. For each patient, ten liver pre-contrast cCTA images were analyzed. Hepatic steatosis(HS) was quantified using liver attenuation, coronary artery calcium score(CS) was used as a marker of CVR, and liver fibrosis trough Fib-4. Patients were stratified into high- and low-risk groups based on degree of CS and HS. LiverCARD integrates clinical variables with embeddings derived from pretrained medical deep learning models. Machine learning models were tested and model explainability was assessed using SHapley Additive exPlanations.
Results: The integrated approach based on XGBoost on combined multimodal dataset achieved strong predictive performance, with an accuracy of 0.89 in internal validation and 0.72 in external validation, outperforming models based on clinical or imaging data alone. The use of multiple liver slices per patient improved LiverCARD efficiency.

Explainability analysis confirmed the truthfulness of our work, including age, number of comorbidities, Fib-4, type 2 diabetes, and male sex, while imaging embeddings provided additional discriminative information.
Conclusion: LiverCARD integrates AI-derived imaging features with routinely available clinical data, providing an interpretable, scalable, and robust framework for CVR stratification in MASLD patients. By combining multimodal information, this approach improves predictive performance beyond traditional clinical or imaging-based models enabling a more accurate identification of high-risk individuals. LiverCARD supports personalized preventive strategies and underscores the clinical value of explainable multimodal artificial intelligence in addressing an important unmet need in MASLD-related CVR assessment.

The global academic hepatology capacity index (IGCAH): a multi-source assessment reveals profound inequities across Latin America

Pablo Coste[1], Ezequiel Ridruejo[2], Luis Antonio Diaz[3], Juan Pablo Arab[4], Mário Pessoa[5], Nélia Hernandez[6], Marco Arrese[3]. *[1]Hospital Doctor Rafael Ángel Calderón Guardia, LiverLab CR, San José, Costa Rica; [2]Sección Hepatología, Departamento de Medicina. Centro de Educación Médica e Investigaciones Clínicas Norberto Quirno "CEMIC", Buenos Aires, Argentina; [3]Pontificia Universidad Católica de Chile, Santiago, Chile; [4]Virginia Commonwealth University, Richmond, United States; [5]Gastroenterology and Nutrition Department, Hospital das Clínicas, Faculdade de Medicina, Universidade de São Paulo, São Paulo, Brasil, São Paulo, Brazil; [6]Hospital de Clínicas, Montevideo, Uruguay*
Email: costepablo@gmail.com

Background and aims: Academic hepatology in Latin America is highly heterogeneous, yet no standardized regional assessment exists. We conducted the first multi-source evaluation of academic and clinical hepatology capacity and developed a composite index to quantify cross-country differences.
Method: National hepatology societies from 20 Latin American countries completed a 54-item structured survey. Five domain indices (human capacity, academic training, scientific productivity, clinical complexity, and collaboration/networking) were constructed, standardized using z-scores, and integrated into the Global Academic Hepatology Capacity Index (IGCAH). Findings were triangulated with an analysis of PubMed-indexed hepatology publications (2015–2025) and thematic analysis of abstracts submitted to the Latin American Association for the Study of the Liver (ALEH) Congress 2025.
Results: Responses were obtained from 100% of affiliated national societies. Marked regional asymmetry was observed across all domains. Five countries concentrated over 80% of trained hepatologists, fellowship programs, research infrastructure, and access to advanced therapies. Formal recognition of hepatology as a specialty was reported by only 45% of countries, and 35% had structured national fellowship programs. Forty- five percent lacked essential laboratory infrastructure, and only 50% met criteria for sufficient diagnostic and therapeutic complexity within the public health system, defined by access to advanced imaging, portal hypertension therapies, locoregional treatments, and liver transplantation. Hepatology services were centralized in one or two major cities in 70% of countries. Scientific productivity was highly concentrated, with four countries accounting for approximately 85% of PubMed-indexed publications, while more than half produced fewer than five papers annually. Congress submissions mirrored these gradients: 75% originated from five countries, with themes dominated by metabolic dysfunction associated liver disease, cirrhosis, and hepatocellular carcinoma, whereas only 5.2% addressed alcohol-associated liver disease despite its substantial regional burden.
Conclusion: Profound asymmetries characterize academic hepatology in Latin America. The IGCAH provides a robust regional framework to identify structural gaps and guide targeted, stage-specific capacity strengthening.

THU-022

Trends in hospitalizations and in-hospital mortality due to primary biliary cholangitis in Brazil (2015–2024): a decade of real-world evidence from the public unified health system

Guilherme Cançado[1], Cláudia Couto[1], Luciana Faria[1], Bernado Moraes[1], Paulo Bittencourt[2], Cristiane A. Villela-Nogueira[3], Vivian Rotman[3], Debora Raquel Terrabuio[4], Eduardo Luiz Rachid Cançado[5], Maria Lucia Ferraz[6]. *[1]Universidade Federal de Minas Gerais, Belo Horizonte, Brazil; [2]Hospital Português, Salvador, Brazil; [3]Universidade Federal do Rio de Janeiro, Rio de Janeiro, Brazil; [4]Universidade de São Paulo, Universidade Federal de São Paulo, São Paulo, Brazil; [5]Universidade de São Paulo, São Paulo, Brazil; [6]Universidade Federal de São Paulo, São Paulo, Brazil*
Email: cancadoguilherme@gmail.com

Background and aims: Primary Biliary Cholangitis (PBC) is a rare autoimmune liver disease with limited epidemiological data in Latin America. We aimed to analyze nationwide trends in PBC hospitalizations within the Brazilian Unified Health System (SUS) from 2015 to 2024.
Method: National PBC-related hospitalizations were identified in Brazil's public health system as inpatient admissions with ICD-10 K74.3 recorded as the primary diagnosis (main reason for admission), using artificial intelligence. We estimated annual hospitalization rates per 100,000 inhabitants, in-hospital mortality, and mean length of stay. For rate calculations, the population denominator was defined as the Brazilian total population estimate from *Instituto Brasileiro de Geografia e Estatística – IBGE* (2025), applied as a fixed reference denominator across all study years to standardize comparisons over time. Temporal changes were evaluated using segmented (interrupted time-series) regression across pre-pandemic (2015–2019), pandemic (2020–2021), and post-pandemic (2022–2024) periods. Data was stratified by macroregion.
Results: From 2015–2024, 2,913 hospitalizations were recorded. The annual hospitalization rate ranged from 0.11 per 100,000 (2022) to 0.19 per 100,000 (2020), with a mean of 0.15 per 100,000 over the study period. The mean in-hospital mortality was 15.4%, varying from 11.7% (2023) to 18.5% (2019). The average length of stay was 7.9 days (range: 6.8–8.4 days), showing minimal fluctuation over time. From 2015–2019, national PBC hospitalization rates increased by 0.008 per 100,000 per year; in 2020, during covid-19 pandemic, there was a significant immediate increase of 0.046 per 100,000 ($p = 0.03$), followed by a significant reduction in slope of 0.009 per 100,000 ($p = 0.04$) after 2021. The Southeast region exhibited the highest hospitalization burden (0.21/100,000).
Conclusion: Hospitalization for PBC in Brazil is infrequent yet associated with substantial mortality. The covid-19 pandemic led to a transient increase in hospitalizations followed by decline. Strengthening outpatient management and regional equity in hepatology care remains a public health priority.
Disclosure: This study was supported by a research grant from IPSEN.

THU-023

Reduced physician confidence in the acute management of decompensated liver disease: Implications for targeted hepatology education

Rachel Edwards[1], Apoorva Hedge[1], Zinu Philipose[1], Jane Fretwell[2], James Liu Yin[1]. *[1]Croydon University Hospital, London, United Kingdom; [2]Lewisham Hospital, London, United Kingdom*
Email: rachelmedwards72@gmail.com

Background and aims: Liver disease represents a growing public health challenge across Europe with rising mortality placing increasing pressure on acute medical services. Education is a key intervention to address this problem. Most UK physicians dual accredit with general medicine and routinely encounter patients with

liver disease during acute hospital admissions. Within our region, we aimed to explore physicians' confidence in the management of decompensated liver disease compared with other medical conditions within the first 24 hours of presentation.

Method: An online survey assessed physician confidence in the management of 13 acute medical conditions, including decompensated liver disease. Confidence was self-rated by the participant on a Likert scale from 1 (lowest) to 10 (highest). Ratings <3 prompted free-text responses exploring contributory factors. An additional free-text question assessed awareness of national mortality trends. Data were collected on physician grade, age, time out of training and prior clinical rotations. Statistical analysis was done using R Studio and JASP.

Results: 69 clinicians responded, aged 20–40 years (43 female, 23 male, 2 non-binary, 1 undisclosed). 32 were general resident doctors, 11 internal medicine trainees, 18 medical speciality trainees and 6 physician assistants. The average time in training was 3.6 years. 39% had taken time out of training. Confidence in managing decompensated liver disease was significantly lower than for other conditions (mean score 6.1, $p < 0.001$), with wide variability (range 1–10). Confidence was higher among those who had undertaken prior gastroenterology/hepatology rotations, those who had completed an advanced life support course, and those who had taken time out of training ($p < 0.05$). We also found a positive correlation between confidence and years of training and time out of training ($p < 0.001$). Only 6% of respondents recognised liver disease as the only major disease group with rising mortality in the UK.

Conclusion: Liver disease is an under-recognised cause of rising mortality in the UK and parts of Europe, and many general physicians lack confidence in its early management. Given the importance of the first 24 hours of care, targeted, locally relevant education for general physicians, particularly junior colleagues who provide frontline care, is needed. This study provides proof of concept for larger national work aimed at improving general physician confidence and patient outcomes.

THU-024-YI

Poorer social deprivation exacerbates clinical outcomes in alcohol related liver disease admissions in Ireland

Clare Foley[1], Dee Noone[2], Meadhbh Keegan[3], Jennifer Russell[1], Stephen Stewart[1], John Ryan[2]. *[1]Mater Misericordiae University Hospital, Dublin, Ireland; [2]Beaumont Hospital, Dublin, Ireland; [3]Pobal, Dublin, Ireland*
Email: foleyclare123@gmail.com

Background and aims: Social deprivation has been linked to poor outcomes in alcohol related liver disease. This has never been investigated in Ireland. This study aims to review alcohol related liver disease admission (ALD) outcomes in Beaumont Hospital, a large urban tertiary centre according to patient specific social deprivation scores.

Method: Hospital In-Patient Enquiry (HIPE) admission data were reviewed from 1/1/2017 to 31/12/2023. Individual social deprivation scores were assigned via collaboration with Pobal, a non-profit organisation that works with the Irish Government to address social inclusion. The total population within each deprivation score of the hospital catchment area was established to determine admissions per 100,000 population. Median length of stay, critical care bed days, Charlson comorbidity indices (CCI), in-hospital mortality and 30 day readmission rates were assessed according to deprivation score.

Results: 499 ALD admissions were reviewed. 61.3% of the admissions resided in below average or more deprived areas in contrast to 37% of the hospital catchment area population that resided in these areas ($p < 0.0001$). Females represented 29.7% of admissions. 55.4% of these female admissions reside in social deprivation categories of marginally below average or more deprived. Admission risk rose significantly with deprivation score; affluent 45/100,000, marginally above average 88/100,000, marginally below average 182/100,000, disadvantaged 179/100,000, very disadvantaged 310/100,000, extremely disadvantaged 92/100,000. Affluent admissions per 100,000 population were significantly lower compared to disadvantaged and very disadvantaged admissions ($p = 0.0006$). Patients from marginally below average or more deprived areas occupied more critical care bed days compared to patients from affluent areas ($p = 0.0221$). Notably, patients from marginally below average or more deprived areas demonstrated significantly increased mortality rates compared to patients from affluent areas ($p = 0.0043$). There was no significant difference in median length of stay, 30 day readmission rates nor average CCI according deprivation score.

Conclusion: Social deprivation increases the risk of admission to hospital with ALD. Important clinical outcomes; morbidity and mortality, are exacerbated by worsening social deprivation group. In areas of poorer social deprivation there is a compelling need for prevention and management strategies against ALD.

THU-025

Impact of social deprivation on liver disease admissions in Ireland

Clare Foley[1], Dee Noone[2], Meadhbh Keegan[3], Jennifer Russell[1], John Ryan[2], Stephen Stewart[1]. *[1]Mater Misericordiae University Hospital, Dublin, Ireland; [2]Beaumont Hospital, Dublin, Ireland; [3]Pobal, Dublin, Ireland*
Email: foleyclare123@gmail.com

Background and aims: Social deprivation has been linked to poor outcomes in liver disease. This has never been investigated in Ireland. This study aims to review liver admission outcomes in Beaumont Hospital, a large urban tertiary centre, according to patient specific social deprivation scores.

Method: Hospital In-Patient Enquiry (HIPE) admission data were reviewed from 1/1/2017 to 31/12/2023. Individual social deprivation scores were assigned via collaboration with Pobal, a non-profit organisation that works with the Irish Government to address social inclusion. The total population within each deprivation score of the hospital catchment area was established to determine admissions per 100,000 population. Median length of stay, critical care bed days, Charlson comorbidity indices and in-hospital mortality rates were assessed according to deprivation score.

Results: 851 liver disease admissions were reviewed. 60.2% of the total admissions resided in below average or more deprived areas in contrast to 37% of the hospital catchment area population that resided in these areas ($p < 0.0001$). Females represented 35.4% of the total admissions, 57.1% of these female admissions reside in social deprivation categories of marginally below average or more deprived. Admission risk rose significantly with deprivation score; affluent 87/100,000, marginally above average 151/100,000, marginally below average 331/100,000, disadvantaged 293/100,000, very disadvantaged 415/100,000, extremely disadvantaged 207/100,000. Affluent admissions were significantly lower compared to disadvantaged, very disadvantaged and extremely disadvantaged admissions ($p = 0.006$, $p = 0.0227$, $p = 0.0023$). While patients from disadvantaged or more deprived areas occupied more critical care bed days compared to patients from affluent areas($p = 0.0044$), no significant differences were observed in relation to Charlson comorbidity indices, overall hospital lengths of stay or mortality rates according to deprivation score.

Conclusion: Social deprivation increases the risk of admission with liver disease to hospital and may impact on disease severity as evidenced by critical care use. However, social deprivation did not impact on overall clinical outcomes. This study highlights the need for targeted awareness and diagnosis of liver disease in areas of social deprivation.

THU-026

Implementation of a health navigator program post-liver transplantation, utilization and outcomes

R. Todd Frederick[1], Krista Ramonas[2], Nina Winterstein[2], Gil Palchek[1], Sylvia Sudat[1], Deborah Franzon[3]. [1]*California Pacific Medical Center Research Institute, San Francisco, United States;* [2]*San Francisco, United States;* [3]*University of California San Francisco, San Francisco, United States*
Email: deborah.franzon@ucsf.edu

Background and aims: Health outcomes are largely influenced by socieconomic status (SES). Outcomes after liver transplantation (LT), such as graft failure and mortality, are associated with race, insurance type and education level. To optimize LT outcomes, interventions targeting unique individual-level SES needs are necessary. We aimed to assess the utilization and impact of a health navigator program on outcomes such as readmissions and post-LT complications in patients receiving navigation services compared with those who have not.
Method: California Pacific Medical Center Liver Transplant program partnered with the Health Navigator Foundation, a not-for profit organization, to provide essential services to transplant patients. Between August 2022 and December, 31 2024 all liver transplant recipients were screened for eligibility for HNF services. Program enrollment was voluntary and cost-free. For 30 days post- LT, patients received navigation services comprised of access to a buddy program, medication adherence education, social services support, and translation services. Vouchers for gas, parking, transportation, and food were provided based on financial eligibility. IRB-approved, retrospective, de-identified data from all LT recipients including patient demographics, geolocation, insurance type, 90 day readmissions, episodes of rejections were extracted from the electronic health record for analysis.
Results: A total of 230 patients underwent LT and 49% (N = 113) received navigation services. LT patients were primarily non-Hispanic (NH) white (49%, N = 112) followed by Hispanic or Latino (29%, N = 66) NH Asian (11.3%, N = 26), NH Black or African American (4%, N = 10), and NH Other (7%, N = 16). Patients who received navigation and those who did not were similar in terms of race/ethnicity (p = 0.77). LT patients were 39% female, and female LT patients were less likely to receive navigation (38% vs. 56%, p < 0.01). On preliminary analysis, 54% of LT patients returned to the hospital in the first 90 days post-discharge; patients who received navigation were more likely to return (61% vs. 47%, p = 0.03). The overall incidence of 90-day rejection episodes was 1% (N = 3).
Conclusion: Navigation services facilitate access to care in order to improve health. In our cohort, patients receiving post LT navigation were more likely to utilize hospital services in the first 90 days. Planned analysis of SES, insurance type, and proximity to transplant center stratified by gender may further inform results and will be presented.

THU-027

Stable alcohol consumption over time in older adults, assessed by PEth

Marie Fredriksson[1], Mårten Werner[1]. [1]*Department of public health and clinical medicine, Umeå University, Umeå, Sweden*
Email: marie.fredriksson@regionvasterbotten.se

Background and aims: Interview studies have previously shown a stable pattern of alcohol consumption in middle-aged and older adults. PEth (phosphatidylethanol) is a blood marker that correlates well with alcohol intake over the past 2–4 weeks. We measured PEth in a study population at two time points separated by a six- to nine-year interval to determine whether the alcohol consumption indicated by PEth remained consistent.
Method: As a sub-study of the Swedish CArdioPulmonary BioImage Study (SCAPIS), we added PEth analysis to the same participants on two occasions. The first samples were collected between May 2016 and August 2018, and the second between April 2024 and May 2025. The baseline age of the study population was 50–65 years.
Results: The number of participants was 1166, comprising 589 men and 577 women. At the first measurement, 56.8% had a PEth < 0.05 µmol/L (35 ng/mL), 33% had a PEth between 0.05 and 0.29 µmol/L, and 10.2% had a PEth ≥ 0.3 µmol/L (210 ng/mL). At the second measurement, 56.7% had a PEth < 0.05 µmol/L, 33.9% had a PEth between 0.05 and 0.29 µmol/L, and 9.4% had a PEth ≥ 0.3 µmol/L. Eighty per cent remained within the same alcohol consumption group between the two samples, and fewer than 1% shifted from the highest to the lowest PEth group, or vice versa. There was a small but statistically significant increase in PEth from SCAPIS 1 to SCAPIS 2 for both men and women. The oldest participants in SCAPIS 1 (aged 60–65 years) showed no significant difference in Peth levels between SCAPIS 1 and 2; however, those aged 50–59 years in SCAPIS 1 had significantly increased Peth levels between the two measures.
Conclusion: In this population, alcohol consumption, measured as PEth, remained at a similar level over 6–9 years, consistent with previous interview-based data. This indicates that PEth, at least in this population, can serve as an indicator of alcohol consumption over periods longer than the single test is valid for.

THU-028

Disability weights for compensated and decompensated cirrhosis: implications of alternative severity weights

Rebekah Hall[1], Elin Gruffydd[1], Ee Lin Kimberly Teo[1], Andrew Lloyd[1], Villum Wittrup-Jensen[2], Preety Gautam[2], Jeff McIntyre[3]. [1]*Acaster Lloyd, London, United Kingdom;* [2]*Boehringer Ingelheim International GmbH, Ingelheim am Rhein, Germany;* [3]*Global Liver Institute, Washington, DC, United States*
Email: preety.gautam@boehringer-ingelheim.com

Background and aims: The current Global Burden of Diseases, Injuries, and Risk Factors Study (GBD) disability weight for decompensated liver cirrhosis (DLC) is 0.178 on a 0 (no disability) to 1 (dead) scale. Conversely, compensated liver cirrhosis (CLC) is assigned a weight of zero, on the assumption that it is asymptomatic. The burden of liver cirrhosis reported by patients in qualitative studies suggests that the methodology used by the GBD may underestimate the true burden of the disease. This study aims to provide an alternate approach to estimate the disability weights associated with CLC/DLC.
Method: An online paired comparison (PC) survey was conducted among the US general population to estimate disability weights associated with newly developed lay health state descriptions of key symptoms and impacts of CLC and DLC based on qualitative interviews with 20 CLC/DLC patients. Survey participants (N = 400) were representative of the US general population based on age distribution, gender, and race. PC results were analysed using probit regression to provide ordinal weights of each health state. Non-parametric (Loess) regression was used to anchor disability weights to a 0 to 1 scale based on GBD 2010 disability weights for 28 indicator health states included in the PC survey.
Results: The estimated disability weights associated with CLC and DLC were 0.245 (95% confidence interval [CI]: 0.151–0.360) and 0.501 (95% CI: 0.374–0.645), respectively. Model statistics demonstrated a good model fit (coefficient of determination = 0.849) indicating strong correlation between the paired comparison estimates from this study and existing GBD estimates. Results suggest that the degree of disability experienced by individuals with CLC may be similar to post-acute effects of an infectious disease (disability weight: 0.219) and moderate chronic obstructive pulmonary disease (disability weight: 0.225). The level of disability experienced by those with DLC was between the level of disability associated with moderate multiple sclerosis (disability weight: 0.463) and terminal cancer with medication (disability weight: 0.540).
Conclusion: The current GBD disability weights may underestimate how liver cirrhosis negatively impacts patients living with liver

diseases such as MASH. This study employed qualitative research to better describe the burden of liver disease. The methods to obtain GBD disability weights should be reconsidered to recognise the true burden of liver disease.

THU-029

Public health implications of metabolic dysfunction-associated steatotic liver disease based on global stepwise approach to surveillance data

Taras Griadil[1]. [1]*Uzhhorod National University, Institute of Postgraduate and Pre-university Education, Department of Therapy and Family Practice, Uzhhorod, Ukraine*
Email: taras.griadil@uzhnu.edu.ua

Background and aims: Metabolic dysfunction-associated steatotic liver disease (MASLD), formerly known as nonalcoholic fatty liver disease, is currently a leading cause of chronic liver disease globally. The new nomenclature emphasizes the presence of at least one of five cardiometabolic risk factors alongside hepatic steatosis. Public health interventions are critical to managing this growing burden. This study aims to estimate the prevalence of risk factors associated with this condition using data from the STEPS (WHO Stepwise Approach to Surveillance) surveys in different countries.
Method: A secondary analysis of cross-sectional data collected via STEPS surveys in six countries between 2020 and 2024 was conducted. The study utilized the standard three-step instrument: questionnaire, physical measurements, and biochemical assessments. We stratified the population based on the new nomenclature, distinguishing between "pure" metabolic dysfunction-associated steatotic liver disease and MetALD; the latter category is defined by alcohol consumption exceeding 140 g/week for females and 210 g/week for males. Statistical significance was defined as $p < 0.05$. The correlation between public health indicators (physical activity, diet) and metabolic dysfunction was assessed.
Results: The analysis included 15,400 participants. The prevalence of individuals meeting the criteria for steatotic liver disease varied significantly by region. Data showed that 35% of the cohort showed signs of metabolic dysfunction-associated steatotic liver disease. Furthermore, 12% were classified into the MetALD category. The analysis revealed that populations with low engagement in public health physical activity programs had a significantly higher prevalence of metabolic risk factors ($p = 0.03$).
Conclusion: The integration of the new nomenclature into public health surveillance systems confirms a significant global burden of metabolic liver diseases. Data from STEPS surveys highlight that public health strategies focused on lifestyle changes are essential. Future policies must target cardiometabolic risk factors to mitigate the progression of steatotic liver disease.

THU-030

Impact of alternative VCTE diagnostic criteria on yearly prevalence estimates of MASLD and significant fibrosis

Carlos Martínez-Cabrera[1], Marcela Castillo-Medina[1], Graciela Torres-Mendoza[1], Luis Gutierrez-Rosas[1], Victor Montoya-Guzmán[1], Vanessa García-Rubio[1], María Fonticoba-Wood[1], FroyLan Martínez-Sánchez[1,2], Oscar Martínez-Barocio[1], Jessica Mayen-del Rio[1], Cynthia Sánchez-Villegas[3], Beatriz Barranco-Fragoso[4], Ruth Robles-Rodríguez[2], Fabiola Burciaga-Villalobos[5], Anibal de la Cruz-Lopéz[6], Raúl Méndez-Castillo[2], Gustavo García-Avelino[4], Ixchel Hernández-Ibarrola[7], Emilio Bermudez[8], Jacqueline Cordova-Gallardo[2], Liliana Tellez-Martínez[2], José Canela-Mayoral[3], Alma Ladrón de Guevara-Cetina[1]. [1]*Centro de Investigación y Gastroenterología, Mexico City, Mexico;* [2]*Secretaría de Salud, Mexico City, Mexico;* [3]*Instituto Mexicano del Seguro Social, Mexico City, Mexico;* [4]*Instituto de Seguridad y Servicios Sociales de los Trabajadores del Estado, Mexico City, Mexico;* [5]*Hospital San Ángel Inn, Mexico City, Mexico;* [6]*Hospital Star Médica, Mexico City, Mexico;* [7]*Clinica Mide San Juan de Aragon, Mexico City, Mexico;* [8]*Torre Médica Salaverry, Mexico City, Mexico*
Email: lauradelg@yahoo.com

Background and aims: Metabolic dysfunction–associated steatotic liver disease (MASLD) is the leading cause of chronic liver disease in Mexico, with reported prevalences approaching 50%. Vibration-controlled transient elastography (VCTE) is increasingly used for population screening, but multiple controlled attenuation parameter (CAP) and liver stiffness measurement (LSM) cutoffs are available. Although these thresholds show high diagnostic agreement, they may yield different prevalence estimates, and the consistency of longitudinal trends across definitions remains unclear. We assessed the impact of alternative VCTE criteria on yearly prevalence estimates of MASLD and significant fibrosis.
Method: We conducted a cross-sectional analysis of adults evaluated between 2022 and 2025 during free liver check-ups in the Mexico City Metropolitan Area. All participants underwent VCTE, and those with other chronic liver diseases were excluded. MASLD was defined as CAP-detected steatosis plus at least one cardiometabolic criterion, using alternative CAP cutoffs (≥275 and ≥288 dB/m). Significant fibrosis was assessed by LSM thresholds (≥7.0 and ≥8.2 kPa) among individuals with MASLD defined by CAP ≥288 dB/m. Annual prevalence estimates and longitudinal trends were compared across thresholds.
Results: 5184 adults were evaluated between 2022 and 2025, annual MASLD prevalence differed clearly according to diagnostic definition. Using CAP ≥275 dB/m, MASLD prevalence varied from 51.4% to 40% across years, whereas estimates using CAP ≥288 dB/m were consistently lower, between 44.3% and 31.4%. The absolute difference in MASLD prevalence between CAP cutoffs ranged from 7.1% to 8.6%. Despite these differences, the overall decline in prevalence was similar across definitions.
Significant fibrosis prevalence in MASLD also differed by liver stiffness threshold, with LSM ≥8.2 kPa yielding lower annual estimates compared with ≥7.0 kPa. Using LSM ≥7.0 kPa, prevalence varied from 22.8% to 21.3%, compared with 13.7% to 12.5% using ≥8.2 kPa. Absolute differences in fibrosis prevalence ranged from 9.1% to 8.8%, while relative prevalence differences varied from 40% to 41.4%. However, the general trend remained consistent across diagnostic criteria.
Conclusion: Prevalence estimates of MASLD and significant fibrosis vary meaningfully according to VCTE diagnostic thresholds, although longitudinal trends remain consistent across definitions, reflecting the impact of diagnostic criteria selection on population-level disease burden estimates.

THU-031

Clinical burden and risk stratification in metabolic dysfunction-associated steatohepatitis using Swedish real-world data

Hannes Hagström[1], Thomas Hambridge[2], Zuleika Aponte Torres[3], Alexandra Wennberg[4], Franziska Fischer[4], Emilie Toresson Grip[4], Jörn M. Schattenberg[5]. [1]*Karolinska Institutet, Department of Medicine, Huddinge, Stockholm, Sweden;* [2]*Boehringer Ingelheim, MIDI, Amsterdam, Netherlands;* [3]*Boehringer Ingelheim Pharmaceuticals, Inc., Ridgefield, United States;* [4]*Quantify Research AB, Stockholm, Sweden;* [5]*Saarland University Medical Center, Hamburg, Germany*
Email: hannes.hagstrom@ki.se

Background and aims: Metabolic dysfunction-associated steatohepatitis (MASH) is a severe form of metabolic dysfunction-associated steatotic liver disease (MASLD) that leads to increased risk of liver-related and cardiovascular outcomes. Liver biopsy remains the gold standard for diagnosis, but its invasiveness limits widespread use.

This study aims to characterise patients with biopsy-confirmed and presumed MASH in Sweden, and to assess the association between histological and non-invasive test (NIT) measures (e.g., Fibrosis-4 Index (FIB-4), Vibration-Controlled Transient Elastography (VCTE)) with long-term clinical outcomes.

Method: This observational study utilises a cohort of patients with presumed MASH identified via ICD-10 codes (K75.81) and/or elevated risk scores (FIB-4) and metabolic risk factors from the HERALD (HEalth outcomes and Risk Assessment in chronic Liver Disease) research platform. Descriptive statistics of baseline characteristics are presented, and survival analyses were performed to estimate incidence rates and cumulative incidence of major adverse liver outcomes (MALO), cardiovascular events (MACE) and mortality.

Results: At diagnosis, patients in the HERALD cohort with presumed MASH had mean age 63 years (SD 16) with mean 28.4 kg/m^2 (SD 8.9) BMI, and 50.2% were women. 85% of patients have data to calculate FIB-4 (n = 146,120): 35.1%, 23.8%, and 41.1% had low (age 35–64: <1.3; age: ≥65: < 2.0), intermediate (age 35–64:1.3–2.67: age: ≥65: 2.0–2.67), and high-risk (age ≥ 35: >2,67) of fibrosis, respectively. Among patients with available VCTE (n = 430), 53.3% had measures <8 kPa, 15.6% with 8-<12 kPa, and 31.2% with ≥12 kPa. Over median follow-up of 5.8 years, 1.9% of patients with presumed MASH had recorded MALO and 2.3% had a recorded diagnosis of cirrhosis. 24.2% of patients experienced a MACE outcome. 25.1% of patients died, where 0.6% of deaths were recorded as liver-related and 4.7% as cardiovascular-related.

Conclusion: This study provides real-world insights into use of FIB-4 and Fibroscan as risk stratification tools for MASH. While FIB-4 score could be widely available but still not automatically calculated, the use of Fibroscan could be expanded.

THU-035

Factors associated with engagement in hepatocellular carcinoma surveillance in a diverse urban population

Apoorva Hegde[1], Rachel Edwards[1], John Dempster[1], Yasmeen Cooper[1], Thomas Kynaston[1], Yusra Mashkoor[1], Sreedevi Rajalingam[1], Zinu Philipose[1], James Liu Yin[1]. [1]*Croydon University Hospital, London, United Kingdom*
Email: rachel.edwards38@nhs.net

Background and aims: Hepatocellular carcinoma (HCC) mortality is rising globally with a 5-year survival rate far below that of other cancers. HCC disproportionately affects racial and ethnic minority groups and socioeconomically deprived populations in whom healthcare discrimination may contribute to poorer outcomes. The survival rate is often affected by the late detection of HCC with some being deemed 'preventable'. Croydon University Hospital (CUH) serves a diverse population in London's most populous and deprived southern London borough with a large immigrant and refugee community. This study aimed to review post-COVID-19 HCC surveillance at CUH to identify factors contributing to non-attendance.

Method: We retrospectively reviewed electronic records of patients enrolled in HCC surveillance to assess attendance over a 3 year period. Demographic data collected included sex, ethnicity, first language, religion, deprivation indices, alcohol intake and liver disease aetiology. Deprivation deciles and ranks were sourced from national databases according to post code. Results were analysed with Excel and R studio.

Results: 310 patient records were reviewed, of which 58.4% were male, with a median age of 60 [IQR 52–68]. Deprivation deciles ranged between 1 and 10 across the cohort. Overall compliance with surveillance was 49.03% (n = 152). The odds of engaging with surveillance was nearly halved for patients who did not have English as a first language (OR 0.660, CI 0.30–1.48). No significant associations were observed with religion or ethnicity. Across all deciles of deprivation less than 10 the odds of attendance were significantly reduced. Ongoing alcohol intake was associated with reduced attendance (OR 0.627, CI 0.33–1.18). Viral liver disease aetiology was associated with lower odds of attendance (OR 0.379, CI 0.14–1.05) compared with ArLD (OR 0.655, CI 0.29–1.46).

Conclusion: In our diverse and socioeconomically deprived population our results identified several areas we can focus on to improve local uptake in HCC surveillance; those with language barriers, ongoing alcohol intake, higher levels of deprivation and viral liver disease. This work should be conducted locally in all hospitals to help individualise surveillance strategies to optimise uptake of this crucial aspect of liver care. This may also help challenge stereotypes and unconscious biases among healthcare professionals, widening access to surveillance in an effort to reduce health inequity.

THU-036

Cost-effectiveness of sequential non-invasive testing strategies to optimise hepatology referrals in MASLD: implications for primary care pathways

Marta Hernández Conde[1], David Marti-Aguado[2], Hugo José Disla[1], Elba Llop Herrera[1], Jesús Rivera Esteban[1], Paloma Lluch-García[2], Francisco Bernabeu[1], Marta López-Gómez[1], Javier Abad Guerra[1], Ana Royuela[1], Desamparados Escudero-García[2], José Luis Calleja Panero[1]. [1]*Hospital Universitario Puerta De Hierro Majadahonda, Majadahonda, Spain;* [2]*Hospital Clínico Universitario, Valencia, Spain*
Email: marta.hernandez.conde@gmail.com

Background and aims: The rapid increase in metabolic-associated steatotic liver disease (MASLD) poses a major challenge to healthcare systems, particularly regarding the efficient allocation of specialist hepatology resources. Primary care-based screening strategies must balance early detection of significant fibrosis (SF) with avoidance of unnecessary referrals. We assessed the cost-effectiveness of two sequential non-invasive testing (NIT) strategies for MASLD-related fibrosis, focusing on their impact on referral efficiency and healthcare resource use.

Method: Using data from 634 patients with MASLD, we developed a referral pathway model comparing 2 sequential algorithms applicable in primary care: (1) Fatty Liver Index (FLI) followed, when indicated, by the Enhanced Liver Fibrosis (ELF) test; and (2) FLI followed by FIB-4. In both strategies, patients with positive NIT results underwent transient elastography (TE), and those with SF (≥8 kPa) were referred to hepatology outpatient care. Costs were estimated from the perspective of the Madrid Regional Health System using 2023 public tariffs and included diagnostic assessment, follow-up, and specialist referrals.

The primary policy-relevant outcome was the number of unnecessary hepatology referrals (false positives after specialist evaluation) per-100 patients screened. Incremental cost per unnecessary referral avoided was calculated.

Results: Per 100 patients screened, the FLI→ELF strategy resulted in 24 unnecessary referrals at a total cost of €6,895, compared with 49 unnecessary referrals at a cost of €6,738 for the FLI→FIB-4 strategy. Adoption of FLI→ELF reduced avoidable referrals by 51%, with a modest incremental cost of €1,844, corresponding to €73.78 per unnecessary referral avoided. At scale, integration of FLI→ELF into MASLD care pathways would substantially reduce pressure on hepatology services while maintaining alignment with EASL-recommended stepwise risk stratification.

Conclusion: From a health system perspective, sequential screening with FLI→ELF in primary care improves the efficiency of hepatology referrals compared with FLI→FIB-4, at a very low incremental cost. These findings support the incorporation of ELF-based sequential algorithms into MASLD care pathways as a scalable and sustainable policy option to optimise specialist resource allocation where ELF testing is available. Further analyses should explore long-term budget impact and system-wide implementation outcomes.

THU-037

Global variation in standard drink definitions compared to the World Health Organization 10-gram benchmark: a 185-country analysis

Kriti Soni[1], Adelina Horhat[2], Ximena Parraga[1], Rylyn Reyes[3], Joshua Chen[4], Hyundam Gu[1], Luis Antonio Diaz[5], Juan Pablo Arab[1]. *[1]Division of Gastroenterology, Hepatology, and Nutrition, Department of Internal Medicine, Virginia Commonwealth University School of Medicine, Richmond, United States; [2]Université Paris-Est Créteil, Henri-Mondor University Hospital, Créteil, France; [3]Department of Epidemiology, Virginia Commonwealth University School of Public Health, Richmond, United States; [4]Department of Internal Medicine, Virginia Commonwealth University School of Medicine, Richmond, United States; [5]MASLD Research Center, Division of Gastroenterology and Hepatology, University of California, San Diego, United States*
Email: kriti.soni@vcuhealth.org

Background and aims: Alcohol consumption is a global public health concern, contributing substantially to morbidity and mortality worldwide. Despite international efforts to promote standardized alcohol metrics, definitions of standard drinks vary widely across countries, limiting epidemiological comparisons and policy evaluation. The WHO recommends a 10 g ethanol standard, yet global adherence to it, and its relationship with national drinking patterns, have not been systematically examined. To address this, we aimed to evaluate global variation in standard drink definitions across 185 countries, assess their alignment with the WHO 10 g benchmark, and examine how these definitions relate to alcohol consumption indicators.
Method: We analyzed data using the 2024 WHO Global Status Report on Alcohol and Health, the World Bank, the WHO Global Information System on Alcohol and Health, national guidelines, and published literature. Variables included standard GDP, definition of "standard drink" (grams of ethanol), per capita alcohol consumption (APC), beverage composition, prevalence of current drinking, and heavy episodic drinking (HED). Definitions were categorized as <10 g, 10–12 g, 12–14 g, 14–25 g, and >25 g. Countries were grouped by WHO region, and descriptive statistics and standardized heatmaps were generated to evaluate patterns.
Results: Among 185 countries, 60.9% (n = 109) lacked an official standard drink definition, while only 15.9% n = 29) aligned with the WHO 10 g benchmark. We identified a numeric standard drink definition for 39.1% (n = 70) countries; 2.2% (n = 4) were below, and 20.7% (n = 37) exceeded WHO guidelines. Standard drink definitions ranged widely (4–25 g). Regional mean values varied substantially, from 10 g in the African Region to 14 g in the Region of the Americas. The Eastern Mediterranean Region had the highest proportion of countries without a definition. Alcohol consumption patterns varied widely across regions. The European region recorded the highest total APC and HED despite WHO-aligned definitions, while the Eastern Mediterranean Region showed consistently low levels across all indicators.
Conclusion: Most countries lack an official definition; among those that have adopted one, the majority define a standard drink above the 10 g benchmark. This variation may limit risk communication, epidemiologic comparison, and policy development. Harmonizing standard drink definitions could strengthen global alcohol control strategies.

THU-038

Real-world epidemiology and clinical outcomes in MASLD: A 20-year nationwide analysis of over 23 million individuals in Taiwan's national health insurance research database

Huei-Tyng (Philippe) Huang[1], Chuan-Pin Lee[2], Laura Temperley[1], Yao-Hsu Yang[2,3,4], Liang-Yu Lin[5,6,7], William Alazawi[1]. *[1]Barts Liver Centre and Barts Metabolism Network, Blizard Institute, Queen Mary University of London, London, United Kingdom; [2]Health Information and Epidemiology Laboratory, Chang Gung Memorial Hospital, Chiayi, Taiwan; [3]Department of Traditional Chinese Medicine, Chang Gung Memorial Hospital, Chiayi, Taiwan; [4]School of Traditional Chinese Medicine, College of Medicine, Chang Gung University, Taoyuan, Taiwan; [5]Institute of Environmental and Occupational Health Sciences, College of Public Health, National Taiwan University, Taipei, Taiwan; [6]Global Health Program, College of Public Health, National Taiwan University, Taipei, Taiwan; [7]Department of Environmental and Occupational Medicine, National Taiwan University Hospital, Taipei, Taiwan*
Email: h.t.huang@qmul.ac.uk

Background and aims: MASLD is associated with increased risk of hepatic and extra-hepatic endpoints. However, most evidence originates from Western cohorts. The impact of MASLD on the unselected East Asian general population remains underexplored. We aimed to determine the prevalence and long-term outcomes of MASLD using Taiwan's National Health Insurance Research Database (NHIRD), which includes over 99% of the population, to bridge these knowledge gaps.
Method: This real-world evidence study used NHIRD data between 2003 and 2022. We identified individuals with MASLD diagnosis using medical codes. Patients with <1 year of follow-up post-NHIRD registration, age <18, or who had pre-existing autoimmune and alcoholic liver disease were excluded. We calculated the point prevalence and analysed time-to-event for cirrhosis, hepatocellular carcinoma (HCC), acute myocardial infarction (AMI), stroke, and chronic kidney disease (CKD). Controls were matched at a 1:4 ratio; those with a prior endpoint were excluded from endpoint analysis.
Results: Over 23 million individuals were active in NHIRD in 2022. We identified 1,304,409 MASLD patients: median age 50, 54.7% male, with high rates of type 2 diabetes (26.7%) and hypertension (39.0%). Recorded prevalence increased by more than 3-fold, from 1.9% in 2003 to 6.31% in 2022 ($p < 0.001$). Clinical outcomes were recorded over a median follow-up of 8.4 to 8.8 years. Incidence rates (per 1000 person-years) for cirrhosis and HCC in the MASLD cohort were 3.8 (95% CI: 3.7–3.8) and 2.2 (95% CI: 2.1–2.2); for AMI 2.2 (95% CI: 2.2–2.3), stroke 6.2 (95% CI: 6.1–6.2) and CKD 12.4 (95% CI: 12.3–12.4). After adjusting for common, known risk factors, MASLD was strongly associated with cirrhosis (aHR 2.68, 95% CI: 2.64–2.71) and HCC (aHR 2.30, 95% CI: 2.25–2.34). Risks for stroke (aHR 1.07, 95% CI: 1.05–1.08) and CKD (aHR 1.13, 95% CI: 1.12–1.14) were also elevated albeit modestly. Notably, MASLD was not associated with an independent increased risk for AMI (aHR 0.93, 95% CI: 0.92–0.95) after adjustment for comorbidities and deprivation index.
Conclusion: This 20-year study provides a population-level depiction of MASLD in an East Asian population. While the recorded prevalence is rising sharply, significant under-diagnosis likely persists. MASLD is an independent risk factor for cirrhosis, HCC, stroke, and CKD. However, its association with AMI was not observed in this study after adjustment.

THU-039

Outcomes and all-cause mortality in people with MASLD in UK primary care: a real-world matched cohort study of 1.8 million individuals

Huei-Tyng (Philippe) Huang[1], Michael Hewitt[1], Wenhao Li[1], Laura Temperley[1], Naveed Sattar[2], William Alazawi[1]. *[1]Barts Liver Centre and Barts Metabolism Network, Blizard Institute, Queen Mary University of London, London, United Kingdom; [2]School of Cardiovascular and Metabolic Health, BHF Glasgow Cardiovascular Research Centre, University of Glasgow, Glasgow, United Kingdom*
Email: h.t.huang@qmul.ac.uk

Background and aims: MASLD is a leading cause of chronic liver disease and often progresses to hepatic outcomes of cirrhosis and liver tumours. It is associated with extra-hepatic outcomes such as cardiovascular disease. We aimed to estimate the risk of hepatic and extra-hepatic outcomes and mortality in patients with MASLD compared with controls in the UK primary care real-world Clinical Practice Research Datalink (CPRD).

Method: We identified individuals with recorded MASLD diagnosis (using NAFLD as a proxy) between 2003 and 2022. Patients with a recorded diagnosis of MASLD were followed up for the incidence of outcomes: cirrhosis, liver tumour, acute myocardial infarction (AMI), stroke, chronic kidney disease (CKD), and all-cause mortality. Hazard ratios (HR) were estimated using Cox models and adjusted for sex, age, ethnicity, smoking, excess alcohol use, and history of hypertension and type 2 diabetes (T2DM), body mass index (BMI), cholesterol and QRISK2 score. Controls were matched 1:4 on sex, age (±5 years), and general practice.
Results: We identified 365,797 patients with recorded MASLD and 1,463,188 controls. MASLD patients were more likely to have T2DM, hypertension, smoking history, and excess alcohol use than matched controls (all $p < 0.001$). Over a median follow-up of 4.8 to 5.3 years, crude incidence rates (per 1000 person-years) in the MASLD cohort were: cirrhosis 3.3 (95% CI: 3.2–3.3), liver tumours 0.3 (95% CI: 0.3–0.3), AMI 2.1 (95% CI: 2.0–2.2), stroke 0.6 (95% CI: 0.6–0.7), CKD 7.0 (95% CI: 6.9–7.1) and all-cause mortality 8.7 (95% CI: 8.6–8.9). The cumulative unadjusted incidences of all outcomes were more common in people with MASLD and hypertension or T2DM and were most common in people with both. In people with MASLD, compared to controls, the fully-adjusted HRs for outcomes were: cirrhosis 3.4 (95% CI: 3.0–3.8), liver tumours 1.4 (95% CI: 0.9–2.1), AMI 1.0 (95% CI: 0.9–1.2), stroke 1.0 (95% CI: 0.8–1.3), CKD 1.5 (95% CI: 1.0–1.1), and all-cause mortality 0.9 (95% CI: 0.8–0.9).
Conclusion: This 20-year real-world evidence shows that a recorded diagnosis of MASLD increases the risk of hepatic and extra-hepatic outcomes and mortality. The impact of common comorbidities emphasises the need for specific integrated care pathways for patients at higher risk.

THU-040

Healthcare provider perspectives on mental health in metabolic dysfunction-associated steatotic liver disease and steatohepatitis: the role of multidisciplinary teams and sex differences

Dana Ivancovsky-Wajcman[1], Marcela Villota-Rivas[1], Melina Manolas[2], Vanessa Villas-Riotorto[3], Anish Arora[4], Paul N. Brennan[5], Didac Mauricio[6], Damien Leith[5], José Willemse[7], Michael Betel[8], Faisal Alnaser[9,10], Mohamed El Kassas[11], Jeffrey Lazarus[12]. *[1]Barcelona Institute for Global Health (ISGlobal), Barcelona, Spain; [2]Department of Endocrinology, Diabetes & Metabolism, Weill Cornell Medicine, New York, United States; [3]Faculty of Medicine and Health Sciences, University of Barcelona, Clinical Health Psychology Section, Hospital Clínic, Barcelona, Spain; [4]Department of Health Sciences, Wilfrid Laurier University, Waterloo, Canada; [5]University of Dundee, Division of Molecular and Clinical Medicine, School of Medicine, Dundee, United Kingdom; [6]Department of Endocrinology & Nutrition, CIBERDEM, Hospital de la Santa Creu i Sant Pau, Faculty of Medicine, University of Vic/Central University of Catalonia, Barcelona, Spain; [7]Liver Patients International, Brussels, Belgium; [8]Fatty Liver Alliance, Toronto, Ontario, Canada; [9]Bahrain Family Physicians Association, Manama, Bahrain; [10]Imperial College London, Primary Care & Public Health, London, United Kingdom; [11]Endemic Medicine Department, Faculty of Medicine, Capital University, Cairo, Egypt; [12]Barcelona Institute for Global Health (ISGlobal), Faculty of Medicine and Health Sciences, University of Barcelona (UB), City University of New York Graduate School of Public Health and Health Policy (CUNY SPH), New York, New York, USA, Barcelona, Spain*
Email: danaivanc@gmail.com

Background and aims: Mental health (MH) comorbidities are increasingly recognised in metabolic dysfunction–associated steatotic liver disease (MASLD) and steatohepatitis (MASH), yet the implementation of MH interventions in routine care remains poorly understood. We assessed healthcare providers' (HCPs) attitudes toward MH intervention provision (MHIP), identified key facilitators, and explored sex differences.
Method: A 22-item survey, including demographic information, was distributed globally to MASLD/MASH HCPs. Attitudes toward MHIP were assessed using 6 statements rated on a Likert scale (0 = strongly disagree, 4 = strongly agree). Statements with >75% agreement (agree/strongly agree) were considered to reflect high consensus. Responses were summed into an overall attitude score, with a positive attitude defined as a score above the sample median (>15). HCPs also identified up to 3 key facilitators of MHIP and factors enhancing patient engagement. Stepwise logistic regression was used to identify predictors of a positive MH attitude.
Results: From 262 responders (36.7% females), 61.0% reported working within a multidisciplinary team (MDT). Only 2 statements achieved high consensus: MH impacts MASLD/MASH outcomes (87.0%), with higher agreement among HCPs who worked in a MDT (90.7% vs 81.8%, P = 0.037), and MH specialists should be in the MDT (81.9%), with higher agreement among females (87.9% vs 77.4%, p = 0.036). Working in a MDT was the only factor that predicted a positive attitude toward MHIP (OR = 4.44, 95% CI 2.55–7.74). Setting-related factors (e.g., longer counselling time) and working in a MDT were identified as the main facilitators for MHIP (69.1% and 57.6%, respectively). In sex-stratified analysis, males more often identified the availability of evidence supporting MH interventions as a key facilitator (47.8% vs 25.3%, $p < 0.001$), while females more frequently identified MDT involvement (67.7% vs 50.3%, p = 0.006). 64.5% and 67.6% of HCPs believed that patient education and multidisciplinary care would enhance patient engagement with MH services, respectively.
Conclusion: Working in a MDT fosters a more positive attitude toward MH integration, particularly among females. Structural barriers affect both sexes, while the perceived lack of evidence primarily limits MHIP among males. Addressing these barriers, strengthening MDT collaboration, and generating robust evidence on the effectiveness of MH interventions are essential steps to improve integration and patient engagement in MASLD/MASH care.

THU-041

Factors influencing mental health care provision for people with metabolic dysfunction-associated steatotic liver disease and steatohepatitis

Dana Ivancovsky-Wajcman[1], Marcela Villota-Rivas[1], Melina Manolas[2], Vanessa Villas-Riotorto[3], Anish Arora[4], Paul N. Brennan[5], Didac Mauricio[6], Damien Leith[5], José Willemse[7], Michael Betel[8], Faisal Alnaser[9], Mohamed El Kassas[10], Jeffrey Lazarus[11]. *[1]Barcelona Institute for Global Health (ISGlobal), Barcelona, Spain; [2]Department of Endocrinology, Diabetes & Metabolism, Weill Cornell Medicine, New York, United States; [3]Faculty of Medicine and Health Sciences, University of Barcelona, Clinical Health Psychology Section, Hospital Clínic, Barcelona, Spain; [4]Department of Health Sciences, Wilfrid Laurier University, Waterloo, Canada; [5]University of Dundee, Division of Molecular and Clinical Medicine, School of Medicine, Dundee, United Kingdom; [6]Department of Endocrinology & Nutrition, CIBERDEM, Hospital de la Santa Creu i Sant Pau, Faculty of Medicine, University of Vic/Central University of Catalonia, Barcelona, Spain; [7]Liver Patients International, Brussels, Belgium; [8]Fatty Liver Alliance, Toronto, Ontario, Canada; [9]Bahrain Family Physicians Association, Manama, Bahrain; [10]Endemic Medicine Department, Faculty of Medicine, Capital University, Cairo, Egypt; [11]Barcelona Institute for Global Health (ISGlobal), Faculty of Medicine and Health Sciences, University of Barcelona (UB), City University of New York Graduate School of Public Health and Health Policy (CUNY SPH), New York, New York, USA, Barcelona, Spain*
Email: danaivanc@gmail.com

Background and aims: Metabolic dysfunction-associated steatotic liver disease (MASLD) and metabolic dysfunction-associated steatohepatitis (MASH) are linked with mental health (MH) challenges, which may limit patient engagement in treatment. However, MH is rarely addressed in clinical guidelines or practice. We aimed to assess

MH intervention provision (MHIP) by healthcare providers (HCPs) in MASLD/MASH care and identify factors influencing this.
Method: An expertly developed and validated survey, including a demographics questionnaire and 22 items, was distributed to MASLD/MASH HCPs worldwide via Qualtrics XM. As part of this survey, MHIP was assessed by asking how often MH interventions were recommended, using a 0–5 Likert scale (0 = never, 5 = more than once a week), with anonymous rankings summed to an overall MHIP score. Interventions recommended at least weekly by >75% of HCPs were defined as highly recommended. MHIP self-efficacy (SE) was assessed using 4 questions via a 0–4 Likert scale (0 = strongly disagree, 4 = strongly agree), with responses summed to an overall SE score. High MHIP and SE were defined as scores above the sample median (>33.5, >11, respectively). Stepwise forward regression was used to identify predictors of high MHIP (SPSS 31). A $p < 0.050$ was considered significant.
Results: Of 286 eligible HCPs, 262 (91.6%) completed the survey and were included in the analysis. Mean age was 52.7 (SD: 10.9) years and 36.7% were female. Dietary modifications (85.1%) and exercise (84.4%) were the only highly recommended interventions. Cronbach's alpha for MHIP and SE questions was 0.910 and 0.792, respectively. MHIP correlated with SE ($r = 0.372$, $p < 0.001$). Being female (OR = 3.42, 95% CI 1.87–6.25, $p < 0.001$), having high SE (OR = 2.96, 1.67–5.26, $p < 0.012$), and working within a multidisciplinary team (OR = 3.30, 1.80–6.03, $p < 0.001$), specifically with a mental health expert (psychiatrist, psychologist, social worker, behavioral change expert) (OR = 5.03, 1.84–13.77, $p = 0.002$), were associated with high MHIP. Working within a multidisciplinary team (OR = 2.38, 1.36–4.18, $p = 0.002$) or in a low- or middle-income country (OR = 2.37, 1.32–4.26, $p = 0.004$) and having MH training (OR = 1.85, 1.02–3.37, $p = 0.043$) were associated with high SE.
Conclusion: MHIP is modest overall but strongly influenced by provider SE and team-based care. Targeted training and interdisciplinary collaboration could help close the gap between MH needs and current clinical practice and improve MASLD/MASH care.

THU-042-YI
Mental distress and social support in adult offspring of parents with alcohol-related liver disease compared to offspring of parents with a cancer diagnosis: a national health survey
Pernille Jessen[1], Jonas Hedelund Rønn[1], Lone Galmstrup Madsen[1], Peter Jepsen[2], Marie Eliasen[3], Gro Askgaard[1]. [1]*Zealand University Hospital, Koege, Denmark;* [2]*Aarhus University Hospital, Aarhus, Denmark;* [3]*Center for Clinical Research and Prevention, Bispebjerg Hospital, Copenhagen, Denmark*
Email: ptoj@regionsjaelland.dk

Background and aims: Offspring of parents with alcohol-related liver disease (ALD) are prone to mental distress and research into support options might be relevant, like the growing field for support options for cancer-offspring. We compared mental distress and social support in offspring of parents with ALD with offspring of parents with cancer and with controls.
Method: Data for this cross-sectional study came from the Danish National Health Surveys 2013–2021 with questions on mental and physical health-related quality of life (HRQoL) by the Short Form-12, Cohens Perceived Stress Scale, depressive and anxiety symptoms, sleep difficulties, perceived social support and loneliness. Information on parental ALD and cancer diagnoses came from national registers. Offspring of parents with ALD were matched randomly by age, sex, and years since parental diagnosis 1:5:5 with offspring of parents with cancer and controls. We used conditional logistic regression to estimate odds ratios (OR) for mental distress and social support adjusted for age and sex, overall and stratified by years since parents' diagnosis.
Results: The study included respondents of which 3216 were ALD-offspring, 16,303 were cancer-offspring and 16,305 were controls of which 45% was men and mean age was 44 years. Time since parents' diagnosis was <2 years in 6% ALD/cancer-offspring, 2–4 years for 12% offspring, 5–10 years for 23% offspring, and >10 years for 59% offspring. For ALD-offspring, cancer-offspring and controls, low mental HRQoL was experienced by 11.4%, 9.8%, and 8.8% and low social support by 15.6%, 13.4%, and 14.2%, respectively. Adjusted OR were higher in ALD-offspring vs. cancer-offspring and in ALD-offspring vs. controls for low mental HRQoL, high perceived stress, anxiety symptoms, depressive symptoms, sleep difficulties, low social support and loneliness but not for physical HRQoL. For example, OR for low mental HRQoL in ALD-offspring was 1.19 (95% CI: 1.05–1.35) compared to cancer-offspring and 1.34 (1.19–1.51) compared to controls and for low social support it was 1.19 (1.07–1.32) and 1.12 (1.00–1.24), respectively. Stratified analyses indicated that mental distress was equally frequent in ALD- and cancer-offspring in the first years after parental diagnosis and more frequent in ALD offspring beyond 2 years.
Conclusion: Offspring of parents with ALD report mental distress more often than offspring of parents with cancer and controls. These findings emphasize the need for a support system for offspring of parents with ALD.

THU-043
Neighborhood deprivation and survival in hospitalized alcoholic hepatitis: a ZIP-code based area deprivation index analysis
Samuel Ji[1], Lankai Xu[1], Maria Aguilar[1], Albert Do[1], Lydia Aye[1], Vikrant Rachakonda[1]. [1]*University of California Davis Medical Center, Sacramento, United States*
Email: vrachakonda@health.ucdavis.edu

Background and aims: Alcohol-associated hepatitis (AH) carries high short-term mortality, but the impact of neighborhood deprivation on outcomes is unclear. We evaluated whether higher Area Deprivation Index (ADI) is associated with survival and eadmissions in AH.
Method: This was a single-center retrospective cohort study of adults admitted with AH to UC Davis Medical Center from July 2017 to September 2024. Clinical, demographic and laboratory data were obtained at admission. Block-group ADI from the Neighborhood Atlas was aggregated to patient ZIP codes using the HUD–USPS ZIP–tract crosswalk. Patients were grouped into ZIP-level ADI quintiles (Q1 least deprived, Q5 most deprived). Straight-line distance from patient ZIP to hospital ZIP was calculated from ZIP centroids. Overall survival was assessed with Cox proportional hazards models and AH readmission with logistic regression.
Results: 582 AH patients were included. Median age was 45 (IQR 37–55) years, median MELD 3.0 was 26 (IQR 21–31), and median BMI was 27.6 (IQR 23.9–32.1) kg/m^2. Age, MELD and BMI were similar across ADI quintiles, but there were more female, English-speaking, and Caucasian patients in lower ADI quintiles (all $p \leq 0.001$). Gastrointestinal bleeding (GIB), intensive care unit (ICU) admission, and AH readmissions were more common in higher-deprivation quintiles ($p = 0.038$, 0.044 and 0.037, respectively), and higher-deprivation patients received fewer prescriptions for alcohol use disorder (AUD) pharmacotherapy at hospital discharge ($p \leq 0.001$). Mean survival decreased stepwise from 407 days (95% CI 373–440 days) in Q1 to 135 days (123–147 days) in Q5. In Cox models, Q5 deprivation quintile was associated with increased mortality in univariable analysis (HR 1.81, 95% CI 1.07–3.04; $p = 0.026$) and remained independently associated with mortality after adjustment (aHR 2.31, 1.36–3.95; $p = 0.002$), along with age, MELD 3.0, GIB and ICU admission. Distance from the hospital was not associated with survival ($p = 0.910$). In multivariable logistic regression models for AH readmission, ADI Q3 had higher odds than Q1 (OR 2.55, 1.23–5.30; $p = 0.012$).
Conclusion: In this cohort, residence in the most deprived neighborhoods was associated with substantially shorter survival and greater risk of AH readmission, independent of MELD and acute illness severity. ADI may help identify socially vulnerable AH patients

who warrant intensified follow-up and targeted post-discharge interventions.

Evaluation of metabolic dysfunction-associated steatotic liver disease in agricultural workers exposed and unexposed to Mancozeb

Hidayat Kassim[1], Dvora Joveleviths[2], Vittoria Sampaio[3], Isabela Carvalhal[4], Nelson Suarez Uribe[3], Raquel Boff[3], Tiago Onofrio Soares[4], Theo Futuro Telöken[5], Ana Lazzari[3], Camila Pereira Baldin[3], Sheila De Castro Cardoso Toniasso[3], Gabriela Nardy Vasconcellos[3], Patricia Riedel[3], Eduardo Klein[3].
[1]UFRGS - HCPA, Ministry of health Mozambique - Health Department Zambezia Province, Porto Alegre, Brazil; [2]UFRGS - HCPA, Porto Alegre, Brazil; [3]UFRGS, Porto Alegre, Brazil; [4]PUC RS, Porto Alegre, Brazil; [5]Universidade Vale de Rio Sinus, Porto Alegre, Brazil
Email: hidayatkassim@hotmail.com

Background and aims: Mancozeb is a widely used agricultural fungicide with potential hepatotoxic effects and metabolic dysfunction-associated steatotic liver disease (MASLD) is highly prevalent in the general population. Few studies have evaluated the direct effects of Mancozeb on liver, hormonal, and metabolic parameters in humans. The investigation of this association may improve the understanding of environmental factors involved in disease progression. This study aimed to compare liver profile (fibrosis index-4, FIB-4), hormonal parameters (thyroid-stimulating hormone [TSH], free thyroxine [FT4], and C-peptide), and metabolic markers (homeostasis model assessment of insulin resistance [HOMA-IR], glycated hemoglobin [HbA1c], and lipid profile) between individuals chronically exposed to Mancozeb and unexposed individuals, all meeting metabolic criteria for MASLD.
Method: This cross-sectional study included 92 participants from Veranópolis, Brazil (46 exposed and 46 unexposed). Groups were compared using statistical tests ($p<0.05$), with sample power of 70% and significance level of 5%.
Results: HOMA-IR values were similar between groups (2.46 vs. 2.6), indicating adequate matching. Higher liver fibrosis risk was observed among exposed individuals, with higher mean FIB-4 values (1.38 vs. 1.12) and FIB-4>2.67 in.4% of exposed participants, absent in unexposed individuals. The unexposed group had more low-risk individuals (31 vs. 24), whereas the exposed group had more individuals at increased fibrosis risk (22 vs. 15). Mean TSH levels were slightly higher in exposed individuals (2.7 µIU/mL vs. 1.9 µIU/mL), while FT4 levels were similar. HbA1c showed no difference, with mean values of 5.5% in both groups. C-peptide levels were comparable (2.4 ng/mL vs. 2.3 ng/mL). Exposed individuals showed lower total cholesterol (192.9 mg/dL vs. 215 mg/dL) and triglycerides (138.1 mg/dL vs. 163.2 mg/dL), likely related to higher occupational physical activity.
Conclusion: Chronic exposure to Mancozeb may be associated with increased hepatic fibrosis risk and subclinical thyroid axis alterations in individuals with cardiometabolic criteria for MASLD, independent of classical metabolic differences. These findings highlight the importance of periodic clinical monitoring, reduction of occupational exposure, and further longitudinal studies.

THU-045

Drivers and precipitators of acute-on-chronic liver failure and acute decompensation in a real-world cirrhotic cohort

Niv Zmora[1], Dor Shirin[1], Helena Katchman[1]. *[1]Ichilov Sourasky Hospital, Tel Aviv-Yafo, Israel*
Email: nivz@tlvmc.gov.il

Background and aims: Acute-on-chronic liver failure (ACLF) and acute decompensation (AD) are critical milestones in cirrhosis progression. While clinical definitions are established, precipitating events and phenotypic expressions vary across populations. We aimed to characterize the clinical, laboratory, and pharmacological profiles of patients with cirrhosis admitted to a tertiary center, comparing those with ACLF, AD, and stable cirrhosis (SC).
Method: Data were extracted from a prospective cohort study (CLEARED Consortium) of non-electively admitted patients with cirrhosis at the Tel-Aviv Sourasky Medical Center (2023–2025). Patients were stratified into ACLF, AD, and SC. Data were analyzed using one-way ANOVA for continuous variables and Fisher's exact test for categorical variables.
Results: The cohort included 92 patients (mean age 63.9 years, 41.3% female). Primary etiologies were MASH (34.7%), HCV (23.9%) and alcohol-associated liver disease (17.3%). 41 (44.5%) had ACLF, 28 (30.4%) had AD, and 23 (25%) were SC.

- Severity scores: ACLF patients had higher MELD-Na scores (20.4) vs. AD (13.5) and SC (13.9; $p < 0.0001$). Child-Pugh scores were also higher in ACLF (8.6) vs. SC (6.7; $p = 0.0004$).
- Hospitalization drivers: Admissions triggered by infection were more frequent in ACLF (and SC) vs. AD (34.1% and 31.8% vs. 7.1%; $p = 0.021$). All infection-triggered AD cases were due to spontaneous bacterial peritonitis (SBP). SBP accounted for 50% of infection-triggered ACLF, while 0% of the SC group had SBP ($p = 0.012$).
- Clinical presentation: Liver-related admission drivers were more frequent in ACLF and AD than SC (75.6% and 89.2% vs. 42.8%; $p = 0.0004$). AD was characterized by higher GI bleeding prevalence (36.0% vs. 12.5% in ACLF; $p = 0.046$), while ACLF was associated with acute kidney injury (33.3% vs. 4.0% in AD; $p = 0.016$).
- Pharmacotherapy: Non-selective beta-blocker use was more prevalent in ACLF (73.2%) and AD (59.3%) vs. SC (23.8%; $p = 0.0006$). Statin use was higher in AD (35.7%) compared to ACLF (17.1%) and SC (4.8%; $p = 0.007$).

Conclusion: Our findings underscore the pathophysiological pathways leading to hospital admission in cirrhosis. Infection serves as a dominant trigger for ACLF, more than for acute decompensation. SBP emerges as a potent catalyst for acute deterioration (either AD or ACLF) rather than a feature of stable cirrhosis. These results suggest that early infectious screening is paramount in hospitalized patients with cirrhosis in preventing the transition to life-threatening ACLF.

THU-046

Association between neck circumference and steatotic liver disease: a systematic review and meta-analysis

Cecilia Katzenstein[1], Regina Longley[1], Nina Rodriguez[1], Jacqueline Slobin[1], Tatyana Kushner[2]. *[1]Icahn School of Medicine at Mount Sinai, New York, United States; [2]Weill Cornell Medicine, New York, United States*
Email: cecilia.katzenstein@icahn.mssm.edu

Background and aims: Neck circumference (NC) reflects visceral adiposity, yet is rarely used in clinical practice. BMI fails to capture fat distribution, and waist circumference can be unreliable in contexts such as obesity, pregnancy, abdominal distension, certain ethnicites, and childhood. NC is simple and reproducible, yet the extent to which it correlates with steatotic liver disease (SLD) remains unclear. We conducted a systematic review and meta-analysis to examine this association across studies using imaging, biochemical, and histological assessments.
Method: PubMed, Embase, Scopus, and Web of Science were searched through October 2025 using a librarian-reviewed strategy. Studies reporting NC in participants with and without SLD, or reporting correlations between NC and SLD were included. Two reviewers independently screened and extracted data. Adjusted odds and hazard ratios were pooled as generic relative effects (RE), and mean NC differences were summarized as standardized mean differences (SMD) using random-effects models. Leave-one-out analyses tested robustness.
Results: Of 337 studies, 39 (n = 67,395) were included. Studies were comprised of community or national (14; 36%), workplace (8; 21%), and clinical cohorts (17; 44%) across 15 countries in Asia (18, 51%), Europe (9, 23%), the Americas (8, 21%), and the Middle East (4, 10%).

Pediatric cohorts accounted for 4 studies (10%). Individuals with SLD had a higher NC than those without (pooled RE = 1.64, 95% CI 1.35–1.99; I2 = 72%). The association remained significant in subgroup analyses of adults (1.58, 1.30–1.92; I2 = 69%), children (2.56, 1.74–3.76; I2 = 61%), women (1.84, 1.42–2.39; I2 = 66%) and men (1.97, 1.30–2.98; I2 = 64%). In studies reporting group means, NC was higher in SLD than non-SLD (SMD = 1.08, 95% CI 0.84–1.32; I2 = 69%). Several studies found NC to be independently associated with SLD after adjustment for BMI and waist measures. Effects were consistent across ultrasound (ORs 1.3–2.5) and CAP-based (AUC 0.65–0.82) assessments. Biopsy-based studies demonstrated clear associations with steatosis but inconsistent findings for fibrosis. No single study altered pooled results.
Conclusion: NC is consistently associated with SLD across populations and SLD diagnostic methods. The magnitude of association is clinically meaningful and often independent of overall adiposity. NC measurement is quick, inexpensive, and reproducible, and may serve as a practical tool for SLD screening and risk-stratification.

THU-047

Effectiveness of a smartphone-assisted lifestyle intervention program on weight reduction: a retrospective study

Stanislav Kravchuk[1], Mykola Bychkov[1]. [1]*Danylo Halytsky Lviv National Medical University, Lviv, Ukraine*
Email: kravchuck.stanislav@gmail.com

Background and aims: Overweight, obesity, and metabolic dysfunction-associated steatotic liver disease (MASLD) remain pressing public health concerns, particularly among women of reproductive and working age. Mobile health (mHealth) programs that integrate nutritional, psychological, and behavioral components offer a scalable approach to promote sustainable lifestyle changes. This study aimed to evaluate the effectiveness of The Body School – a 3-month, smartphone-assisted lifestyle intervention combining dietary counseling, health education, guided cooking, and psychological support – in improving anthropometric outcomes among women with overweight and obesity.
Method: A retrospective analysis was conducted using data from 101 women who completed the program between 2023 and 2024. The program combined nutrition support through a mobile app, educational modules, psychological support, and physical activity recommendations. The primary outcomes were changes in body weight, body mass index (BMI), and waist- to-hip ratio (WHR), self-recorded by participants in the app. The Wilcoxon signed-rank test was used for statistical analysis ($p < 0.001$).
Results: The program resulted in a statistically significant reduction in all primary anthropometric indicators: median weight loss was 4.0 kg (–5%), BMI decreased by 1.83 kg/m^2, and WHR by 0.016.
Conclusion: The Body School smartphone-assisted lifestyle program resulted in significant reductions in body weight, BMI, and WHR among women with overweight, with a mean participant age of 36.9 years. These findings highlight the program's potential as an effective digital tool for comprehensive, multidisciplinary weight management in different metabolic pathologies, including MASLD.

THU-050

Assessing Europe's policy readiness to confront the MASLD/MASH public health threat

Email: Jeffrey.Lazarus@isglobal.org

Background and aims: Metabolic dysfunction-associated steatotic liver disease (MASLD) is closely linked to obesity and type 2 diabetes, being now the second most common chronic liver disease in Europe, yet largely absent from policy agendas, exposing a major gap in Europe's metabolic health response. This study aimed to provide the evidence on national policies and clinical practice guidelines (CPGs) for MASLD/metabolic dysfunction-associated steatohepatitis (MASH) in Europe.
Method: MASLD/MASH policies (i.e., government strategies/action plans and CPGs) were reviewed in 25 European countries (in the European Union (EU) and the United Kingdom) and reported via a standardised data collection tool completed by a country lead. Each country's data-collection tool was reviewed by a core study team of three researchers and cross-referenced with public documents in any language to ensure accuracy.
Results: No country had a national MASLD/MASH strategy or action plan issued by a government body, though two (8.0%), Romania and Sweden, had sub-national strategies. Twelve (48.0%) had at least one national or subnational strategy or action plan in which MASLD/MASH was mentioned (within alcohol, cancer, CVD, diabetes, healthy lifestyle/diet, liver disease, noncommunicable disease, obesity, or

"other" strategies). Among the national or subnational strategies or action plans mentioning MASLD/MASH, obesity and diabetes (n = 9 out of 24 countries, 36.0% and n = 8, 32.0%, respectively) were the most frequent ones mentioning MASLD/MASH.
Fifteen (60.0%) countries had national level MASLD/MASH CPGs. Regarding the mention of MASLD/MASH in national level clinical guidelines for dyslipidaemia, obesity, diabetes, alcohol, hypertension, CVD, end of stage liver disease (ESLD)/cirrhosis, liver cancer, liver transplantation, primary care, or "other," 22 (88.0%) of the respondent countries had at least one clinical practice guideline mentioning MASLD/MASH. Obesity guidelines (n = 17, 68.0%), followed by guidelines for diabetes (n = 12, 48.0%), ESLD/cirrhosis (n = 10, 40.0%), liver transplantation (n = 6, 24.0%), and primary care (n = 5, 20.0%) most commonly included MASLD/MASH.
Conclusion: MASLD remains insufficiently addressed in national policy, leaving health systems underprepared despite important diagnostic and therapeutic advances. Integrating MASLD/MASH into existing NCD frameworks and policies is urgently needed to address this public health threat.

THU-051
Extremes and persistence of body mass index increase risks of HCC and mortality regardless of MASLD status
Mei-Hsuan Lee[1], Szu-Ching Yin[1], Xia-Rong Liu[1]. [1]*National Yang Ming Chiao Tung University, Taipei, Taiwan*
Email: lee.meihsuan@gmail.com

Background and aims: Body mass index (BMI) is a key metabolic determinant of HCC and mortality, yet its associations across the BMI spectrum and in relation to metabolic dysfunction–associated steatotic liver disease (MASLD) remain incompletely defined. We examined associations between BMI, HCC incidence, cause-specific mortality, and all-cause mortality, and assessed effect modification by MASLD status.
Method: We conducted a prospective cohort study of individuals undergoing health examinations at a private screening center between 1998 and 2013. BMI (kg/m^2) was classified using Asian-specific criteria as underweight (<18.5), normal (18.5–<23), overweight (23–<25), or obese (≥25). MASLD was defined by ultrasound-detected hepatic steatosis in the absence of other chronic liver diseases. Participants were followed through linkage with national cancer and death registries until 2022. Associations with HCC incidence, liver-related mortality, cardiovascular disease (CVD) mortality, and all-cause mortality were estimated using Cox proportional hazards models, stratified by MASLD status. Longitudinal BMI patterns based on repeated measurements were also evaluated.
Results: Among 287,718 participants, 6.7% were underweight, 42.9% normal weight, 21.6% overweight, and 28.8% obese; MASLD prevalence was 46.0% among overweight and 76.4% among obese individuals. Both underweight and obesity were associated with increased risks of HCC, liver-related mortality, CVD mortality, and all-cause mortality, demonstrating a J-shaped relationship. Compared with normal BMI, adjusted hazard ratios (HRs) for HCC were 1.06 (95% CI 0.79–1.42) for underweight, 1.29 (1.12–1.49) for overweight, and 1.89 (1.67–2.13) for obesity. Corresponding HRs for all-cause mortality were 1.34 (1.27–1.41) and 1.23 (1.19–1.26). These patterns were consistent across MASLD and non-SLD subgroups. In longitudinal analyses, persistent overweight or obesity was associated with higher risks of HCC and liver-related mortality. Among individuals with MASLD, persistent overweight or obesity was associated with increased risks of HCC (HR 1.91, 95% CI 1.23–2.97), liver-related mortality (HR 1.87, 1.19–2.93), and CVD mortality (HR 1.87, 1.19–2.93).
Conclusion: Extremes of BMI and persistent excess adiposity are associated with increased risks of HCC and mortality, independent of MASLD status. These findings emphasize sustained adiposity exposure, rather than MASLD status alone, as a key determinant of long-term liver and cardiometabolic outcomes.

THU-052
Association between sarcopenic obesity and vibration-controlled transient elastography-assessed hepatic steatosis and significant fibrosis: a cross-sectional analysis of NHANES 2017–2018
Jiayue Li[1]. [1]*Sun Yat-sen University, Guangzhou, China*
Email: 1347832609@qq.com

Background and aims: Sarcopenic obesity (SO), defined as the coexistence of sarcopenia and obesity, is a global public health concern. Both sarcopenia and obesity are risk factors of liver-related morbidity and mortality. However, data showing the relationship between SO and the development of metabolic dysfunction-associated steatotic liver disease remain scarce. We aimed to investigate the association between SO and vibration-controlled transient elastography (VCTE)-assessed hepatic steatosis and significant fibrosis, and effect modifiers including age, sex, and race/ethnicity.
Method: This cross-sectional study analyzed data from the 2017–2018 National Health and Nutrition Examination Survey (NHANES). Hepatic steatosis (controlled attenuation parameter [CAP] ≥248 dB/m) and fibrosis (liver stiffness measurement [LSM]≥8 kPa) were assessed by VCTE. Sarcopenia was defined by sex-specific appendicular lean mass/body mass index (BMI) ratios (males: <0.789; females: <0.512) and obesity by BMI≥30 kg/m^2. SO is a composite status of sarcopenia and obesity.
Results: A total of 2,401 participants were included in the analyses after screening 5,809 initial NHANES participants. The prevalence of SO was 3.4% among these participants. Compared with people with neither sarcopenia nor obesity, SO was significantly associated with higher CAP (beta-coefficient: 61.02, 95% confidence interval [CI]: 49.766–72.275, $p < 0.001$), higher LSM (beta-coefficient: 2.137, 95% CI: 1.227–3.046, $p < 0.001$), hepatic steatosis (odds ratio [OR]: 7.622, 95% CI: 3.866–16.522, $p < 0.001$), and significant fibrosis (OR: 8.177, 95% CI: 4.195–15.68, $p < 0.001$). The associations with SO were stronger than those of obesity or sarcopenia alone. Subgroup analyses showed the strongest association with hepatic steatosis in participants aged 30–44 years (OR 27.63, $p = 0.002$), males (OR 32.88, $p < 0.001$) and non-Hispanic Whites (OR 9.37, $p = 0.001$), and with significant fibrosis in those aged 18–29 years (OR 26.00, $p < 0.001$), males (OR 10.07, $p < 0.001$) and non-Hispanic Whites (OR 6.36, $p = 0.006$).
Conclusion: In a nationally representative cohort, SO is strongly associated with hepatic steatosis and significant fibrosis, with a more pronounced effect than obesity or sarcopenia alone. The associations vary by age, sex, and race/ethnicity, supporting targeted screening in high-risk subgroups. Longitudinal studies are warranted to confirm causality.

THU-053
Reassessing obesity in US adults with MASLD under the lancet commission diagnostic criteria
Rutao Lin[1], Renqiang Zeng[1], Xuting Shen[2], QinMei Sun[1], Xin Xin[1], Jiamei Chen[1], Yiyang Hu[1], Qin Feng[1]. [1]*Institute of liver diseases, Shuguang hospital affiliated to Shanghai university of traditional Chinese medicine, Shanghai, China;* [2]*Department of Clinical Laboratory, Shuguang Hospital Affiliated to Shanghai University of Chinese Traditional Medicine, Shanghai, China*
Email: linrutao_2000@163.com

Background and aims: The newly proposed Lancet Commission on Obesity criteria integrate anthropometric and body composition measures, but their implications for Metabolic dysfunction–associated steatotic liver disease (MASLD), including lean-MASLD, are unclear. The study aims to evaluate the impact of the new criteria on obesity prevalence and reclassification patterns in adults with MASLD, including implications for lean-MASLD.
Method: We analyzed data from National Health and Nutrition Examination Survey 2017–2018, including adults with MASLD diagnosed by vibration-controlled transient elastography. We

compared obesity assessment using the new Lancet Commission on Obesity diagnostic criteria with the traditional BMI-based criteria. Under the new criteria, obesity assessment incorporated waist circumference, waist-to-hip ratio, waist-to-height ratio, and body fat percentage measured by dual-energy X-ray absorptiometry (DEXA). Obesity was defined by any of 4 criteria: (1) BMI ≥ 40 kg/m^2; (2) elevated BMI in plus ≥ 1 elevated anthropometric measure; (3) ≥ 2 abnormal anthropometric measures regardless of BMI; (4) excess body fat by DEXA. Traditional obesity was BMI ≥ 30 kg/m^2 (≥ 27.5 for Asian). Lean MASLD was BMI < 25 kg/m^2 (< 23 for Asian).
Results: Among adults with MASLD, obesity prevalence increased from 66.8% (95% CI, 60.6%–72.4%) by traditional criteria to 98.3% (95% CI, 97.3%–99.0%) by the new criteria. Among BMI-defined non-obese MASLD, 94.9% were reclassified as obese and had intermediate hepatic and metabolic abnormalities compared with concordant non-obesity and concordant obesity groups. The prevalence of lean MASLD was 5.4% (95% CI, 2.8%–7.9%) in MASLD; under the new criteria, 84.2% of lean MASLD were met new obesity criteria, reducing lean MASLD prevalence to 0.8% (95% CI, 0.5%–1.2%).
Conclusion: In US adults with MASLD, the new criteria substantially increase estimated obesity prevalence and reclassify most BMI-defined non-obesity, including most lean MASLD as obese. Multidimensional adiposity assessment may improve risk stratification beyond BMI alone.

THU-054
Analysis and 15-year projection of the disease burden of cirrhosis attributable to metabolic dysfunction-associated steatotic liver disease in China, 1990–2021
Ge Liu[1], Jian Jiao[1]. [1]*China-Japan Union Hospital, Jilin University, Changchun, Jilin Province, China*
Email: liuge23@mails.jlu.edu.cn

Background and aims: The global incidence of chronic liver disease attributed to metabolic dysfunction-associated steatotic liver disease (MASLD) is increasing. This study aimed to assess the trends in the burden of MASLD-related cirrhosis in China from 1990 to 2021 and to project its future trajectory over the next 15 years.
Method: Data were obtained from the Global Burden of Disease (GBD) 2021 study. Trends were analysed using Joinpoint regression to calculate the average annual percentage change (AAPC). Age-period-cohort (APC) modelling was applied to estimate the independent effects of age, time period, and birth cohort. An autoregressive integrated moving average (ARIMA) model was used to project incidence, prevalence, and mortality rates for the period 2022–2036.
Results: In 2021, the incidence, prevalence, and mortality rates of MASLD-related cirrhosis in China were 621, 15,606, and 0.31 per 100,000 population, respectively. From 1990 to 2021, the age-standardized incidence rate (ASIR) increased significantly (AAPC = 0.74%; 95% CI: 0.69% to 0.78%), while the age-standardized death rate (ASDR) decreased (AAPC = −1.73%; 95% CI: −2.06% to −1.40%). APC analysis indicated the highest period risk for morbidity occurred in 2017–2021 (rate ratio, RR = 1.16; 95% CI: 1.11 to 1.21). For the cohort born between 1977 and 2002, there was a significant increase in morbidity risk but a decrease in mortality risk. Projections suggest the ASIR will rise from 621.18/100,000 in 2021 to 662.27/100,000 by 2036, with a substantial increase in females offsetting a decrease in males. The overall ASDR is projected to decline slightly from 0.31 to 0.29 per 100,000, with a minor increase noted in females.
Conclusion: The burden of MASLD-related cirrhosis in China is projected to continue rising over the next 15 years, presenting a growing public health challenge. The shifting epidemiology, characterized by a rising incidence in females, highlights the urgent need for sex-specific prevention strategies and early intervention programs focused on MASLD management.

SAT–003-YI
Risk of advanced fibrosis and cancer in a population-based colorectal cancer screening program: implications for EASL case-finding strategies
Maria Capilla[1], Inmaculada Lorca[1], Carmen Quiñones[1], Lucas Sebastián-Peris[2], Jose Miguel Carot[2], Concepción Gómez[1], Clara Alfaro-Cervello[1], Pilar Aguilar[1], Susana Castán-Cameo[3], Silvia Gimeno-Martos[3], Marta Ponce[1], Paloma Lluch-García[1], Isabel Pascual-Moreno[1], Arturo Carratalá[1], Andres Peña[1], David Marti-Aguado[1]. [1]*Incliva - Instituto De Investigación Sanitaria, Valencia, Spain;* [2]*Universitat Politècnica de València, Valencia, Spain;* [3]*Department of Universal Healthcare and Public Health, Valencia, Spain*
Email: davidmmaa@gmail.com

Background and aims: The EASL-EASD-EASO guidelines recommend active case-finding for advanced fibrosis in individuals with MASLD and strict adherence to extrahepatic cancer screening programs. Population-based colorectal cancer (CRC) screening programs provide an ideal setting to implement these recommendations. The aims of this study were: (I) to determine the prevalence of advanced fibrosis among participants in a CRC screening program; and (II) to evaluate the association between fibrosis risk and CRC detection.
Method: We prospectively included participants within a Spanish regional population–based established CRC screening program (n = 28,314 participants during study period 2021–2024). Individuals aged 50–70 years with a positive faecal immunochemical test (FIT+) who were referred for screening colonoscopy were eligible. Prior to colonoscopy, routine blood tests were performed to calculate FIB-4. Participants were classified as having low, intermediate, or high risk of advanced fibrosis according to recommended, age-adjusted FIB-4 cut-offs. The primary endpoint was CRC detected at colonoscopy.
Results: A total of 1,733 FIT+ participants were included; 48% were women, 25% had obesity, and 16% had diabetes. Among the 1,562 individuals with available pre-colonoscopy blood tests, 62% (n = 980) were classified as low risk (FIB-4 <1.3), 33% (n = 510) as intermediate risk, and 5% (n = 72) as high risk for advanced fibrosis (FIB-4 ≥2.67). CRC was detected in 5.5% of participants (n = 97). CRC prevalence according to fibrosis risk category was 6.2% in the low-risk group, 4.9% in the intermediate-risk group, and 6.9% in the high-risk group. No significant association between fibrosis risk category and CRC detection was observed (p = 0.28). No significant differences in CRC prevalence were observed according to the presence of obesity and/or diabetes.
Conclusion: The prevalence of advanced fibrosis risk among participants in a population-based CRC screening program is substantially higher than that reported in the general population at risk for MASLD. While the prevalence of advanced fibrosis risk is high in CRC screening participants, fibrosis risk is not associated with increased CRC detection. These findings support CRC screening programs as an opportunity for liver disease case-finding, but do not suggest fibrosis-based CRC risk stratification.

SAT–004
An observational study of alcohol related liver disease hospitalisations in Australia before and during the COVID-19 pandemic, using routinely collected national data
Edward Meehan[1], Nicholas Mulkearns[2], Liam Brennan-Xie[2], Margery Zhang[2], Niranjan Arachchi[1]. [1]*Sunshine Hospital, Saint Albans, Australia;* [2]*University of Melbourne, Melbourne, Australia*
Email: ejmeehan@gmail.com

Background and aims: Alcohol consumption increased significantly during the COVID-19 pandemic. Previous single-centre Australian studies reported a concurrent increase in alcohol-associated hepatitis admissions, but impacts at a national level are unknown. We aimed to compare trends in hospital separations for alcohol-associated liver disease (ALD) before and during the pandemic, using routinely collected administrative health data.

Method: We searched the Australian Institute of Health and Welfare National Hospital Morbidity Database using ICD-10 codes and extracted annual hospital separation counts for the financial years 2014–15 to 2021–22. We included only multi-day stays, as elective procedure cancellations during COVID-19 significantly altered same-day separations. Elective procedures requiring multi-day stays may have produced residual confounding, which would likely cause underestimation of disease burden increase. We calculated crude rates per 100,000 residents of hospitalisations chiefly due to ALD (ICD-10 code K71), all diseases of the liver (K70-K77), all diseases of the digestive system (K00-K93), and for any cause. We used chi-square tests to compare ALD admissions as a proportion of each of these categories in 2018–19 and 2020–21.
Results: Across all years, there were 43,260 multi-day ALD separations, 98,310 disease of liver separations, 3,566,648 digestive disease separations, and 38,173,066 all-cause separations. The rate of multi-day ALD hospitalisations declined slightly from 18.6 to 16.3 per 100,000 between 2014–15 to 2018–19. However, during the COVID-19 pandemic, sharp increases occurred in 2019–20 (18.48; +13.3%) and 2020–21 (22.72; +22.9%), contrasting with an overall decrease in contemporary all-cause separations. Between 2018–19 and 2020–21, ALD admissions increased as a proportion of all liver disease admissions (41.7% to 47.7%, $p < 0.00001$), all digestive disease admissions (1.01% to 1.37%, $p < 0.00001$), and all admissions for any cause (0.09% to 0.13%, $p < 0.00001$).
Conclusion: During the COVID-19 pandemic, multi-day ALD admissions increased disproportionately compared to overall liver, digestive disease, and all-cause admissions. We were limited by a lack of granularity in this health administrative dataset, which is not produced to answer specific research questions. Our results may suggest a need for proactive resourcing of hepatology and substance disorder services in future pandemics and recessions.

SAT-005
Sex-specific coronary calcification risk across MASLD and obesity phenotypes in rural Indian adults: reach rural India study

Avinash Kumar Ragupathy[1], Abirami Perumal[1], Vijaya Prakash Madesh[2], Ganesan Velmurugan[3], Pudhiavan Arun[2], Mathew Cherian[2], Thomas Alexander[2], Arulraj Ramakrishnan[4], Sundaresan Mohanraj[1]. *[1]Dr NGP Arts & Science College, KMCH Research Foundation, Coimbatore, India; [2]Kovai Medical Centre & Hospital, Coimbatore, India; [3]KMCH Research Foundation, Coimbatore, India; [4]KMCH Research Foundation, Liver Unit, Kovai Medical Center and Hospitals, Coimbatore, India*
Email: drarulraj@kmchhospitals.com

Background and aims: Metabolic dysfunction–associated steatotic liver disease (MASLD) is increasingly recognized as a systemic metabolic disorder with potential cardiovascular implications. However, the interaction between BMI-defined obesity, MASLD phenotypes, and subclinical atherosclerosis particularly in rural South Asian populations remains poorly characterized. This present study aims to investigate sex-specific associations between BMI–MASLD metabolic phenotypes and coronary artery calcification among rural Indian adults.
Method: In this community-based cross-sectional study, a total of 3,006 rural adults aged 35–65 years were initially screened for coronary artery calcification. After excluding participants with missing data on key metabolic and imaging variables required for phenotype classification and regression modeling, 2,027 participants were included in the final analysis. Participants underwent coronary artery calcium scoring using multidetector computed tomography. Study subjects were classified based on BMI–MASLD into metabolic phenotypes: lean; overweight; obese; lean MASLD; overweight MASLD; obese MASLD and MASLD with central/metabolic obesity. Sex-stratified multinomial logistic regression was performed using CAC = 0 as the reference and any CAC > 0 as the outcome.
Results: Among 2,027 rural adults, CAC prevalence was highest among MASLD phenotypes, with lean MASLD demonstrating the highest CAC prevalence (30.5%), followed by MASLD with central obesity (28.7%), overweight MASLD (28.1%), and obese MASLD (27.6%). In sex-stratified multinomial logistic regression, BMI–MASLD phenotypes were not significantly associated with CAC in men. In contrast, all MASLD and obesity phenotypes were strongly associated with CAC in women. Compared with lean metabolically normal women, MASLD with central obesity (OR 3.17, 95% CI 1.42–7.05; $p = 0.005$), overweight (OR 2.95, 95% CI 1.22–7.11; $p = 0.016$), obesity (OR 1.98, 95% CI 1.05–3.76; $p = 0.036$), lean MASLD (OR 2.93, 95% CI 1.29–6.65; $p = 0.010$), overweight MASLD (OR 2.63, 95% CI 1.37–5.05; $p = 0.004$), and obese MASLD (OR 2.29, 95% CI 1.25–4.20; $p = 0.008$) independently predicted CAC presence.
Conclusion: Lean MASLD and metabolically unhealthy obesity showed the highest burden of subclinical coronary atherosclerosis in rural Indian adults. MASLD, irrespective of BMI, conferred a 2–3-fold higher CAC risk in women, highlighting hepatic steatosis with metabolic dysfunction as one of the driver of coronary calcification beyond BMI alone.

SAT-006
Real-time AI–hepatologist intervention against 'liver detox' misinformation: a prospective social media–based RCT

Yavuz Özden[1]. *[1]Kayseri City Hospital, University of Health Sciences, Kayseri, Türkiye*
Email: yavuzozden@gmail.com

Background and aims: Social media is a major platform for public health information and is a key driver of medical misinformation. The pervasive "liver detox" myth and related liver-health misinformation promote unproven regimens that conflict with evidence-based hepatology practice. Although systematic reviews have described the scope of such misinformation, prospective interventional studies targeting liver-related myths are limited. Therefore, we evaluated a real-time intervention model integrating artificial intelligence with hepatologist oversight to counter liver-related misinformation on social media platforms.
Method: We conducted a 12-week platform-specific randomized controlled study on TikTok and Instagram. Public posts containing liver-related hashtags (e.g., "liver detox") were monitored using an artificial intelligence–assisted system informed by hepatology guidelines for guideline-concordant responses. Posts classified as misleading were randomly assigned to either a real-time intervention consisting of hepatologist-reviewed responses posted within 30 min or to no response. Primary outcomes were 48-hour engagement rate (normalized to post-level impressions) and changes in comment sentiment. Secondary outcomes included response time efficiency and qualitative patterns of user interaction.
Results: Among 842 eligible posts (421 per group), intervention posts showed a 52.3% lower engagement rate (reduced amplification) than controls (95% CI: −58.1 to −46.5; $p < 0.001$). Comment analysis demonstrated a substantial increase in expressions of trust and gratitude, with 31.8% of original content creators engaging constructively (e.g., acknowledging corrections). The AI-supported workflow reduced mean response time to 8.4 minutes, compared with over 45 min using manual review alone.
Conclusion: This model supports scalable strategies for evidence-based hepatology risk communication on social media by enabling timely, expert-led responses against organ-specific misinformation. Limitations include two platforms and a 12-week follow-up.

SAT-007

Economic and healthcare resource burden of metabolic dysfunction-associated steatotic liver disease and metabolic dysfunction-associated steatohepatitis: a United States system dynamics model

David W. Victor Iii[1], Amreen Dinani[2], Elisabeth de Laguiche[3], Fotis Tefos[3], Fryderyk Wilczynski[4], Thomas Padgett[4]. [1]*Houston Methodist Hospital, Houston, United States;* [2]*Duke University School of Medicine, Durham, United States;* [3]*Novo Nordisk A/S, Søborg, Denmark;* [4]*Health Economics and Outcomes Research, Cardiff, United Kingdom*
Email: dwvictor@houstonmethodist.org

Background and aims: Metabolic dysfunction-associated steatotic liver disease (MASLD) is projected to increase globally and impact a third of the United States (US) population. Metabolic dysfunction-associated steatohepatitis (MASH), characterized by hepatic steatosis, inflammation, hepatocyte injury and fibrosis, is associated with all cause and liver related mortality. This study aimed to predict the impact of rising MASLD/MASH prevalence on direct costs and healthcare resource utilization (HCRU), based on current standard of care practices in the US.
Method: A US system dynamics model was developed to predict the prevalence and burden of MASLD/MASH and its complications, stratified by age and disease stage, from 2025 to 2060. Disease stage was derived by mapping Fibrosis-4 (FIB-4) to fibrosis stage (F-stage). The model was calibrated to National Health and Nutrition Examination Survey (NHANES)-derived data (2006–2020) and validated by two clinical experts. Model outcomes included direct healthcare costs and HCRU, including primary care contacts and hospital bed days.
Results: Under current standard of care practices in the US, MASLD/MASH prevalence is projected to increase by 28%, from 104 million in 2025 to 133 million in 2060. People with MASH F2-F4 drive the projected burden, with the greatest percentage increase occurring for F3 (126%) and F4 (116%). The total annual direct costs attributable to MASLD/MASH are predicted to increase from $1.8 trillion in 2025, to $2.5 trillion in 2060, an increase of 37%. Of this, $38 billion is attributed to individuals with F4 fibrosis. Annual HCRU attributable to MASLD/MASH is projected to rise, with primary care visits increasing by 29% and hospital bed days by 39%, growing from 1.0 billion and 98 million in 2025, to 1.3 billion and 137 million by 2060, respectively. In 2060, people with MASH F4 would represent approximately 0.7% of the MASLD/MASH population and account for 12.4 million primary care visits and 6.6 million hospital bed days.
Conclusion: The economic and HCRU burden of MASLD/MASH is projected to rise substantially under current standard of care practices in the US, driven by increasing prevalence and disease severity. This underscores an urgent need for intervention and prevention strategies to mitigate the impact of MASLD/MASH.

SAT-008

A pan European observational cohort study describing clinical characteristics, treatment patterns and outcomes in patients diagnosed with hepatocellular carcinoma

George Papatheodoridis[1], Rohini Sharma[2], Hannes Hagström[3], Andrea Casadei Giardini[4], Carlos Lopez Lopez[5], Ana Matilla[6], Rui Gaspar[7], Kavitha Balaji, Ph.D[8], Mufiza Farid-Kapadia[9], Joe Hickey[10], Pompilia Radu[11]. [1]*National And Kapodistrian University Of Athens, Athina, Greece;* [2]*Imperial College London, London, United Kingdom;* [3]*Karolinska University Hospital, Stockholm, Sweden;* [4]*Università Vita-Salute San Raffaele, Milano, Italy;* [5]*Marqués de Valdecilla University Hospital, IDIVAL, UNICAN, Santander, Spain;* [6]*Gregorio Marañón University Hospital, Madrid, Spain;* [7]*Centro Hospitalar de São João, Porto, Portugal;* [8]*AstraZeneca, Gaithersburg, United States;* [9]*AstraZeneca, Mississauga, Canada;* [10]*Open Health, London, United Kingdom;* [11]*University of Bern, Bern, Switzerland*
Email: iuliana-pompilia.radu@insel.ch

Background and aims: As the most common type of liver cancer, hepatocellular carcinoma (HCC) is a significant global health problem. However, real-world treatment patterns and outcomes are not well characterized in patients with HCC. The OPAL study aimed to address this evidence gap and evaluate treatment patterns and outcomes in European patients with HCC.
Method: OPAL was a European, observational, longitudinal cohort study including adults (≥18 years) with a new diagnosis of HCC between 1 January 2010 and 31 December 2021 from Greece, Italy, Portugal, Spain, Sweden, Switzerland, and the United Kingdom. Study objectives were assessment of demographics, patient and disease characteristics, treatment patterns, overall survival (OS), and progression-free survival (PFS). Analyses were descriptive and stratified by Barcelona Clinic Liver Cancer (BCLC) stage at diagnosis (0–D) and by initial treatment approach: curative therapy (resection, ablation), locoregional therapy (transarterial chemoembolization, transarterial radioembolization), and systemic therapy.
Results: Overall, 6,030 patients were included. Across BCLC stages/treatment types, mean age ranged from 65.1–68.2 years/65.3–68.2 years, proportion of male patients ranged from 76%–85%/80%–93%, proportion of patients with ECOG 0–1 ranged from 14%–95%/90%–97%, and proportion of patients with Child-Pugh A ranged from 20%–78%/73%–94%. Arterial hypertension was the most frequent baseline comorbidity across all BCLC stages. Esophageal varices were the most common baseline complication in BCLC 0 (43%), A (40%), and B (32%), whereas macrovascular invasion was most frequent in BCLC C (45%) and ascites in BCLC D (57%). Median PFS (mPFS) by BCLC stage ranged from 7.26–20.16 months in BCLC 0, 9.48–15.15 in A, 3.0–8.11 in B, 2.16–7.62 in C, and 1.32–8.57 in D. mPFS by treatment type ranged from 12.3–20.9 months for curative, 3.0–15.0 for locoregional, and 3.2–12.34 for systemic therapy. Median OS (mOS) by BCLC stage ranged from 10.0–87.0 months in BCLC 0, 12.0–56.0 in A, 10.0–30.0 in B, 2.76–13.4 in C, and 0.11–1.99 in D. mOS by treatment type ranged from 31.51–54.8 months for curative, 23.0–39.0 for locoregional, and 6.40–29.9 for systemic therapy.
Conclusion: This analysis reports real-world outcomes of European patients with HCC, including outcomes such as PFS and OS up to 5 years post-diagnosis, and evidences the variability in these outcomes across disease stages and treatment approaches.

SAT-009

Real-world patient profiles and outcomes of hepatocellular carcinoma patients treated with embolization procedures: a European observational longitudinal study

George Papatheodoridis[1], Rohini Sharma[2], Hannes Hagström[3], Andrea Casadei Giardini[4], Carlos Lopez Lopez[5], Ana Matilla[6], Rui Gaspar[7], Kavitha Balaji, Ph.D[8], Mufiza Farid-Kapadia[9], Angela Wang[9], Joe Hickey[10], Pompilia Radu[11]. [1]*National And Kapodistrian University Of Athens, Athina, Greece;* [2]*Imperial College London, London, United Kingdom;* [3]*Karolinska University Hospital, Stockholm, Sweden;* [4]*Università Vita-Salute San Raffaele, Milano, Italy;* [5]*Marqués de Valdecilla University Hospital, IDIVAL, UNICAN, Santander, Spain;* [6]*Gregorio Marañón University Hospital, Madrid, Spain;* [7]*Centro Hospitalar de São João, Porto, Portugal;* [8]*AstraZeneca, Gaithersburg, United States;* [9]*AstraZeneca, Mississauga, Canada;* [10]*Open Health, London, United Kingdom;* [11]*University of Bern, Bern, Switzerland*
Email: iuliana-pompilia.radu@insel.ch

Background and aims: Hepatocellular carcinoma (HCC) is the most common type of liver cancer. Embolization procedures, like transarterial chemoembolization (TACE) or transarterial radioembolization (TARE), are used mainly for intermediate HCC patients. Given limited evidence on characteristics and outcomes in this population, this European observational longitudinal study aimed to describe real-world patient profiles, disease characteristics, and clinical outcomes among patients treated with these embolization procedures.
Method: Adults (≥18 years) with a new diagnosis of HCC between 1 January 2010 and 31 December 2021 who received TACE or TARE were

included. Patient and tumor characteristics, treatment details, and survival outcomes were obtained from cancer registries and electronic health records. Analyses were descriptive. Overall survival (OS) was assessed from the date of diagnosis to death or last follow-up. Results were summarized at the country level and pooled where appropriate for a pan-European cohort.

Results: A total of 2595 patients receiving TACE (n = 2546) or TARE (n = 49) were identified from Greece (n = 131), Sweden (n = 222), Italy (n = 122), Portugal (n = 51), Spain (n = 104), Switzerland (n = 58), and UK (n = 1907). Most patients were male (82%), and the average age was 66.3 years. For Child Pugh staging, 75% patients were in Class A and 24% in Class B. Across individual countries, alcohol (17.1%–76.0%), HBV (0.4%–36.2%), and HCV (0.3%–44.1%) were the most prevalent aetiologies. Esophageal varices were commonly reported (25%), and diabetes mellitus was the most common comorbidity at baseline (40%). At diagnosis, 24% of patients had 1–3 nodules <3 cm), while 32% had multiple nodules without extrahepatic spread. OS from initial diagnosis was 96% at 6 months, 85% at 1 year, 56% at 2 years, 33% at 3 years, 19% at 4 years, and 11% at 5 years, while median OS across individual countries ranged from 23 to 42 months.

Conclusion: TACE represents the predominant embolization procedure for HCC patients across Europe. The clinical outcomes after embolization procedures are suboptimal, with steep attrition in OS, aligning with results from previous studies. Many patients had metabolic comorbidities at baseline, which adds to treatment complexity. Overall, these findings reveal important unmet needs in current embolization-based care and support the development of more effective therapies, alongside more consistent real-world reporting to guide practice.

SAT-010-YI

Interim findings from the KIDS-LIVE study: metabolic phenotypes and burden of MASLD in Indian children and adolescents

Abirami Perumal[1], Abisheak Kandasamy[2], Vijaya Prakash Madesh[3], Sujatha Chinnappan[3], T Abiramalatha[3], S Sivanandam[4], S Jeevithan[4], Thooran Sibi[3], Aravindh Somasundram[3], Arulraj Ramakrishnan[3], Sundaresan Mohanraj[2]. *[1]Dr NGP Arts & Science College, KMCH Research Foundation, Coimbatore, India; [2]KMCH Research Foundation, Dr. NGP Arts and Science College, Coimbatore, India; [3]Kovai Medical Centre & Hospital, Coimbatore, India; [4]KMCH Institute of Health Sciences & Research, Coimbatore, India*

Email: mohanrajs.kmchrf@gmail.com

Background and aims: The epidemiological transition in India has led to an alarming rise in metabolic dysfunction with impact on children and adolescents as well. Metabolic dysfunction–associated steatotic liver disease (MASLD) phenotypes as a component of metabolic syndrome has not been well characterized in a community-based Indian pediatric setting. This present study aims to estimate the prevalence of MASLD and to characterize metabolically stratified MASLD phenotypes among children and adolescents in an ongoing community-based cohort.

Method: The KIDS-LIVE study is a community-based cohort evaluating hepatic and metabolic health among school-aged children (aged, 6–12 years) and adolescents (aged, 13–18 years). In this interim analysis, 980 participants (49.5% males; 50.5% females) were evaluated. Anthropometry, biochemical metabolic profiling, and liver steatosis assessment were performed. Participants were categorized into metabolically healthy and unhealthy phenotypes (MASLD criteria) across lean, overweight, and obese groups.

Results: The prevalence of overweight, obesity, and abdominal obesity were 10.0%, 4.9%, and 5.3%, respectively. Overall MASLD prevalence is 7.6%, with higher prevalence in males (9.6%) than females (5.6%, $p < 0.001$). Dyslipidemia (40.2%) and pre-diabetes (9.5%) were the most frequent metabolic dysfunction, predominantly affecting the 10–15-year age group. Interim analysis showed a higher MASLD prevalence among metabolically healthy obese (MHO) children (61.5%) compared to metabolically unhealthy obese (MUO) children (41.7%, $p < 0.001$). However, after multivariable adjustment, MHO was not independently associated with MASLD (OR = 0.05; $p = 0.804$), whereas MUO demonstrated a significantly elevated risk (OR = 11.3; 95% CI: 5.1–24.9; $p < 0.001$). Adolescents aged 13–18 years were the most affected age group, and gender-stratified analysis revealed a 100% prevalence of MASLD among MHO males.

Conclusion: Despite an apparently higher crude prevalence of MASLD among metabolically healthy obese children, adjusted analyses reveal that metabolically unhealthy obesity is the true independent driver of pediatric MASLD. These findings highlight the critical need for early community-based screening strategies and phenotype-specific preventive interventions to mitigate future cardiometabolic and hepatic disease burden in pediatric populations.

SAT-011

Can poor sleep signal fatty liver disease risk? Evidence from a rural population in North India

Tushar Prabhakar[1], Satya Vir Singh[1], Gahan Jois[1], Bronica Saini[2]. *[1]Amrita School of Medicine, Faridabad, India; [2]ESIC Model Hospital Rohini, Delhi, India*

Email: tusharprabhakar@yahoo.in

Background and aims: Metabolic-dysfunction associated fatty liver disease (MAFLD) is a major emerging liver disorder, including in lean populations. While metabolic risk factors are well-studied, rural populations remain underrepresented in such research, despite their high burden of unrecognized MAFLD. Poor sleep may influence hepatic steatosis via insulin resistance, inflammation, and circadian rhythm disruption. The study hypothesized that poor sleep quality and short duration are independently associated with high MAFLD risk, and that sleep parameters could serve as non-invasive, scalable risk markers.

Method: This community-based cross-sectional study recruited 550 adults (≥18 years) residing in catchment area of a primary health centre in North India. Sleep quality and duration were assessed using the Pittsburgh Sleep Quality Index (PSQI). Sleep duration was categorized as <6 h (short), 6–8 h (normal), >8 h (long). MAFLD risk was evaluated using a validated non-laboratory 15-point Self-Assessment Score. Descriptive statistics, chi-square, and multivariable logistic regression were used. Additional analyses included ROC curve for predictive validity of PSQI, test for trend across sleep duration categories, and interaction analysis with BMI and sex.

Results: Among 550 participants (mean age: 42.6 ± 13.5 years; 56.4% female), 38.2% had poor sleep quality and 31.6% had high MAFLD risk. High MAFLD risk was observed in 47.9% of poor sleepers vs 22.1% of good sleepers ($p < 0.001$). MAFLD risk was also elevated in short sleepers (44.6%) vs normal (28.5%) and long sleepers (23.8%) ($p = 0.002$; p-trend <0.01). On multivariable regression, poor sleep quality (AOR = 2.31; 95% CI: 1.58–3.38) and short sleep (AOR = 1.76; 95% CI: 1.15–2.69) were independently associated with high MAFLD risk. ROC analysis yielded an AUC of 0.71 (95% CI: 0.65–0.77) for PSQI in predicting high MAFLD risk. Significant interaction was noted between poor sleep and elevated BMI (p-interaction = 0.03), indicating amplified risk in overweight individuals.

Conclusion: Poor sleep quality and short sleep duration are strong, independent predictors of MAFLD risk, with moderate discriminatory ability on ROC analysis. These findings suggest that sleep assessment could serve as a low-cost, non-invasive surrogate marker for hepatic risk stratification in primary care. Integrating sleep-focused screening into MAFLD preventive strategies may improve early risk identification and intervention, especially in resource-constrained settings.

European Reference Network of Rare Hepatological Diseases (ERN RARE-LIVER), Clichy, France
Email: aurelie.plessier@aphp.fr

Background and aims: aims Rare liver diseases are associated with significant care challenges, including delayed diagnosis, inconsistent management, and limited patient support. Empowering patients has been shown to improve disease control and reduce distress. Structured patient pathways can help overcome these barriers by providing coordinated, evidence-based guidance throughout the patient's journey with the disease. Our initiative aimed to develop a harmonised framework for patient pathways tailored to rare liver diseases, through multidisciplinary collaboration within the European Reference Network RARELIVER.
Method: A multidisciplinary core group of hepatologists, specialist nurses, and patient representatives from several European countries conducted an iterative, co-creative development process. A structured literature review informed the evidence base, while patient and public involvement ensured integration of lived experience and psychosocial dimensions. Draft pathways underwent dual peer review by scientific experts and patient advocacy organisations to ensure accuracy, usability, and alignment with patient priorities.
Results: A generic patient pathway framework was created, organised around four key phases: pre-diagnosis, diagnosis, management, and long-term follow-up. Core components include early recognition and referral, standardised diagnostic protocols, multidisciplinary management, and patient-focused follow-up. The framework is adaptable across rare liver diseases and includes disease-specific subsections, educational resources, and "10 key questions" to promote shared decision-making. Finalised pathways for non-cirrhotic portal vein thrombosis, polycystic liver disease, and portosinusoidal vascular disorder are now publicly available through ERN RARELIVER.
Conclusion: This initiative represents the first pan-European effort to develop harmonised, multidisciplinary, and patient-centred pathways for rare liver diseases. By integrating scientific evidence, clinical expertise, and patient perspectives, these pathways provide a scalable model to improve diagnostic efficiency, care coordination, and patient outcomes, supporting sustainable and equitable rare disease care.

SAT-013-YI

Marginal structural models to evaluate the prognostic utility of steatotic liver disease subclasses in association with all-cause mortality

Carmela Rapino[1], Giada Sebastiani[2], Jessica Burnside[3], Cindy Wen[1,3], Alnoor Ramji[4], Mark Swain[5], Keyur Patel[6], Sahar Saeed[1]. *[1]Public Health Sciences Department, Queen's University - 62 Fifth Field Company Lane, Kingston, Ontario, Kingston, Canada; [2]Department of Medicine, McGill University - 2001 McGill College Avenue, Suite 1310, Montreal, QC, Canada, H3A 1G1, Montréal, Canada; [3]Queen's University, School of Medicine - 15 Arch Street, Kingston, Ontario, K7L 3L4, Kingston, Canada; [4]University of British Columbia, Vancouver, Canada; [5]Calgary Liver Unit, Cumming School of Medicine, University of Calgary - 3280 Hospital Drive NW, Calgary, Alberta, Canada, T2N 4Z6, Calgary, Canada; [6]Division of Gastroenterology and Hepatology, University Health Network - 190/200 Elizabeth Street, Toronto, Ontario, Canada, M5G 2C4, Toronto, Canada*
Email: 19cfr@queensu.ca

Background and aims: The subclassifications of Steatotic Liver Disease (SLD) were introduced to provide a clinically meaningful framework that considers metabolic dysfunction and alcohol consumption. However, little consideration is given to the disease's dynamic nature and evolving risk over time. We aimed to evaluate the prognostic utility of the SLD subtypes in association with all-cause mortality, accounting for both time-varying disease status and confounding.
Method: We analyzed data from the Canadian Longitudinal Study on Aging, a prospective cohort study following adults aged 45–85 years from 2012–2021. Participants were classified by SLD subtype at BL and FUP1 (+3 years) using the NAFLD Ridge Score's (NRS) dual cut-off to identify steatosis, laboratory measures and medication data to determine the presence of cardiometabolic factors, and self-reported data to determine weekly alcohol consumption. The NRS is a non-invasive test that was validated against the gold standard proton magnetic resonance spectroscopy, with an AUROC of 0.87, sensitivity of 92%, and specificity of 90%. Marginal Structural Cox proportional hazards models were used to estimate the association between increasing levels of alcohol consumption and mortality among those with and without steatosis, adjusting for age, sex, history of binge drinking at baseline and time-updated income, lifestyle, and cardiometabolic factors.
Results: A total of16,560 participants (52.1% female, median age 58 (IQR: 51–66)) were included. At baseline, MASLD was the most prevalent subtype at baseline (33.9%). In 3 years, 35.4% of people with ALD, 23.7% MetALD, and 22.6% MASLD transitioned to different SLD subtypes. Over a median of 7.8 years, 1041 deaths occurred. Females with MetALD and ALD had higher incident mortality rates than males with MetALD (7.05; 95% CI: 2.29–16.45 vs. 5.07; 95% CI: 2.53–9.08) and ALD (11.37; 95%CI: 0.29–63.33 vs. 5.60 95% CI: 1.15–16.36). Overall, steatosis increased the risk of death by almost 2 times, and after accounting for time-varying exposures and confounders**,** ALD had the highest risk of all-cause mortality (adjusted hazard ratio (aHR) 6.11; 95% CI: 1.76–21.19), while MetALD was not found to be statistically significant (aHR 1.07; 95% CI: 0.59–1.94).
Conclusion: SLD is a dynamic condition, where prognosis and evolving mortality risk cannot be captured by relying solely on static

baseline classifications. Incorporating more holistic and longitudinal risk assessments is key to improving clinical risk stratification.

SAT-014

Income and sex disparities in prognosis among individuals with MASLD: a survival analysis from the Canadian longitudinal study on aging

Carmela Rapino[1], Giada Sebastiani[2], Jessica Burnside[3], Cindy Wen[1,3], Alnoor Ramji[4], Mark Swain[5], Keyur Patel[6], Sahar Saeed[1]. *[1]Public Health Sciences Department, Queen's University - 62 Fifth Field Company Lane, Kingston, Ontario, Kingston, Canada; [2]Department of Medicine, McGill University - 2001 McGill College Avenue, Suite 1310, Montreal, QC, Canada, H3A 1G1, Montréal, Canada; [3]Queen's University, School of Medicine - 15 Arch Street, Kingston, Ontario, K7L 3L4, Kingston, Canada; [4]University of British Columbia, Vancouver, Canada; [5]Calgary Liver Unit, Cumming School of Medicine, University of Calgary - 3280 Hospital Drive NW, Calgary, Alberta, Canada, T2N 4Z6, Calgary, Canada; [6]Division of Gastroenterology and Hepatology, University Health Network - 190/200 Elizabeth Street, Toronto, Ontario, Canada, M5G 2C4, Toronto, Canada*
Email: 19cfr@queensu.ca

Background and aims: Income and sex are influential determinants of disease burden, but their influence on Metabolic Dysfunction-Associated Steatotic Liver Disease (MASLD) prognosis remains poorly understood. We aimed to evaluate the differences in prognosis by income and sex in association with all-cause mortality, among individuals with MASLD.

Method: We analyzed data from the Canadian Longitudinal Study on Aging, a prospective cohort of adults aged 45–85 years from 2012–2021. MASLD was defined as hepatic steatosis, as measured through the NAFLD ridge score (NRS), self-reported weekly alcohol use <140 g in females and <210 g in males, and the presence of at least one cardiometabolic factor identified through laboratory measures and medication data. The NRS is a non-invasive test that was validated against the gold standard proton magnetic resonance spectroscopy, with an AUROC of 0.87, sensitivity of 92%, and specificity of 90%. Incident mortality rates were calculated for each income quintile and by sex. Cox proportional hazards models were used to estimate the adjusted association between total household income quintiles and all-cause mortality, relative to the lowest income quintile, both overall and stratified by sex. Models were adjusted for age, physical activity, diet, and smoking.

Results: Between 2012 and 2015, 8,430 participants were classified with MASLD at (64.3% male, median age 63 (IQR:56–71)). Most individuals reported income between $50,000–$99,999.99 (32.3%; n = 2,797). Over a median follow-up of 7.7 years, 629 deaths occurred. Incident mortality rates were highest among participants in the lowest income quintile (<$20,000: 17.17 per 1,000 person-years) and decreased progressively with higher income. After adjustment, participants reporting incomes of $20,000–$49,999 and $50,000–$99,999 had significantly lower risk of all-cause mortality compared to <$20,000 (adjusted HR 0.68, 95% CI: 0.48–0.97; and 0.61, 95% CI: 0.42–0.88, respectively). Among females, higher income was consistently associated with lower mortality (e.g., $50,000–$99,999: aHR 0.47, 95% CI: 0.26–0.83; $100,000–$149,999: aHR 0.29, 95% CI: 0.10–0.85). Mortality risk among males decreased with increasing income, though were not statistical significance.

Conclusion: Lower income is associated with higher all-cause mortality among individuals with MASLD, with income disparities particularly more pronounced in females. These findings highlight the need to consider holistic risk assessments when approaching clinical management.

SAT-015-YI

Multidisciplinary assessment of unemployment risk factors in liver transplant recipients: final results of the RICReaTI project

Margherita Saracco[1], Alessandro Godono[2], Silvia Strona[1], Maria Vittoria Picciaiola[2], Massimo Maci[2], Astrid Cecilia Surra[2], Fllippo Angelino[2], Bruno Papaleo[3], Paolo Boffetta[4], Cinzia Frascheri[5], Marco Miniotti[6], Paolo Leombruni[6], Enrico Pira[2], Donatella Cocchis[7], Giorgio Maria Saracco[8], Renato Romagnoli[7], Silvia Martini[1]. *[1]SSD Insufficienza Epatica e Trapianto Epatico, AOU Città della Salute e della Scienza di Torino, Torino, Italy; [2]Department of Public Health and Pediatrics, University of Turin, Torino, Italy; [3]INAIL Research, Department of Occupational and Environmental Medicine, Epidemiology and Hygiene, Roma, Italy; [4]Department of Medical and Surgical Sciences, Alma Mater Studiorum University of Bologna, Bologna, Italy; [5]Labor law expert - Responsible for Cisl national Health and safety at work, Roma, Italy; [6]"Rita Levi Montalcini" Department of Neuroscience, University of Turin, Torino, Italy; [7]General Surgery 2U and Liver Transplant Center, AOU Città della Salute e della Scienza di Torino, Torino, Italy; [8]Gastroenterology Unit, AOU Città della Salute e della Scienza di Torino, University of Turin, Torino, Italy*
Email: margherita.saracco@gmail.com

Background and aims: Reintegration to work is crucial for transplanted patients (pts), and especially in liver transplant (LT) it can be demanding due to multiple social factors. The RICReaTI project aimed to evaluate how liver disease and LT impacted work ability and perceived disability, analyzing correlations between clinical, social, and employment status before and after LT, to elaborate guidelines for healthcare providers.

Method: We retrospectively enrolled all LT pts transplanted from 2018 to 2023 in our high-volume LT Centre, aged 18 to 68 years (y), not yet retired before LT. Participants completed WHODAS 2.0 (World Health Organization Disability Assessment Schedule) and Work Ability Index (WAI) questionnaires, supplemented with clinical and occupational data. From 12/2023, pts were prospectively included, interviewed before LT and after 6 months. Pts were enrolled until 12/2024, follow up closed in 06/2025.

Results: 1123 LT were performed in the study period. 329 of 695 eligible pts (47%) accepted to be interviewed (48 prospectively). 65% were male, average age 52 y (41% >60 y). 83% had cirrhosis (41% viral, 15% alcoholic). 90% were Italian residents, 55% had an elementary/middle-school education, 56% history of alcohol/drugs use, 56% active/previous smoke, 74% was employed before LT. 66% identified the partner as caregiver, 4% a caregiver outside the family. After LT, 40% were unemployed (67% already unemployed before LT) and 55% reported that health issues affected their job search. Only 4 unemployed pts before LT found a job after LT. Unemployment was significantly associated with female sex, age >60 y, other caregiver, lower education and lower low self-perception of work capacity (WAI) (all $p < 0.05$). Lower WAI was independently associated with psychiatric disease, age >60 y, lower MELD at LT, and again lower education (all $p < 0.05$). Worse disability scores (WHODAS) correlated with alcohol abuse, non-Italian nationality and again female sex (all $p < 0.05$). In prospectively included patients, both WHODAS e WAI scores significantly improved between pre-LT and post-LT (all $p < 0.05$).

Conclusion: Return to work after LT remains suboptimal. Employment status and perceived work ability are influenced by a complex interplay of clinical, demographic, and socioeconomic factors. The RICReaTI study group is developing with the National Department of Occupational and Environmental Medicine, Epidemiology and Hygiene (INAIL) a multidisciplinary pathway as part of standard post-transplant care.

SAT-019

Continuity and safety in cross-sectoral care in hepatology: a prospective study of an interprofessional training ward

Schlosser-Hupf Sophie[1], Jonas Dörr[1], Stephan Schmid[1], Claudia Kunst[1], Martina Müller-Schilling[1]. [1]*Department of Internal Medicine I, University Hospital Regensburg, Regensburg, Germany*
Email: sophie.schlosser@ukr.de

Background and aims: Transitions from hospital to community care, particularly in hepatology-focused wards, are well-established as high-risk periods for communication failures, medication errors, and discontinuity of care, which can lead to adverse events and increased readmissions. Interprofessional collaboration during inpatient care has been shown to improve patient satisfaction and perceived quality, but its direct impact on post-discharge outcomes remains insufficiently studied, especially in hepatology settings. This study investigated whether an interprofessional training ward could improve quality of care, medication safety, and cross-sectoral collaboration following hospital discharge compared with conventional wards (CW).
Method: From May to October 2024, a prospective single-centre observational study at University Hospital Regensburg compared patients treated on interprofessional and conventional wards with a hepatology focus, using post-discharge interviews and physician surveys to assess patient-perceived quality of care, discharge processes, cross-sectoral collaboration, and medication management.
Results: Of 328 screened patients, 228 consented and 131 (57.5%) completed follow-up (A-STAR n = 33; conventional wards n = 98). Baseline characteristics were comparable. Forty follow-up physicians responded (30.5%). Patient-reported post-discharge quality (U = 1396.5; p = 0.088) and continuity of care (U = 1530; p = 0.45) did not differ between groups, nor did understanding of medical history (93.9%; $\chi^2(1) = 0$; p = 0.99). Provider-rated cross-sectoral collaboration was similar (U = 126.5; p = 0.49), and all discharge summaries were complete. Health improvement was comparable ($\chi^2(1) = 1.032$; p = 0.31), while new symptoms occurred less frequently in A-STAR patients (3.0% vs 22.5%; $\chi^2(1) = 6.431$; p = 0.011). Unintentional weight loss showed no significant difference ($\chi^2(1) = 3.397$; p = 0.065). No A-STAR patients required post-discharge medication changes, compared with 12.6% on conventional wards (p = 0.036). Readmission rates and follow-up scheduling were similar.
Conclusion: In conclusion, in a hepatology setting, interprofessional care on the A-STAR ward achieved outcomes comparable to conventional wards, with fewer new symptoms and improved medication safety, supporting its value for patient care and training.

SAT-020

Patient characteristics and functional impairment in MASLD: a remote prospective cross-sectional real-world study in Germany

Anja Schulz-Kuhnt[1], Lars Herrmann[1], Ramona Ziegler[1], Hubert Steindl[1], Christoph Abels[1]. [1]*Bionorica SE, Neumarkt, Germany*
Email: christoph.abels@bionorica.de

Background and aims: The estimated global prevalence of MASLD is > 30%. Nevertheless, only <5% of patients with MASLD are aware of it, as particularly in early stages of MASLD, symptoms are commonly non-liver-specific and subtle, likely affecting quality of life, such as fatigue. Therefore, the functional impairment associated with cardiometabolic dysfunctions/MASLD was assessed in a real-world study using two validated patient-reported outcome measures (PROMs), the short-form-health-survey-12 (SF-12) and functional assessment of chronic illness therapy-fatigue (FACIT-F).
Method: The remote prospective cross-sectional real-world study was carried out in 06–07/2024 and targeted subjects (at risk of) having MASLD. German-speaking participants were recruited via online advertisements targeted at overweight subjects aged 35–70 years (based on the limited awareness of MASLD) and forwarded to a proprietary questionnaire covering general information on e.g. lifestyle and medical history, with the subsequent option to answer FACIT-F and SF-12.
Results: 6,788 participants started and 4,991 completed the online survey (86% 35–69 years of age, 84% female) within four weeks. Almost all participants reported at least one cardiometabolic risk factor for MASLD, with 94% of participants (4,698/4,991) being at least overweight (BMI ≥ 25 kg/m^2), 31% (1,568/4,991) having elevated blood lipid levels and 49% (2,464/4,991) suffering from cardiovascular disease. 19% of participants (967/4,991) reported to be already diagnosed with MASLD. The assessment of fatigue via FACIT-F showed a significant decrease in the total FACIT-F score (indicating increased fatigue) in participants with diagnosed MASLD (mean ± SD: 25.65 ± 11.29, N = 522) compared with overweight participants without self-reported diagnosed liver disease (28.78 ± 10.94, N = 1,540, p < 0.001), with both scores being markedly lower than in the general German population (43.5 ± 8.3; Montana *et al.*, *Value in Health* 2018). Additionally, results suggest a positive correlation between liver disease severity and fatigue as the lowest FACIT-F scores (22.65 ± 11.57, N = 20) were observed in participants with end stages of MASLD (cirrhosis/hepatocellular carcinoma). Results for SF-12 indicate a similar trend for health-related quality of life.
Conclusion: Real-world data indicate a functional impairment already in early MASLD stages without liver-specific symptoms that worsens with disease progression and thus demands early intervention.

SAT-021

Transparent and dynamic network-based risk assessment for development of hepatic encephalopathy

Yuxi Shi[1], Zixing Wang, Huiying Rao[1], Xin Wen[1], Tianyi Xue[1], Yanpei Mai[1], Suzhen Jiang[1], Shuo Yang[1], Qinshuo Wang[1], YanHui Yang[1], Linlin Cao[1]. [1]*Peking University People's Hospital, Beijing, China*
Email: wangzixing@pkuph.edu.cn

Background and aims: Hepatic encephalopathy (HE) is a common and prognostically severe neurological complication in cirrhosis. Early identification of high-risk patients remains a major clinical challenge. The multifactorial nature of HE suggests a need for more integrated assessment approaches that can capture its complex pathophysiology beyond the scope of single biomarkers or conventional risk scores.
Method: We included 3,487 patients with multi-etiology cirrhosis, divided into training (n = 2,789) and validation (n = 698) sets. A Bayesian network-based risk assessment model was constructed by integrating expert knowledge and data-driven mining. The model incorporates complication sequences (e.g., ascites, gastroesophageal varices, peritonitis) and nine core laboratory indicators selected from 980 candidates (including ammonia, INR, RDW-SD, fibrinogen, triglycerides, MCH, neutrophil count, sodium, and total CO_2), and is compatible with partially missing data.
Results: During a maximum follow-up of 14 years, 398 patients developed overt HE. HE occupied a central hub within the complication network. Its onset was significantly associated with ascites (adjusted relative risk [aRR] = 4.8), gastroesophageal varices (aRR = 3.6), peritonitis (aRR = 2.2), hepatorenal syndrome (aRR = 2.1), variceal hemorrhage (aRR = 1.9), and hepatocellular carcinoma (aRR = 1.5); all p < 0.05. The network model demonstrated superior predictive performance in the validation set: baseline AUROC was 0.926 (95% CI: 0.882–0.962), improving to 0.962 (0.933–0.984) in longitudinal follow-up. This significantly outperformed MELD (AUROC 0.670) and BABS scores (0.745) (both p < 0.001). The model maintained robust performance across demographic subgroups and supported both a simplified key-node assessment (age ≥75, hyponatremia, hyperammonemia, elevated INR, elevated RDW-SD) and smart device-integrated dynamic updating for complication warning.

Conclusion: This dynamic network model integrates temporal complication sequences and multi-system biomarkers to provide transparent, precise, and dynamic HE risk assessment. It holds strong potential for clinical translation in patient risk stratification, individualized screening optimization, and complication prevention, offering a novel strategy for holistic cirrhosis management.

SAT-022

Trends in mortality due to liver neoplasms in Portugal (2013–2022): a decade of rising challenges

Mario Jorge Silva[1,2], Pedro Lages Martins[1,2], Filipe Calinas[1], Paulo Nogueira[3]. [1]*Unidade Local de Saúde de São José – Serviço de Gastrenterologia, Lisboa, Portugal;* [2]*NOVA Medical School, Lisboa, Portugal;* [3]*Instituto de Saúde Ambiental, Laboratório Associado TERRA, Faculdade de Medicina, Universidade de Lisboa, Lisboa, Portugal*
Email: mariojorgesilva01@gmail.com

Background and aims: The burden of liver neoplasms may have been changing recently, given the shifts in predominant etiologies of chronic liver disease (e.g. decrease in hepatitis C-related liver disease, increase in metabolic dysfunction-associated steatotic liver disease). Mortality due to liver tumors over the past decade in Portugal is largely unknown. We aim to analyze the mortality due to liver neoplasms in Portugal from 2013 to 2022, focusing on temporal trends, tumor subtypes and regional distributions.
Method: Statistics Portugal (*Instituto Nacional de Estatística*) provided data on annual mortality from liver neoplasms (International Classification of Diseases-10: C22), including specific tumor subtypes: hepatocellular carcinoma (C22.0), intrahepatic bile duct carcinoma (C22.1) and malignant neoplasm of the liver not otherwise specified (C22.8 + C22.9). These data derive from coding of death certificates. Mortality rates were calculated per 100,000 inhabitants. Trends were analyzed with R software version 4.4.1 (R Foundation for Statistical Computing, Vienna, Austria), using linear regression (LR) and nonparametric Mann-Kendall (M-K) test to identify significant temporal patterns. Differences were considered statistically significant when $p < 0.05$ (two-sided). Specific analyses were performed for tumor subtypes and for geographic regions.
Results: Between 2013 and 2022, total deaths from liver neoplasms increased by 20% ($p = 0.0005$ in LR, $p = 0.0024$ in M-K): from 1,037 deaths in 2013 to 1,248 deaths in 2022. Regional disparities were observed: in 2022, the highest mortality rates were observed in the Madeira region (15.4/100,000 inhabitants) and the lowest in the Algarve (9.9/100,000 inhabitants). During the 10-year period, there was a striking 42% rise in deaths due to intrahepatic bile duct carcinoma ($p = 0.00002$ in LR, $p = 0.00068$ in M-K). Considering mortality due to all liver neoplasms, the proportion of deaths due to intrahepatic biliary neoplasms increased from 32.9% (341/1037) in 2013 to 38.9% (485/1248) in 2022. Deaths due to hepatocellular carcinoma increased by 21% ($p = 0.0168$ in LR, $p = 0.0318$ in M-K) between 2013 ($n = 496$) and 2022 ($n = 602$). Mortality due to liver neoplasms not otherwise specified remained stable ($p = 0.433$ in LR, $p = 0.928$ in M-K) during the 10-year period.
Conclusion: Between 2013 and 2022, there was a significant increase in mortality due to liver neoplasms in Portugal: including both hepatocellular carcinoma and, particularly, intrahepatic bile duct carcinoma.

SAT-023

From guidelines to practice : Expert advisory board insights on nutritional intervention in patients with liver cirrhosis in India

Nagaraja Padaki[1], KR Vinayakumar[2], Jyoti Mohapatra[3], Akash Roy[4], Abhishek Banerjee[5], Sourabh Sonawale[6], Nandan Joshi[6]. [1]*Asian Institute of Gastroenterology Private Limited (Banjara Hills) Gaffar Khan Colony, Telangana 500045, Hyderabad, India;* [2]*Ananthapuri Hospitals and Research Institute in Trivandrum, Thiruvananthapuram, India;* [3]*Peerless Hospital, Kolkata, Kolkata, India;* [4]*Apollo Gleneagles Hospitals Kolkata, Kolkata, India;* [5]*Manipal Hospitals Kolkata, Kolkata, India;* [6]*Dr. Reddy's and Nestle Health Science Limited, Hyderabad, India*
Email: nandanarunjoshi@drreddysnestle.com

Background and aims: Malnutrition and sarcopenia are frequent yet under-recognised complications of liver cirrhosis and are associated with infections, hepatic encephalopathy (HE), reduced quality of life, and increased mortality. Globally, malnutrition affects ~ 20–30% of patients with compensated cirrhosis and over 50–60% with decompensated disease, while sarcopenia is reported in 30–70% of cases. Indian studies indicate a high burden, with malnutrition and sarcopenia affecting approximately 47–84% of patients. European Association for the Study of the Liver (EASL) and European Society for Clinical Nutrition and Metabolism (ESPEN) guidelines recommend early nutritional screening, adequate energy intake, protein intake of at least 1.2–1.5 g/kg/day, and avoidance of unnecessary protein restriction, including in HE. However, real-world implementation remains inconsistent. This initiative aimed to capture real-world insights into nutritional assessment practices in cirrhosis and the role of branched-chain amino acids in HE.
Method: This was a cross-sectional, descriptive analysis using live polling and expert discussion from 5 advisory board meetings conducted over 3 months. A total of 68 gastroenterologists across India participated. Discussions focused on patients with established cirrhosis, including compensated and decompensated stages and those with HE.
Results: Routine nutritional assessment was inconsistent: 50 percent assessed nutrition every three months, 10% every six months, while 40% assessed only after clinical deterioration. Nutritional supplementation was mainly guided by disease severity, with 70% relying on Child - Pugh class. Limited awareness, restricted access to dietitians, and patient non-compliance were reported as barriers by approximately 80% of participants. High-protein oral nutritional supplements were prescribed in up to 75% of patients. Experts reported better tolerance with high-quality protein sources such as whey protein isolate due to low fat content and negligible lactose. Protein intolerance was uncommon; when present, branched-chain amino acids were preferentially used for HE, with approximately 80% reporting routine use.
Conclusion: A clear gap exists between guideline recommendations and routine nutritional assessment in liver cirrhosis, while nutrition prescription practices and branched-chain amino acid use in HE appear largely aligned with current guidance. Strengthening structured nutritional pathways is essential to optimise nutritional care.

SAT-024-YI

Contacts to general practice by patients with liver cirrhosis: a Danish nationwide cohort study

Marie Storgaard[1,2,3], Bo Christensen[3,4], Morten Daniel Jensen[2], Joe West[1,5,6,7], Peter Jepsen[1,2,3,5]. [1]*Department of clinical medicine, Aarhus university, Aarhus, Denmark;* [2]*Department of hepatology and gastroenterology, Aarhus university hospital, Aarhus, Denmark;* [3]*Department of clinical epidemiology, Aarhus university hospital, Aarhus, Denmark;* [4]*Department of public health, Research unit of general medicine, Aarhus, Denmark;* [5]*Lifespan and population health, School of medicine, University of Nottingham, Nottingham, United Kingdom;* [6]*NIHR Nottingham biomedical research centre (BRC), Nottingham university hospitals NHS trust and the University of Nottingham, Nottingham, United Kingdom;* [7]*Clinical practice research datalink, Medicines and healthcare products regulatory agency, Nottingham, United Kingdom*
Email: marieaa@clin.au.dk

Background and aims: General practitioners (GPs) can play a crucial role in preventive care and management of comorbidities in patients with cirrhosis; however, the pattern of GP contacts in this population remains poorly characterized. We aimed to describe the number, rates, and trends of GP consultations among patients with cirrhosis.

Method: In a nationwide registry-based cohort study, we included all Danish patients with an incident hospital-based diagnosis of cirrhosis in 2015–2023, along with 5:1 sex-, birth year-, and age-matched comparators from the general population. We assessed rates and predictors of GP consultations and described characteristics and survival among patients who experienced going one full year without a GP consultation.
Results: We included 17,263 patients with cirrhosis and 86,315 comparators (median age 64 years; 64% male). Patients with cirrhosis had higher annual GP consultation rates than their comparators, both for in-person consultations (6.2 [95% CI: 6.2–6.2] vs 4.1 [4.1–4.1]) and telephone consultations (4.7 [4.6–4.7] vs 2.0 [2.0–2.0]). GP consultation rates declined over calendar time in both cohorts. This decline was most pronounced among patients with cirrhosis (in-person: HR 0.95 [0.94–0.95] vs 0.97 [0.97–0.97] per year; telephone: HR 0.91 [0.90–0.92] vs 0.95 [0.94–0.95] per year). Consultation rates were highest in the first year after cirrhosis diagnosis and decreased afterward. Higher consultation rates were associated with decompensated cirrhosis (decompensated vs compensated: HR 1.08 [1.07–1.10]), female sex (female vs male: HR 1.16 [1.08–1.15]), and living in rural municipalities (rural municipality vs capital city municipality: HR 1.29 [1.23–1.35]). A total of 3,161 patients went an entire year without a GP in-person consultation. On the date, when they had not seen their GP for a full year, these patients had less severe cirrhosis than those who had seen their GP within the previous year, and they had a lower mortality (HR 0.80 [0.74–0.87]).
Conclusion: Danish patients with cirrhosis had substantially higher GP consultation rates than the general population, and these rates were highest among female and decompensated patients. Most patients saw their GP every year, and those who experienced going one year without a GP consultation represented a healthier subgroup with a favorable prognosis. This high level of GP involvement highlights the potential to increase collaboration between GPs and hepatologists to improve the overall care for patients with cirrhosis.

SAT-025
Sociodemographic associations between increasing alcohol sales and new hospitalizations for alcohol-related cirrhosis in Alberta, Canada

Liam Swain[1], Jenny Godley[2], Juan G Abraldes[3], Abdel Aziz Shaheen[4].
[1]*University of Calgary Cumming School of Medicine, Calgary, Canada;* [2]*University of Calgary Department of Anthropology and Archaeology, Calgary, Canada;* [3]*Liver Unit, Department of Medicine, Division of Gastroenterology, University of Alberta, Edmonton, Canada;* [4]*Department of Community Health Sciences, University of Calgary, Department of Medicine, Division of Gastroenterology and Hepatology, Cumming School of Medicine, University of Calgary, Calgary, Canada*
Email: aashahee@ucalgary.ca

Background and aims: Few studies have examined the temporal association between alcohol sales and alcohol-related cirrhosis (AC) hospitalization rates. We examined how an elevation in alcohol sales impacts subsequent AC hospitalizations, in Alberta.
Method: We obtained monthly Alberta alcohol sales (all beer/wine/liquor stores) from 2019 to 22. Using a validated coding algorithm (PPV > 90%), we identified all monthly AC hospitalizations in Alberta from the Discharge Abstract Database. Using the 2021 Census, we calculated monthly alcohol sales per capita (ASPC) and AC hospitalization rates/100,000 population. Hospitalization rates were stratified by sex, age (≥ vs <55 years), and dissemination area median after tax household income (> vs ≤$67,430). We stratified our analysis by Alberta region, including Calgary, Edmonton, and all regions outside of Calgary/Edmonton (i.e., rural). We used a Newey-West 1–12 month lagged linear regression model with monthly AC hospitalization rates/100,000 as the outcome and monthly ASPC as the exposure. The cumulative linear regression coefficients from 1–6 vs 7–12 months and 95% confidence intervals (CI) are presented.
Results: From 2019–22, there were 9553 AC admissions. In Alberta, a $1 increase in ASPC led to a 0.25 (CI 0.25–0.40) unit increase in AC hospitalization rates/100,000 1-6 months later; ≈8 AC hospitalizations. In Alberta, AC hospitalization rates increased 1–6 months after a $1 ASPC increase only for those living in lower income areas (0.51, CI 0.31–0.70); ≈15 AC hospitalizations. In Edmonton, females had a 0.13 unit increase in AC hospitalization rates 7–12 months after a $1 ASPC increase; ≈1 AC admission. In rural Alberta, a $1 ASPC increase led to ≈ 1 AC hospitalization for males 1–6 months later (0.22, CI 0.07–0.37), while rural females had an increase in AC hospitalization rates 1–6 (0.09, CI 0.04–0.14) and 7–12 (0.08, CI 0.02–0.13) months later; ≈1 AC hospitalization. In rural regions, a $1 increase in ASPC led to an increase in AC hospitalization rates 1–6 and 7–12 months after for younger individuals (0.17, CI 0.09–0.25; 0.12, CI 0.05–0.20), but only 1–6 months after for older individuals (0.13, CI 0.06–0.20).
Conclusion: In Alberta, monthly increases in alcohol sales predict new AC hospitalizations, but only for those living in lower income areas. The lagged effect of alcohol sales on AC hospitalizations was primarily seen in rural areas and had the largest impact on females and younger populations.

SAT-026
Sociodemographic associations between increasing alcohol sales and new hospitalizations for alcohol-related hepatitis in Alberta, Canada

Liam Swain[1], Jenny Godley[2], Juan G Abraldes[3], Abdel Aziz Shaheen[4].
[1]*University of Calgary Cumming School of Medicine, Calgary, Canada;* [2]*University of Calgary Department of Anthropology and Archaeology, Calgary, Canada;* [3]*Liver Unit, Department of Medicine, Division of Gastroenterology, University of Alberta, Edmonton, Canada;* [4]*Department of Community Health Sciences, University of Calgary, Department of Medicine, Division of Gastroenterology and Hepatology, Cumming School of Medicine, University of Calgary, Calgary, Canada*
Email: aashahee@ucalgary.ca

Background and aims: Few studies have examined the temporal association between alcohol sales and alcohol-related hepatitis (AH) hospitalization rates. We examined sociodemographic drivers that link increasing alcohol sales and subsequent AH hospitalizations, in Alberta.
Method: We obtained Statistics Canada monthly Alberta alcohol sales (all beer/wine/liquor stores) from 2019 to 22. Monthly AH hospitalizations in Alberta were identified using a validated coding algorithm (PPV > 90%) from the Discharge Abstract Database. Using the 2021 Census, we calculated monthly alcohol sales per capita (ASPC) and AH hospitalization rates/100,000 population. Hospitalization rates were stratified by sex, age (≥ vs <45 years), and dissemination area median after tax household income (> vs ≤$71,168). We stratified our analysis by Alberta region, including Calgary, Edmonton, and all regions outside of Calgary/Edmonton (i.e., classified as rural). We used a Newey-West 1–12 month lagged linear regression model with monthly AH hospitalization rates/100,000 as the outcome and monthly ASPC as the exposure. The cumulative linear regression coefficients from 1 to 6 vs 7–12 months and 95% confidence intervals (CI) are presented.
Results: From 2019–22 in Alberta, there were 1081 AH admissions. In Alberta, a $1 increase in ASPC led to a 0.06 (CI 0.03–0.09) unit increase in AH hospitalization rates/100,000 1-6 months later (Table 1); ≈ 2 AH hospitalizations. In Alberta, AH hospitalization rates/100,000 increased 1–6 months after a $1 ASPC increase only for those living in lower compared to higher income areas (0.15, CI 0.10–0.19); ≈2 AH hospitalizations. In rural Alberta, a $1 ASPC increase led to a 0.03 (CI 0.01–0.05) and a 0.02 (CI 0.002–0.05) unit increase in female AH hospitalization rates 1–6 and 7–12 months later, respectively. In contrast, rural males had an increase in AH hospitalization rates only 1–6 months after a $1 ASPC increase (0.05, CI 0.03–0.07). In rural regions, only younger individuals had an

increase in AH hospitalization rates/100,000 1–6 months after, after a $1 ASPC increase (0.08. CI 0.06–0.11).
Conclusion: In Alberta, AH hospitalizations increased 1–6 months after a monthly elevation in alcohol sales. The relationship between increasing alcohol sales and new AH hospitalizations was only observed in lower income and rural areas. In rural Alberta, increasing alcohol sales had a large impact on AH hospitalizations for younger and female populations.

SAT-027
Temporal and seasonal trends in alcohol sales and alcohol-related liver disease hospitalizations in Alberta, Canada
Liam Swain[1], Jenny Godley[2], Juan G Abraldes[3], Abdel Aziz Shaheen[4]. [1]*University of Calgary Cumming School of Medicine, Calgary, Canada;* [2]*University of Calgary Department of Anthropology and Archaeology, Calgary, Canada;* [3]*Liver Unit, Department of Medicine, Division of Gastroenterology, University of Alberta, Edmonton, Canada;* [4]*Department of Community Health Sciences, University of Calgary, Department of Medicine, Division of Gastroenterology and Hepatology, Cumming School of Medicine, University of Calgary, Calgary, Canada*
Email: aashahee@ucalgary.ca

Background and aims: Few studies have examined the seasonality and temporal trends of alcohol sales in North America and its relation to hospitalizations for alcohol-related liver disease (ALD). We examined temporal trends and the seasonality of alcohol sales per capita in Alberta, Canada, from 2012–22. We compared trends in alcohol sales to ALD hospitalizations.
Method: We obtained monthly alcohol sales (all beer/wine/liquor stores) in Alberta, from 2012 to 22. Using validated algorithms (PPV > 90%) we identified all alcohol-related cirrhosis/hepatitis hospitalizations (age ≥ 20 yr) in Alberta from the Discharge Abstract Database between 2012–22. We used 2016/21 Census data to calculate monthly alcohol sales per capita and annual age-adjusted ALD hospitalization rates/100,000 population. Between 2019–22, we stratified monthly alcohol sales per capita within 3 Alberta regions: the 2 major urban areas Calgary and Edmonton, and the rest of Alberta. We used Kruskal-Wallis tests to compare regional median monthly alcohol sales. Trends in alcohol sales per capita and ALD hospitalizations/100,000 were assessed using joinpoint analysis, annual percent change (APC), and average annual percent change (AAPC).
Results: From 2012–22, Alberta had $29.89 billion in alcohol sales. From 2019–22, the median monthly alcohol sales per capita was higher for regions outside of Calgary and Edmonton ($86.52), vs Calgary ($65.65, $p < 0.001$) and Edmonton ($80.79, $p = 0.017$). Edmonton had higher alcohol sales per capita vs Calgary ($p < 0.001$). From 2012–22, total Alberta alcohol sales increased by 2.25%/year (AAPC 95% CI 1.82–2.65). Total Alberta alcohol sales per capita significantly increased from 2012–17 by 5.25%/year, decreased by −8.13%/year from 2017–18, increased by 9.30%/year from 2018–20, and decreased by −3.09%/year from 2020–22. The alcohol sale APC and inflection points paralleled our observed ALD trends, with inflection points occurring in 2016/19/21. Our regionally stratified analysis of monthly alcohol sales per capita from 2019–22 identified annual bimodal peaks in alcohol sales per capita occurring in December and June-July for all regions.
Conclusion: Between 2012–22, alcohol sales per capita increased in Alberta, with the highest sales observed in more rural regions. Trends in ALD hospitalization rates and alcohol sales paralleled each other in Alberta. We observed a bimodal seasonality in alcohol sales across Alberta with the highest sales occurring in December and the early summer months.

SAT-028
Geographic variation in primary biliary cholangitis across Alberta: Validated incidence and prevalence estimates with Joinpoint trends
Bryce Tkachuk[1], Liam Swain[1], Aldo J Montano-Loza[2], Abdel-Aziz Shaheen[1]. [1]*University of Calgary, Calgary, Canada;* [2]*University of Alberta, Edmonton, Canada*
Email: az.shaheen@ucalgary.ca

Background and aims: Rates of primary biliary cholangitis (PBC) in Alberta are among the highest in North America; provincially validated estimates by sex, age, and health zone are needed to guide care planning. We estimated trends and zonal differences in PBC prevalence and incidence by sex, age group, and health zone (Calgary, Edmonton, Rest-of-Alberta).
Method: We created a provincial adult (≥18 y) PBC cohort using linked inpatient, ambulatory, physician-claims, and registry data (prevalence: 2002–2021; incidence: 2004–2021 with a 2-year washout). Within 3,250 potential PBC cases, chart review confirmed true PBC. Rates were age-standardized to the 2021 Canadian population. Incidence rate ratios (IRRs) were estimated using negative binomial models with population offsets; trends used Joinpoint to derive Annual Percentage Change (APC) / Average Annual Percentage Change (AAPC) (95% CI).
Results: We confirmed 1,470 incident cases (total confirmed PBC = 1,845; median age 58 y; 88.2% female). In 2021, age-adjusted prevalence was 84.5 per 100,000 in females and 10.9 per 100,000 in males; mean annual incidence was 3.2 per 100,000. Prevalence increased 2002–2021 (Alberta AAPC 11.8%, 95% CI 11.4–12.4) with zonal variation ($p < 0.001$): Calgary 10.0% (9.5–10.8), Edmonton 12.4% (11.8–13.9), Rest-of-Alberta 13.4% (12.9–14.0). Incidence rose 2004–2017 (APC 6.4%, 95% CI 4.2–11.1; $p < 0.001$) then declined 2017–2021 (APC −9.8%, 95% CI −35.5 to −2.0; $p = 0.024$); Edmonton declined 2016–2021 (APC −13.7%, 95% CI −37.4 to −4.6; $p = 0.007$); Calgary's 2016–2021 decline was non-significant, and Rest-of-Alberta trended down in 2020–2021. In adjusted models (ref = Calgary), Rest-of-Alberta had higher incidence (IRR 1.19, 95% CI 1.02–1.38; $p = 0.02$) while Edmonton was not different (IRR 1.11, 0.95–1.28; $p = 0.18$). Females had markedly higher incidence than males (IRR 7.00, 95% CI 5.96–8.23) with strong age gradients vs 20–34 y: 35–49 y IRR 7.56, 50–64 y IRR 18.72, and ≥ 65 y IRR 18.18 (all $p < 0.001$).
Conclusion: PBC prevalence is high and rising in Alberta with persistent health zone differences, while incidence has stabilized/declined since 2017. Findings support zone-specific diagnostic strategies and resource allocation, particularly for older women and higher-burden regions. These validated, chart-confirmed estimates establish a provincial baseline for zone-level service planning (diagnostic testing, UDCA monitoring, hepatology access), and for evaluating future policies or pathway interventions across Alberta populations.

SAT-029
Socio-economic deprivation is overrepresented in Australian cirrhosis patients seeking acute hospital-based care, suggesting disparities in utilisation of structured outpatient services
Tess Bittermann[1], Elizabeth Goode[1,2], Gunter Hartel[1], Vikas Bhasker[1], Danielle Gallegos[3], Elizabeth E. Powell[1], Patricia C. Valery[1]. [1]*QIMR Berghofer, Herston, Australia;* [2]*Royal Brisbane and Women's Hospital, Herston, Australia;* [3]*Queensland Universtity of Technology, Brisbane, Australia*
Email: patricia.valery@qimrb.edu.au

Background and aims: Socio-economic deprivation (SED) influences health outcomes, yet its impact on cirrhosis remains underexplored. Using Z-codes from hospital records of cirrhosis patients, we examined mortality, healthcare use, and costs by SED.
Method: Population-based retrospective cohort analysis of all adults hospitalised with cirrhosis in Queensland, Australia (2007–2022) included 2,160 patients with SED (ICD code Z59) vs 20,228 without.

They were followed from the first hospitalisation or emergency presentation with cirrhosis until death or 31-Dec-2022, whichever came first. In multivariable analysis adjusting for sociodemographic and clinical factors, we examined cause-specific mortality (Fine and Gray models), rate of hospitalizations and emergency presentations (Poisson regression), and ratio of costs of hospitalizations (Poisson regression) by SED. The costs were inflated to Jun-2025.

Results: SED was over sixfold more common among cirrhosis admissions (9.6% vs 1.5%; p < 0.001) compared with all adult admissions in Queensland during 2007–2022. Patients with cirrhosis facing SED were younger at first admission (53.0 vs 62.2 years; p < 0.001), and male (69.0% vs 65.7%: p < 0.001) and First Nations patients (20.5% vs 7.2%) were overrepresented vs patients without SED. During a median follow-up of 6.9 years (IQR 3.5–11.2), 12,309 patients died (50.3% from liver disease). Compared to patients without SED, patients facing SED had increased risk of mortality due to external causes (e.g. accident, self-harm – sHR = 1.99, 95%CI 1.51–2.63; p < 0.001) and cardiovascular disease (adj-sHR = 1.52, 95%CI 1.24–1.86; p < 0.001), were less likely to die of liver disease (sHR = 0.70, 95%CI 0.64–0.77; p < 0.001) and extrahepatic cancer (adj-sHR = 0.70, 95%CI 0.54–0.90; p < 0.001), had more emergency presentations for cirrhosis (adjusted incidence rate ratio (adj-IRR) = 1.29, 95%CI 1.16–1.45; p < 0.001), and fewer planned same-day cirrhosis admissions (adj-IRR = 0.69, 95%CI 0.57–0.83; p < 0.001). Over 10.5 years, 19,820 cirrhosis admissions cost A$1.14 billion (Jul-2012 to Dec-2022). Costs were 1.69-fold higher for patients with SED (95%CI 1.58–1.80; p < 0.001).

Conclusion: Cirrhosis places a heavy burden on the community, particularly among those facing SED. Fewer planned admissions and more emergency presentations among deprived patients points to barriers in structured follow-up care. Increased non-liver mortality in patients with SED indicates a need for tailored prevention approaches.

SAT-030

Improving patient knowledge — A feasible target to enhance motivation for lifestyle change in patients with MASLD in Australia

Patricia C. Valery[1], Elizabeth E. Powell[1], Barbara Leggett[2], Karen Simmons[3], Katie McGuire[3], Vikas Bhasker[1], Melanie Aikebuse[1], Georgina Peacock[2], Richard Skoien[2], James O'Beirne[3]. *[1]QIMR Berghofer, Herston, Australia; [2]Royal Brisbane and Women's Hospital, Herston, Australia; [3]Sunshine Coast University Hospital, Sunshine Coast, Australia*

Email: patricia.valery@qimrb.edu.au

Background and aims: Motivation to adopt lifestyle changes may be influenced by patients' knowledge of MASLD, their illness perceptions, and sociodemographic or clinical characteristics. This study examined motivation to modify diet and physical activity among MASLD patients in Queensland, Australia.

Method: This cross-sectional study included 142 adults ascertained from three Hepatology outpatient clinics (Sep-2023 to Aug-2025) who fit the definition of MASLD (including alcohol use below harmful thresholds). The self-completed questionnaire included two questions about motivation to change diet/physical activity with answers categorised as '*low motivation*', '*high motivation*', and '*not applicable*' (healthy diet/physically active). The questionnaire included the Brief Illness Perception Questionnaire (BIPQ), six questions on MASLD knowledge, the Generalized Anxiety Disorder Scale, the Patient Health Questionnaire to assess depression, alcohol use (AUDIT-C), and the Self-Administered Comorbidity Questionnaire. We examined factors associated with 'low motivation' to change lifestyle (multivariable logistic regression - aforesaid factors were considered for inclusion in the models).

Results: The mean age was 60.5 years (SD = 13.6), 61.3% were female, 61.3% had higher educational level (e.g. trade, diploma), 62.4% were obese, 21.8% had liver stiffness measurement >12.5 kPa, 64.2% had self-assessed anxiety and 89.4% depression, and 53.5% reported continued alcohol use. Over 50% of patients self-reported having hypertension, back pain, and diabetes, and over 33% reported arthritis and obstructive sleep apnoea. 62.0% of the patients had 4–6 correct answers to the MASLD knowledge questions. The mean total BIPQ score was 37.2 (SD 12.1), indicating a moderate illness perception. In multivariable analysis, poor MASLD knowledge (0–3 correct answers out of six, adj-OR = 5.38, 95%CI 1.62–17.90; p = 0.006), higher educational level (adj-OR = 4.16, 95%CI 1.09–15.95; p = 0.038), and continued alcohol use (vs no alcohol use; adj-OR = 3.95, 95%CI 1.01–15.38; p = 0.048) were associated with low motivation to change diet. Poor MASLD knowledge (adj-OR = 2.87, 95%CI 1.15–7.16; p = 0.024) was the only factor associated with low motivation to change physical activity.

Conclusion: Patient knowledge appears to be a readily modifiable factor that could enhance motivation for lifestyle change among individuals with MASLD.

SAT-031-YI

Validated early detection metrics reduces the population requiring liver fibrosis screening

Email: l.vankleef@erasmusmc.nl

Background and aims: Diabetes, obesity, and elevated ALT are indicators to screen for liver disease. Yet, guidelines differ on which features should trigger screening. Given the increasing prevalence of metabolic comorbidities and feasibility issues of screening programs, we sought to refine screening criteria using population-based data.

Method: We included adults aged 18–80 years from NHANES 2017–2020 with BMI ≥18.5 kg/m^2, without excessive alcohol consumption, and with complete screening indicator data. Weighted proportions of individuals meeting EASL, AASLD, AGA, and ADA screening criteria were estimated. We assessed the prevalence of liver stiffness measurement (LSM) ≥8 kPa across screening indicators using stratified analyses. The refined criteria were validated in three independent general population cohorts from Rotterdam, Barcelona and the US and linked with LRE in UK-biobank.

Results: The derivation included 5,904 adults (mean age 47 years, 49% male); 8.9% had LSM ≥8 kPa. Current guidelines identified 60–76% for screening, yielding PPVs of 11–14% and NPVs of 98% for LSM ≥8 kPa. A refined strategy based on the stratified analyses triggered screening in 22% while maintaining a high NPV (96%) and improved PPV (28%) for LSM ≥8 kPa. In the pooled validation cohort (n = 13,295), 7.0% had LSM ≥8 kPa and 14% met the refined screening criteria. Validation results were consistent across different LSM thresholds: PPV 22% and NPV 96% for LSM ≥8 kPa; PPV 13% and NPV 98% for LSM ≥10 kPa; and PPV 8% and NPV 99% for LSM ≥12 kPa. In the UK-Biobank (n = 282,582), high-risk individuals had an approximate 6-fold higher risk (1.02%) of 10-year incident cirrhosis or liver-related death (0.40%) than those not meeting the refined screening criteria (0.18% and 0.07% resp.).

Conclusion: Current guidelines target 60–76% of the US adult population for MASLD-induced advanced chronic liver disease screening, creating a diagnostic capacity challenge that hinders implementation. To overcome this, we developed and validated in 302,051 adults a refined set of indicators for screening prioritisation: (1) T2DM with elevated ALT or obesity or (2) obesity class III regardless of other factors OR obesity class II with elevated ALT OR Obesity class I with elevated ALT and ≥ 3 metabolic risk factors. These criteria reduce the target population to 10–22%, improve PPV while maintaining high NPV for LSM ≥8 kPa. Importantly, LRE were rare among those without screening indicators, justifying targeted screening of those with more profound risk factors.

SAT-035

Impact of fibrotic MASH as a new indication on semaglutide eligibility in the U.S. adult population

Laurens A. van Kleef[1], Maurice Michel[2], Mesut Savas[1], Jesse Pustjens[1], Willy Theel[1], Elisabeth van Rossum[1], James M. Paik[3], Zobair M. Younossi[3], Harry L.A. Janssen[1], Christian Labenz[4], Jörn M. Schattenberg[2], Willem Pieter Brouwer[1]. *[1]Erasmus MC, Rotterdam, Netherlands; [2]Department of Internal Medicine II, Saarland University Medical Center, Homburg, Germany; [3]The Global NASH Council, Washington, United States; [4]University Medical Center Mainz, Mainz, Germany*
Email: l.vankleef@erasmusmc.nl

Background and aims: Semaglutide, a glucagon-like peptide-1 receptor agonist, is effective in the treatment of fibrotic (F2–F3) metabolic dysfunction-associated steatohepatitis (MASH) and has recently received accelerated FDA approval. However, the extent to which this new indication expands treatment eligibility beyond existing approvals for type 2 diabetes mellitus (T2DM) and obesity remains unclear.
Method: We analyzed nationally representative NHANES data (2017–2020) on U.S. adults, excluding individuals with viral hepatitis or excessive alcohol consumption. Semaglutide eligibility was defined according to FDA-approved indications for weight loss (BMI ≥ 27 kg/m^2 with weight related comorbidity), high-risk T2DM (T2DM with CVD or high risk of CVD or impaired renal function), or fibrotic MASH (LSM 8–15 kPa with MASLD [CAP ≥ 275 db/m + metabolic dysfunction]). Findings were validated in the Mainz (Germany) biopsy cohort (n = 213) with biopsy-proven MASLD and F2–F3 fibrosis.
Results: We included 6,936 adults, the weighted median age was 47 years [32–61], 47.9% were male, MASLD was present in 41.0% and fibrotic MASH in 5.2%. In the adult U.S. general population, 51.5% met indications for semaglutide for weight loss (41.8 of 51.5%), high-risk T2DM (2.0 of 51.5%) or both (7.7 of 51.5%). Among individuals with MASLD, 80.9% qualified for treatment based on conventional indications, increasing to 95.4% in those with fibrotic MASH. Including fibrotic MASH as an additional indication marginally increased overall eligibility (from 51.5% to 51.8%), reflecting that most individuals with fibrotic MASH already met eligibility criteria through obesity or high-risk T2DM. In the Mainz cohort, 80.3% of patients with biopsy-proven F2–F3 fibrosis were eligible for semaglutide irrespective of fibrotic MASH, in agreement with the findings from the general population.
Conclusion: Semaglutide eligibility is high among U.S. adults. The new fibrotic MASH indication largely overlaps with pre-existing indications, primarily obesity, which uses the same dose as fibrotic MASH. These findings highlight the intertwined nature of metabolic comorbidities and liver disease and emphasize the need for an integrated, patient-centred approach to semaglutide, alongside policies that improve access and reimbursement.

Artificial intelligence in scientific abstract review: complement or contradiction to human judgment? Insights from a Latin American hepatology cohort

Pablo Coste[1], Ezequiel Ridruejo[2], Marco Arrese[3], Javier Díaz Ferrer[4], Melisa Dirchwolf[5], Jorge Luis Garavito Rentería[6], Kriss Rodríguez Romero[7], Aldo Torre[8], Cristiane A. Villela-Nogueira[9], Francisco Vargas-Navarro[1], Maria Lynch-Mejia[1], Wagner Ramirez-Quesada[1], Nélia Hernandez[10]. *[1]Hospital Dr. Rafael Ángel Calderón Guardia, LiverLab CR, San José, Costa Rica; [2]Sección Hepatología, Departamento de Medicina. Centro de Educación Médica e Investigaciones Clínicas Norberto Quirno "CEMIC," Buenos Aires, Argentina; [3]Department of Gastroenterology, Pontificia Universidad Católica de Chile, Santiago, Chile; [4]Departamento de Aparato Digestivo, Hospital Nacional Edgardo Rebagliati Martins (HNERM) – EsSalud, Facultad de Medicina, Universidad Nacional Mayor de San Marcos, Facultad de Medicina, Universidad Peruana de Ciencias Aplicadas, Lima, Peru; [5]Hospital Privado de Rosario, Rosario, Argentina; [6]Servicio de Gastroenterología, Hospital Nacional Arzobispo Loayza, Lima, Peru; [7]Clínica Delgado, Lima, Peru; [8]Gastroenterology Department, Medical Center ABC, Mexico City, Mexico; [9]Universidade Federal do Rio de Janeiro, Rio de Janeiro, Brazil; [10]Hospital de Clínicas, Facultad de Medicina, Universidad de la República, Montevideo, Uruguay*
Email: costepablo@gmail.com

Background and aims: Artificial intelligence (AI) is increasingly used in biomedical research, including peer-review processes. However, its concordance with expert clinical judgment remains poorly understood in the context of hepatology congresses, particularly in Latin America. This study aims to compare AI-generated abstract scores with those assigned by human reviewers, assessing concordance, bias, and potential for integration.
Method: We conducted a comparative analysis of 191 abstracts submitted to the ALEH 2025 Congress. Each abstract was independently scored by three hepatology experts using a standardized 18-point rubric and by an AI-based algorithm trained for scientific content appraisal. We calculated mean scores, standard deviations, absolute differences, and performed paired t-tests. Pearson correlation was used to assess concordance. Agreement and bias were further evaluated using scatterplots with identity lines and Bland-Altman plots. Abstracts were ranked globally and by topic (MASLD, viral hepatitis, cirrhosis, liver cancer, transplantation, etc.) based on combined human–AI scores.
Results: The mean AI score (15.3 ± 2.0) was significantly higher than the mean human score (11.5 ± 2.9; $p < 0.001$), with a mean difference of 3.8 points. Pearson correlation showed moderate positive concordance ($r = 0.58$; $p < 0.001$). The Bland-Altman plot revealed a consistent negative bias, with AI overestimating scores, particularly in lower-scoring abstracts. No significant differences were found in bias across study types ($p = 0.321$). Combined scoring enabled a more nuanced selection of top abstracts, mitigating subjective variation.
Conclusion: AI tends to systematically overestimate abstract quality compared to human experts, yet maintains moderate concordance. When integrated with human judgment, it may enhance the objectivity of scientific selection processes. This work highlights both the promise and limitations of AI-assisted evaluation in hepatology and supports hybrid models for future congress abstract review.

SAT-037

Excess mortality from cirrhosis by neighbourhood deprivation, aetiology, and clinical presentation: a Swedish register-based cohort study

Juan Vaz[1], Jeffrey Lazarus[2], Hannes Hagström[3], Ulf Strömberg[1].
[1]*School of Public Health and Community Medicine, Institute of Medicine, Sahlgrenska Academy, University of Gothenburg, Gothenburg, Sweden;* [2]*Barcelona Institute for Global Health (ISGlobal), Barcelona, Spain;* [3]*Department of Medicine, Huddinge, Karolinska Institutet, Stockholm, Sweden*
Email: juan.vaz@gu.se

Background and aims: Socioeconomic inequalities are a persistent determinant of health inequity, but their influence on excess mortality from cirrhosis in high-income countries with universal healthcare is not well characterised. We aimed to estimate cirrhosis-related excess mortality across neighbourhood deprivation levels in Sweden.
Method: We conducted a nationwide, register-based cohort study, including all individuals aged ≥40 years residing in Sweden between 2012–2022. The open, underlying cohort was stratified by calendar year, sex, 5-year age groups, and residential neighbourhood. Neighbourhood strata were collapsed into deprivation quintiles (*Q*s), as per the national distribution of inhabitants with a low disposable household income, with *Q1* being the least and *Q5* the most deprived. Incident cirrhosis cases within the age span 40–74 years were identified using validated diagnostic algorithms, and followed for up to five years. Excess mortality rate ratios (EMRRs) were estimated using Poisson regression within a relative survival framework. To estimate the number of excess deaths across *Q1*–*Q5*, the incidence rate in each stratum was taken into account.
Results: Among 21,583 individuals with incident cirrhosis, among whom the median age was 63 years and 35% were female, 8,814 deaths occurred during 65,170 person-years of follow-up. Five-year excess mortality was 19% higher in *Q5* than in *Q1* (EMRR 1·19, 95% CI 1·10–1·29), after adjusting for calendar year, sex, age, aetiology, and cirrhosis severity. At the population level, the age-standardised number of excess deaths within five years of diagnosis was substantially higher in deprived areas: with 2018 as the year of diagnosis, there were 23 excess deaths per 100,000 inhabitants in *Q5* versus 12 in *Q1*, representing a 95% higher excess mortality burden.
Conclusion: Even within a universal healthcare system, cirrhosis-related excess mortality substantially increases with level of neighbourhood deprivation. Prevention and more optimal post-diagnostic management targeted towards deprived neighbourhoods are urgently needed to reduce avoidable deaths.

SAT-038

Socioeconomic disparities in access to curative treatment among individuals with surveillance-detected hepatocellular carcinoma in Sweden: a nationwide cohort study

Juan Vaz[1], Adam Bergman[1], Malin Sternby Eilard[2], Hannes Hagström[3].
[1]*School of Public Health and Community Medicine, Institute of Medicine, Sahlgrenska Academy, University of Gothenburg, Gothenburg, Sweden;* [2]*Department of Surgery, Sahlgrenska Academy, University of Gothenburg, Gothenburg, Sweden;* [3]*Department of Medicine, Huddinge, Karolinska Institutet, Stockholm, Sweden*
Email: juan.vaz@gu.se

Background and aims: Surveillance for hepatocellular carcinoma (HCC) aims to enable early detection and access to potentially curative treatment. While surveillance improves stage at diagnosis and survival, it remains unclear whether socioeconomic disparities persist among individuals whose HCC is detected through surveillance within universal healthcare systems. We aimed to identify sociodemographic and clinical factors associated with failure to receive curative treatment among individuals with surveillance-detected HCC in Sweden, and to assess survival across socioeconomic strata.
Method: We conducted a nationwide register-based cohort study including all adults diagnosed with surveillance-detected HCC between 2011 and 2021, using data from the Swedish national quality register (SweLiv) linked to population registers. Multivariable logistic regression was used to assess factors associated with receipt of curative treatment (resection, ablation, or transplantation). The final model was adjusted for age, sex, region of birth, household income, aetiology, tumour size and number, extrahepatic metastasis, tumour thrombosis, Child-Pugh score, performance status, arterial hypertension, diabetes mellitus, cardiovascular disease, chronic kidney disease, and chronic obstructive pulmonary disease. Overall survival was analysed using Kaplan–Meier estimates and Cox proportional hazards models stratified by treatment modality.
Results: Among 1,401 individuals with surveillance-detected HCC, 906 (65%) received curative treatment. After adjustments, individuals with medium and low household income had substantially lower odds of receiving curative treatment compared with those with high income (adjusted odds ratios 0.47 [95% CI 0.30–0.76] and 0.40 [0.25–0.65], respectively). Overall survival differed by socioeconomic status, with lower survival among individuals with low household income. Socioeconomic differences in survival were observed among individuals treated with ablation, where low income was independently associated with higher mortality (adjusted hazard ratio 1.49 [1.04–2.13]), but not among those undergoing resection or transplantation.
Conclusion: Despite surveillance-based detection of HCC, marked socioeconomic disparities persist in access to curative treatment and survival in Sweden. These findings highlight inequities within the surveillance-to-treatment pathway and underscore the need for targeted strategies to ensure equitable implementation of HCC surveillance and downstream care.

SAT-039

Burden, trends and projections of liver cancer in China and G20 countries: a comparative study based on the global burden of disease database 2023

Yikai Wang[1], Yaping Li[1], Muqi Wang[1], Liu Yang[1], Meng Zhang[1], Zihan Liu[1], Mei Li[1], Juanjuan Shi[1], Wenjun Wang[1], Shuangsuo Dang[1], Xiaoli Jia[1]. [1]*The Second Affiliated Hospital of Xi'an Jiaotong University, Xi'an, China*
Email: 17795626586@163.com

Background and aims: This study compares the disease burden of liver cancer and its attributable risk factors between China and the Group of Twenty (G20) countries from 1990 to 2023, and predicts the trends in incidence, mortality, and disability-adjusted life years (DALYs) over the next 27 years.
Method: Utilizing data from the GBD 2023 database to assess trends in the disease burden of liver cancer. Analyzing the relationships between risk factors, human development index (HDI), and socio-demographic index (SDI). Employing the joinpoint regression model to calculate the average annual percentage change (AAPC) to evaluate trends. Using the autoregressive integrated moving average (ARIMA) model to predict liver cancer burden trends from 2024 to 2050.
Results: In 2023, China's age-standardized incidence rate (ASIR), age-standardized mortality rate (ASMR), and age-standardized disability-adjusted life years rate (ASDR) for liver cancer were showing a certain degree of decline compared to 1990, but higher than those in G20 countries during the same period. Hepatitis B and C viruses remain the primary causative factors, but the impact of non-alcoholic steatohepatitis (NASH) is increasing. By risk factors, the burden of liver cancer caused by drug use in G20 countries and tobacco in China also needs attention. Additionally, countries with higher SDI tend to have lower incidence and mortality rates of liver cancer. Joinpoint regression analysis revealed that between 1990 and 2023, the ASIR, ASMR, and ASDR generally showed a downward trend. Projections indicate that over the next 27 years, the ASIR, ASMR, and ASDR will maintain relatively stable or declining trends, though with differences between genders.

Conclusion: Although the burden of liver cancer in China has declined, but remains a certain gap compared to G20 countries during the same period. China should develop more targeted prevention and control strategies for different genders and age groups in the future.

SAT-040

Burden, trends and projections of cirrhosis in China and G20 countries: a comparative study based on the global burden of disease database 2023

Yikai Wang[1], Yaping Li[1], Muqi Wang[1], Liu Yang[1], Meng Zhang[1], Zihan Liu[1], Mei Li[1], Juanjuan Shi[1], Wenjun Wang[1], Shuangsuo Dang[1], Xiaoli Jia[1]. [1]*The Second Affiliated Hospital of Xi'an Jiaotong University, Xi'an, China*
Email: 17795626586@163.com

Background and aims: This study compares the disease burden of cirrhosis and its attributable risk factors between China and the Group of Twenty (G20) countries from 1990 to 2023, and predicts the trends in incidence, mortality, and disability-adjusted life years (DALYs) over the next 27 years.
Method: We used data from the GBD 2023 database to assess trends in the disease burden of cirrhosis. We analyzed the relationships between risk factors, human development index (HDI), and socio-demographic index (SDI). The joinpoint regression model helped us calculate the average annual percentage change (AAPC) and evaluate trends. The autoregressive integrated moving average (ARIMA) model was used to predict cirrhosis burden trends from 2024 to 2050.
Results: In 2023, China's age-standardized incidence rate (ASIR), age-standardized mortality rate (ASMR), and age-standardized disability-adjusted life years rate (ASDR) for cirrhosis were showing a certain degree of decline compared to 1990. The three indicators of G20 countries also showed a downward trend, but ASMR and ASDR were consistently higher than those in China. The proportion of cirrhosis caused by non-alcoholic steatohepatitis (NASH) has significantly increased, while the proportion caused by HBV has significantly decreased. By risk factors, the prevalence of drug-use-attributed cirrhosis in G20 countries is significantly higher than in China, while alcohol use shows little difference between the two. Additionally, across countries, higher SDI is associated with lower ASIR for liver cirrhosis. However, overall, the ASIR for liver cirrhosis is lowest in China and G20 countries when the SDI is at 0.6. Joinpoint analysis revealed that the ASIR for cirrhosis in China and G20 countries reached its lowest point in 2005, followed by a rise, while ASMR and ASDR generally showed a downward trend from 1990 to 2023. Projections indicate that, over the next 27 years, the ASIR, ASMR, and ASDR will continue to decline; however, these trends will differ by gender.
Conclusion: The burden of liver cirrhosis in China has declined, with some indicators already surpassing those of G20 countries. China should develop more targeted prevention and control strategies for different genders and age groups in the future.

SAT-041

Inefficiency of risk-based screening for steatotic liver disease in primary care: a multi-cohort analysis of more than 15,000 individuals

Bernhard Wernly[1], Patrick Langthaler[1], Bernhard Iglseder[1], Eugen Trinka[1], Georg Semmler[2], Elmar Aigner[1], Christian Datz[1]. [1]*Salzburg, Austria;* [2]*MedUni Wien, Wien, Austria*
Email: bernhard@wernly.at

Background and aims: Current EASL clinical practice guidelines recommend a risk-based screening strategy for steatotic liver disease (SLD), utilizing metabolic triggers such as obesity or type 2 diabetes as entry criteria for further diagnostic evaluation. This approach aims to optimize resources by focusing on high-risk populations. However, real-world data on the diagnostic performance of this strategy in unselected primary care populations remain limited. This study evaluated the diagnostic precision and clinical workload of EASL screening criteria across two large, independent primary care cohorts.
Method: We analyzed two distinct primary care populations: the P10 cohort (n = 9,838) and the SAKKOPI cohort (n = 5,935). Screening positivity was defined by EASL criteria (obesity, type 2 diabetes, or elevated alanine aminotransferase). Performance was benchmarked against the FIB-4 score (low < 1.30, intermediate 1.30–2.67, high ≥ 2.67), liver stiffness measurement (LSM; high risk ≥ 8 kPa), and the presence of steatotic liver disease according to diagnostic criteria.
Results: In P10, the median age was 55 years (IQR 50–62; 49% male), while in SAKKOPI it was 58 years (IQR 52–66; 52% male). EASL criteria were met by 48.0% of the P10 population and 59.8% in SAKKOPI, representing substantial diagnostic workload. Among screen-positive individuals, the positive predictive value for high-risk FIB-4 (≥ 2.67) was only 1.9% in P10 and 4.4% in SAKKOPI. Notably, 60% to 68% of screen-positive individuals presented with low-risk FIB-4 scores (< 1.30), indicating considerable over-referral. The reliance on metabolic pre-screening created significant diagnostic gaps. First, the criteria failed to capture 28% (P10) and 19% (SAKKOPI) of all individuals with steatotic liver disease. Second, metabolic screening missed 26.3% (P10) and 26.4% (SAKKOPI) of individuals with elevated liver stiffness (LSM ≥ 8 kPa).
Conclusion: While intended to streamline diagnostics, the current EASL risk-based screening paradigm generates disproportionate clinical burden in primary care without achieving adequate sensitivity. Our data demonstrate that a sequential metabolic gateway is inefficient for comprehensive case detection, missing one-quarter of patients with elevated liver stiffness while over-referring two-thirds of screen-positive individuals with low fibrosis risk. Direct implementation of the FIB-4 score as the primary screening tool could enhance both diagnostic safety and resource efficiency in the primary care setting.

SAT-042

Estimation of liver fibrosis risk using non-invasive biomarker tests in people living with HIV and pre-diabetes in Tanzania

Trenton M White[1], Jeffrey Lazarus[1], Kaushik Ramaiya[2], Sokoine Kivuyo[1], Sayoki Mfinanga[3], Erik van Widenfelt[4], Paul N. Brennan[5], Hannes Hagström[6], Rickard Strandberg[6], Anupam Garrib[4]. [1]*Barcelon Institute for Global Health (ISGlobal), Barcelona, Spain;* [2]*Tanzania NCDs Alliance, Dar Es Salaam, Tanzania;* [3]*National Institute for Medical Research, Dar es Salaam, Tanzania;* [4]*University College London, London, United Kingdom;* [5]*The University of Dundee, Dundee, United Kingdom;* [6]*Karolinska Institutet, Huddinge, Sweden*
Email: trenton.white@isglobal.org

Background and aims: Metabolic dysfunction-associated steatotic liver disease (MASLD) and liver fibrosis are increasingly common comorbidities among people living with HIV (PLHIV), particularly in ageing populations with rising metabolic dysfunction. Data on fibrosis risk in sub-Saharan Africa remain scarce. We aimed to estimate liver fibrosis risk and the 10-year risk of cirrhosis using non-invasive tests (NITs) among PLHIV with pre-diabetes in Tanzania.
Method: We conducted a cross-sectional analysis of baseline data from 1,691 PLHIV with pre-diabetes enrolled in the META Trial, a phase III randomised controlled trial of metformin, in Tanzania. Liver fibrosis risk was assessed using the Fibrosis-4 (FIB-4) Index, Metabolic Dysfunction-Associated Fibrosis-5 (MAF-5) score, NAFLD Fibrosis Score (NFS), and the LiverRisk score; cirrhosis risk was estimated using the Cirrhosis Outcome Risk Estimator (CORE). Clinical and demographic variables were summarised, and risk categories were defined using validated and age-adjusted cut-offs.
Results: Participants had a mean age of 49.4 years (SD 9.4), 75.0% were female, and 99.2% were Black. Using age-adjusted FIB-4 thresholds, 31.8% were classified as indeterminate risk and 3.0% as high risk, while NFS classified 50.9% as indeterminate and 8.3% as

high risk. In contrast, MAF-5 categorised 59.9% of participants as high risk, whereas fewer than 1% were classified as medium or high risk by LiverRisk. Using CORE, 5.8% of participants were estimated to have a ≥1% 10-year risk of developing cirrhosis or a cirrhosis-related outcome. Females were more often classified as low risk than males by FIB-4 (70% vs. 50%, $p < 0.001$), while males had higher risk classifications by MAF-5, LiverRisk, and CORE; no sex differences were observed for NFS.
Conclusion: Non-invasive fibrosis tests yielded divergent estimates of liver fibrosis risk among PLHIV with pre-diabetes in Tanzania. While FIB-4 and NFS identified most as low risk, MAF-5 suggested nearly half were high risk. These discrepancies underscore the need for locally validated NITs and integration of liver health assessments into HIV care in Africa, particularly as MASLD/MASH and metabolic comorbidities are common in this population.

SAT-043

The rising burden of adolescent MASLD: a global analysis of incidence trends and modifiable risk factors

Tianyuan Yang[1], Tong Bu[1], Qi Wang[1]. [1]*Center of Liver Diseases, Beijing Ditan Hospital, Capital Medical University, Beijing, China, Beijing, China*
Email: tyy66303@gmail.com

Background and aims: The global prevalence of metabolic dysfunction-associated steatotic liver disease (MASLD) among adolescents has risen markedly. However, a comprehensive description of its recent epidemiological trends is lacking, and the key modifiable risk factors driving its incidence remain poorly characterized.
Method: Age-specific incidence rates (1990–2023) were obtained from the GBD 2023 database for trend and mapping analysis. To identify risk factors, we independently screened candidate exposures, applying a random forest model with SHAP analysis for feature ranking. Key factors were subsequently evaluated using negative binomial regression to estimate relative risks (RRs).
Results: Globally, adolescent MASLD incidence increased by 25.2% from 1990 to 2023 (866.5 to 1084.9 per 100,000). The rise was most pronounced in middle SDI regions (+35.7%), while high- and low-SDI regions increased by 30.5% and 21.5%, respectively. At the regional level, the highest 2023 incidence was observed in Middle SDI areas (1436.5 per 100,000), whereas the lowest was in High-income Asia Pacific (868.4 per 100,000). SHAP analysis identified high body-mass index and ambient particulate matter pollution as the two most influential risk factors. Subsequent negative binomial regression confirmed their significant association with increased incidence, yielding relative risks of 1.13 (95% CI: 1.09–1.17) for high BMI and 1.07 (95% CI: 1.04–1.10) for ambient particulate matter pollution.
Conclusion: Our study confirms a significant global rise in adolescent MASLD incidence and identifies high body-mass index and ambient particulate matter pollution as key modifiable risk factors. These findings highlight the urgent need for integrated public health strategies targeting both metabolic health and environmental protection to curb the growing burden of MASLD in adolescent.

SAT-044

Health literacy and associated factors in patients with cirrhosis in Latin America: the PHAROS study

Ismael de Jesus Yepes Barreto[1], Alejandra Ochoa[2], Andres Solera[2], Patricia Guerra[3], Diana Castillo[4], Katerin Saravia[5], Francisco Vargas-Navarro[6], Pedro Montes[7], Valentina Yepes[8], Juan Carlos Restrepo[9]. [1]*Universidad de Cartagena, Asociacion Colombiana de Hepatologia, Cartagena de Indias, Colombia;* [2]*Hospital Doctor Rafael Ángel Calderón Guardia, San José, Costa Rica;* [3]*Instituto de Gastroenterología Boliviano Japonés (IGBJ), La Paz, Bolivia;* [4]*Hospital Punata, Punata, Bolivia;* [5]*Hospital del Norte, Cochabamba, Bolivia;* [6]*Clínica de Puriscal, Santiago, Costa Rica;* [7]*Hospital Nacional Daniel Alcides Carrión, Bellavista, Peru;* [8]*University Of Copenhagen, København K, Denmark;* [9]*Hospital Pablo Tobón Uribe, Medellín, Colombia*
Email: ismayep@yahoo.com

Background and aims: Health literacy is essential for disease self-management and informed decision-making. In patients with cirrhosis, limited health literacy has been associated with worse clinical outcomes and increased healthcare costs. Although factors associated with health literacy in cirrhosis have been described, most evidence derives from high-income countries and may not be generalisable to Latin America, where data remain scarce. The aim of the PHAROS study was to identify factors associated with adequate health literacy among patients with cirrhosis in Latin America.
Method: We conducted a multicentre cross-sectional study in four Latin American countries across seven outpatient hepatology centres. Adult patients with cirrhosis attending routine outpatient clinics were invited to participate. After written informed consent, health literacy was assessed using the Short Assessment of Health Literacy in Spanish (SAHL-S), an 18-item validated instrument. A score greater than 15 defined adequate health literacy. Clinical and sociodemographic variables were collected. Univariate and multivariable logistic regression analyses were performed to identify factors associated with adequate health literacy.
Results: A total of 243 patients were included. Mean age was 63.9 ± 11.8 years, and 57.2% were female. Most patients lived in urban areas (83.1%), and 61.4% had completed secondary education or higher. Overall, 62.1% were classified as Child–Pugh A. Ascites, hepatic encephalopathy, and oesophageal varices were present in 35.4%, 22.2%, and 44.9% of patients, respectively. MASLD was the most frequent aetiology (34.2%). Adequate health literacy was identified in 68.7% of patients. In multivariable analysis, higher educational level was independently associated with adequate health literacy (OR 1.94, 95% CI 1.49–2.53), whereas older age (OR 0.96, 95% CI 0.93–0.99), oesophageal varices (OR 0.42, 95% CI 0.21–0.85), and more advanced Child–Pugh class (OR 0.50, 95% CI 0.32–0.78) were associated with lower odds of adequate health literacy.
Conclusion: In this multicentre Latin American cohort, inadequate health literacy was common among patients with cirrhosis and was associated with older age and more advanced liver disease, while higher educational level was protective. These findings support integrating health literacy assessment and tailored educational strategies into routine cirrhosis care in Latin America to improve outcomes and optimise healthcare resource use.

SAT-045

Global trends and disparities in preventable premature liver deaths due to metabolic dysfunction-associated steatotic liver disease (MASLD): a 20-year study in 204 countries

James M. Paik[1], Linda Henry[1], Andrei Racila[1], Markos Kalligeros[1,2], Fatema Nader[1], Zobair M. Younossi[1]. Email: james.paik@inova.org

Background and aims: Premature deaths (PDs) due to MASLD may vary across countries, but the proportion of these deaths that are preventable remain unknown.
Method: This global ecological analysis included 204 countries (2004–2023) using Global Burden of Disease (GBD) data with UN/WHO covariates. Premature death (PD) was defined as death <70 years. Based on the 2023 distribution, countries were grouped as follows: Group A comprised countries in the top quartile of MASLD prevalence and bottom quartile of the mortality-to-prevalence ratio (MPR; n = 51) to isolate benchmark-like performers and improve comparability given known GBD mortality-prevalence measurement asymmetries. Remaining countries were classified by sociodemographic index (SDI) tertiles (low <0.60, middle 0.60-<0.75, high ≥0.75) into Group B (high SDI; n = 50), Group C (middle SDI; n = 41), and Group D (low SDI; n = 62). Within each group, 10th percentile of MPR (2004) served as the benchmark. Expected PD rates were calculated as MASLD prevalence × benchmark MPR. Preventable PD

rates were defined as excess observed/expected rates, and preventability proportion as preventable divided by observed PD rates. Determinants were evaluated using stratum-specific linear mixed-effects models with country random intercepts.

Results: From 2004–2023, 1,262,126 MASLD-related liver PDs occurred globally, of which 49.3% (622,459 deaths) were potentially preventable. Groups A–D accounted for 6.0%, 41.0%, 41.1%, and 11.9% of all preventable PDs. Mean preventability changed over time: Group A, 23.5% (IQR 0–45.9%) to 21.3% (0–30.2%); Group B, 57.4% (42.2–73.4%) to 52.7% (39.1–67.7%); Group C, 57.8% (44.7–72.1%) to 61.3% (49.1–75.4%); and Group D, 50.5% (37.6–65.2%) to 53.0% (38.6–65.4%) ($p < 0.002$ for time trend). In Group A, preventability was lower with SDI ($\beta = -0.789$) and male population ($\beta = -0.016$) and higher with diabetes ($\beta = 0.009$), age ($\beta = 0.016$), and urbanization ($\beta = 0.004$) (all $p < 0.002$). In Group B, preventability increased with obesity ($\beta = 0.011$) and decreased with age ($\beta = -0.021$) ($p < 0.001$) and Universal Health Coverage ($\beta = -0.003$, $p = 0.059$). In Group C, preventability increased with obesity ($\beta = 0.006$) and age ($\beta = 0.008$) ($p < 0.030$). In Group D, preventability increased with age ($\beta = 0.010$) and urbanization ($\beta = 0.002$) and decreased with male population ($\beta = -0.022$) ($p < 0.007$).

Conclusion: Nearly half of premature MASLD-related deaths are preventable, underscoring socioeconomic inequities across countries and the need for policy action.

Email: zobair.younossi@cldq.org

Background and aims: Ultra-Processed Foods (UPFs), characterized by high energy density, added sugars, unhealthy fats, and food additives, have been associated with obesity and MASLD. The contribution of UPFs to hepatic fibrosis in MASLD remains insufficiently understood. We aimed to elucidate the association of UPF intake in fibrosis in patients with MASLD using an international registry.

Method: We analyzed data from the Global NASH/MASH Registry™ (N = 1,266 patients with established diagnosis of MASLD or MASH; 11 countries). Dietary intake was assessed using the Short-Processed Food Questionnaire (SPFQ; 23 food items including 15 UPF), and associations with obesity and fibrosis severity using liver stiffness measurement (advanced fibrosis: LSM≥10 kPa) were examined.

Results: Mean (SD) UPF intake was 2.32 ± 2.38 portions/day. Dietary patterns varied markedly by country ($p < 0.0001$), with UPF intake ranging from 1.85 ± 1.78 to 8.41 ± 2.62 portions/day and UPFs comprising 32 ± 19% to 67 ± 9% of intake. UPF intake was higher in participants with obesity than in overweight or lean individuals (2.48 ± 2.57 vs. 2.15 ± 2.20 vs. 2.00 ± 1.88 portions/day; $p = 0.04$). Healthy food intake and the proportion of intake from UPFs were similar across BMI categories ($p = 0.20$ and $p = 0.37$, respectively), indicating that absolute UPF burden might distinguish obesity. Obesity was associated with higher intake of multiple UPF subcategories, including butter/margarine/ghee, sweet breakfast cereals, fried fast foods, processed meats, and savory snacks (all $p < 0.05$). MASLD patients with advanced fibrosis (LSM ≥10 kPa) had higher UPF intake (2.80 ± 2.37 vs. 2.05 ± 2.22 portions/day; $p = 0.001$). MASLD-related advanced fibrosis (pooled prevalence 12%) was more prevalent in the highest UPF tertile compared to the lowest (18% vs. 9%; $p = 0.007$). UPF items consumed more frequently in MASLD with advanced fibrosis included sugar-sweetened dairy products, processed meats, processed dressings/sauces, and sweetened diet drinks (all $p < 0.05$). In multivariable analyses adjusted for age and sex, individual UPF items [sugar-sweetened dairy products, OR (95% CI) = 2.24 (1.35–3.73), and sweetened diet drinks, OR = 2.63 (1.53–4.53) per portion/day] were associated with advanced fibrosis. These associations were attenuated with the inclusion of country of enrollment.

Conclusion: The UPF intake is associated with obesity and potentially with fibrosis in MASLD, identifying UPFs as a modifiable dietary target.

SAT-047

How food-system conditions shape burden of metabolic dysfunction associated steatotic liver disease (MASLD) in low- and high-sdi countries

James M. Paik[1], Markos Kalligeros[1,2], Annette Paik[1], Shira Zelber-Sagi[1,3], Farah Qaderi[1], Zobair M. Younossi[1]. *[1]The global NASH/MASH council, Washington DC, United States; [2]Division of Gastroenterology and Hepatology, Beth Israel Deaconess Medical Center, Harvard Medical School, Boston, MA, USA, Boston, United States; [3]School of Public Health, Faculty of Social Welfare and Health Sciences, University of Haifa, Haifa, Israel, Haifa, Israel*
Email: zobair.younossi@cldq.org

Background and aims: Food affordability and retail environment shape dietary patterns and metabolic risks, but their relationship to the global MASLD burden across different countries at different socioeconomic developmental levels is not well defined.

Method: A cross-national ecological study was conducted including 156 countries with harmonized data from Global Burden of Disease and United Nations' Food and Agriculture Organization database. Ultra-Processed Agrifood Environment Index (UPAEI) was calculated by combining ultra-processed energy share, agrifood emissions, urbanization, and protein dilution. Countries were stratified according to Sociodemographic Index (SDI <0.70 vs ≥0.70). Structural equation models assessed potential associations linking the food-

system characteristics, metabolic factors with MASLD prevalence and mortality.
Results: Low-SDI countries (n = 98) had younger populations (mean median age 22.3 vs 37.8 years), were less urbanized (49.1% vs 73.4%), and had lower political stability (−0.47 vs 0.38), lower healthcare access and quality index (HAQ 42.3 vs 76.5), lower import dependence (6.79 vs 91.6), and lower UPAEI (36.4 vs 45.8), but higher food-price burden (8.7 vs 1.8) compared with high-SDI countries (n = 58). MASLD prevalence (16,240 vs 13,662 per 100,000) and MASLD-related mortality (2.77 vs 1.85 per 100,000) were both higher in low-SDI countries (all $p < 0.01$). In low-SDI countries, UPAEI was associated with sugar share ($\beta = 0.42$, $p < 0.001$). Both sugar share and caloric surplus were associated with obesity ($\beta = 0.45$ and $\beta = 0.35$; $p < 0.001$), and caloric surplus associated with type 2 diabetes (T2D) ($\beta = 0.56$, $p < 0.001$). Obesity and T2D were associated with MASLD prevalence ($\beta = 0.37$, $p < 0.001$; $\beta = 0.22$, $p = 0.015$). Political stability showed an inverse association with MASLD prevalence ($\beta = -0.38$, $p < 0.001$).
In high-SDI countries, food-price burden ($\beta = 0.57$, $p < 0.001$) and import dependence ($\beta = 0.22$, $p = 0.027$) were associated with reliance on staple carbohydrates, which was associated with higher obesity ($\beta = 0.41$, $p < 0.001$). Sugar share was associated with higher obesity ($\beta = 0.34$, $p = 0.002$). Only T2D showed a strong association with MASLD prevalence ($\beta = 0.88$, $p < 0.001$). Higher HAQ was consistently associated with lower MASLD-related mortality ($\beta = -0.44$, $p < 0.001$).
Conclusion: MASLD pathways differ by country's socio-economic development level, with ultra-processed food-driven metabolic risk dominating in low-SDI settings and food affordability pathways in high-SDI settings.

SAT-050

Type 2 diabetes (T2D) is the major driver of advanced metabolic dysfunction–associated steatohepatitis (MASH) and associated liver-related mortality in Europe

Email: zobair.younossi@cldq.org

Background and aims: Individuals with type 2 diabetes (T2D) have a high prevalence of MASH with more rapid disease progression and a disproportionate clinical burden. We used a modelling approach to estimate the clinical burden of MASH by T2D status in 5 major European countries.
Method: An age-stratified Markov model estimated the clinical burden of MASH according to T2D status from 2025 to 2040 in Germany, Spain, France, Italy, and the United Kingdom (EU-4+UK). Transition probabilities were derived from published natural history studies and calibrated to country-specific epidemiology, aligning model outputs with nationally reported rates for decompensated cirrhosis, hepatocellular carcinoma, and liver transplantation. Treatment effects were applied directly to annual transition probabilities using country-specific assumptions for approval, coverage, adherence, and persistence, with projected uptake of GLP-1 receptor agonists and resmetirom. Prevalent and incident MASH cohorts were stratified by T2D status and updated annually to reflect demographic aging and projected trends in T2D prevalence informed by International Diabetes Federation data and expert input from each country.
Results: Across EU-4+UK, MASH cases are projected to increase from 12.04 million (2025) to 13.96 million (2040), with rising MASH prevalence in all of these countries (Germany: 4.42% to 4.78%; Spain: 4.64% to 5.35%; France: 4.08% to 4.48%; Italy: 4.69% to 5.34%; UK: 4.76% to 5.17%). MASH with advanced fibrosis (AF, F3/F4) is also expected to increase from approximately 2.77 million to 3.24 million. Annual liver-related deaths attributable to MASH in these countries will rise from 26,322 to 33,151 while liver transplants increase from 596 to 909 per year. Although emerging therapies may slow down the overall disease progression, the metabolic severity of the MASH population will intensify. The proportion of all MASH cases with T2D remains relatively stable (27–30%), yet T2D becomes increasingly more concentrated among MASH with severe outcomes. The share of MASH+AF in individuals with T2D will increase (e.g., Germany 41% to 44%; Spain 38% to 45%; France 38% to 45%). Similar trends are observed for liver-related mortality and transplantation (T2D in 71% of MASH transplants by 2040 in some countries).
Conclusion: Despite therapeutic advances, the burden of MASH in Europe is expected to grow over the next two decades, with T2D increasingly concentrated among MASH with advanced liver disease or more severe liver-related outcomes.

SAT-051

Central obesity is a key determinant of advanced fibrosis across the spectrum of steatotic liver disease (SLD): a population-based analysis

Markos Kalligeros[1,2], James M. Paik[1], Albert Tan[1], James Estep[1], Andrei Racila[1], Zobair M. Younossi[1]. *[1]The global NASH/MASH council, Washington DC, United States; [2]Division of Gastroenterology and Hepatology, Beth Israel Deaconess Medical Center, Harvard Medical School, Boston, MA, USA, Boston, United States*
Email: zobair.younossi@cldq.org

Background and aims: Obesity, typically defined by body mass index (BMI), is associated with metabolic dysfunction-associated steatotic liver disease (MASLD); however, the contribution of visceral adiposity (central obesity) across SLD spectrum remains incompletely characterized. We evaluated the association between central obesity and SLD in a population-based cohort.
Method: This cross-sectional study included adults (≥18 years) from the National Health and Nutrition Examination Survey 2017–2020. SLD was defined by controlled attenuation parameter (CAP) ≥285 dB/m. MASLD, metabolic dysfunction–associated alcohol-related liver

disease (MetALD), and alcohol-associated liver disease (ALD) were classified using consensus definitions. Alcohol intake was adjusted for sex- and frequency-specific underreporting and calibrated to national per-capita ethanol consumption. Alcohol phenotypes included abstainers (none), former drinkers (none in past year), low intake (<20–30 g/day women/men), moderate intake (20–49.9 and 30–59.9 g/day), or heavy intake (≥50 and ≥60 g/day). Advanced fibrosis and cirrhosis were defined by liver stiffness ≥12.0 kPa and ≥20.0 kPa. Central obesity was assessed using body roundness index (BRI) ≥6.5.

Results: Among 5,095 participants (age 49.5 years), 35.4% had SLD [MASLD 27.9%, MetALD 3.6%, and ALD 4.0%]. The entire cohort was classified as abstainers (7.7%), former (15.0%), low (54.3%), moderate (12.6%), and heavy (10.4%). In MASLD cohort, alcohol phenotypes were abstainers (10.5%), former (21.0%), and low drinkers (68.5%). Among SLD, advanced fibrosis and cirrhosis were present in 8.44% and 3.35%. By SLD subtype, advanced fibrosis and cirrhosis occurred in MASLD (9.01%, 4.25%), MetALD (4.82%, 2.04%), and ALD (10.53%, 2.70%). Central obesity was associated with higher prevalence of advanced fibrosis in MASLD (13.24% vs. 2.18%) and ALD (15.31% vs. 7.31%) (both $p < 0.05$), but not MetALD (4.93% vs. 3.97%; $p = 0.792$). Advanced fibrosis prevalence was even higher in MASLD with central obesity across alcohol phenotypes [abstainers (10.60% vs. 0.00%), former (12.48% vs. 5.50%), and low (13.83% vs. 1.82%; all $p < 0.05$)]. In stratified multivariable models, central obesity was independently associated with advanced fibrosis in MASLD (OR 6.27; 95% CI 2.71–14.50) and ALD (OR 2.30; 95% CI 1.03–5.15), but not MetALD (OR 2.91; 95% CI 0.36–23.28).

Conclusion: Central obesity is the most clinically relevant predictor of advanced fibrosis in MASLD and ALD.

SAT-052

Mapping the risk of liver cirrhosis by occupational groups in Sweden: a population-based case-control study

Marie Zalesiak[1], Juan Vaz[1,2], Martin Henriksson[3], Eralda Asllanaj[4], Hannes Hagström[1,5], Ying Shang[1]. *[1]Departement of Medicine, Karolinska Institutet, Stockholm, Sweden; [2]School of Public Health and Community Medicine, Institute of Medicine, Sahlgrenska Academy, University of Gothenburg, Gothenburg, Sweden; [3]Center of Medical Technology Assessment, Department of Medical, Heath and Caring Science, Linköping, Sweden; [4]Boehringer Ingelheim, Amsterdam, Netherlands; [5]Unit of Hepatology, Department of GUT, Karolinska University Hospital, Stockholm, Sweden*
Email: marie.zalesiak@ki.se

Background and aims: Liver cirrhosis is frequently diagnosed at an advanced stage and is associated with poor prognosis. Identifying high-burden groups beyond traditional healthcare settings may facilitate earlier detection. We mapped the relative risk of incident cirrhosis across occupational groups in Sweden to inform targeted case-finding.

Method: We conducted a nationwide case–control study within the Swedish Decoding the Epidemiology of Liver Disease in Sweden (DELIVER) cohort (2002–2021). Cases were individuals aged 35–65 years with liver cirrhosis and were matched to up to four controls on age, sex, calendar year, and municipality using incidence-density sampling. Labor market status in the year preceding the index date (i.e., cirrhosis diagnosis) was obtained from registers and categorized as employed, unemployed, disability/long-term sick leave, or early retirement. Occupational group was identified among employed individuals. Conditional logistic regression estimated odds ratios (ORs) with 95% confidence intervals (CIs), using physical and engineering science professionals as the reference group (low risk for cirrhosis and homogeneous group). Analyses were stratified by underlying etiology.

Results: The study included 23,038 cases and 92,125 matched controls. Cases were more likely to clustered in lower socioeconomic strata, reflected by lower income and educational attainment and higher proportions outside the labor market. Occupational analyses were restricted to employed and unemployed individuals, resulting in 7,485 cases and 63,747 controls. Compared with the reference group, unemployment was associated with the highest odds of cirrhosis (OR 10.9, 95% CI 8.3–14.1). Among employed individuals, food-related occupations showed markedly elevated risks, including food preparation workers (OR 3.2, 95% CI 2.2–4.5) and butchers/bakers/food processors (OR 4.9, 95% CI 2.1–11.6). Higher risks were also observed for refuse collectors/ recycling workers (OR 3.3, 95% CI 2.4–4.5) and social workers (OR 2.5, 95% CI 1.7–3.7). Stratified analyses by etiology demonstrated broadly similar occupational risk patterns.

Conclusion: Incident cirrhosis in Sweden is unevenly distributed across the working-age population, with the highest risk among unemployed individuals and increased risk in specific occupations. Occupation-based risk mapping could support targeted case-finding and facilitate earlier detection for liver cirrhosis.

SAT-053

Clinical obesity is strongly associated with steatotic liver disease and advanced fibrosis: evidence from NHANES 2017–2018

Laura Sol Grinshpan[1,2], Shira Zelber-Sagi[1,2], James Paik[1,3], Dana Ivancovsky-Wajcman[1], Linda Henry[1,3], Zobair M. Younossi[1,3]. *[1]The global NASH/MASH council, Washington DC, United States; [2]School of public health, faculty of social welfare and health sciences, University of Haifa, Haifa, Israel; [3]Center for outcomes research in liver diseases, Washington DC, United States*
Email: szelber-s@univ.haifa.ac.il

Background and aims: Obesity is a major driver of steatotic liver disease (SLD), yet its conventional definitions may inadequately capture adiposity-related risk. A Lancet commission recently defined obesity based on adiposity measures beyond body mass index (BMI) and coined the term clinical obesity- a condition of illness that results from the effect of excess adiposity on the function of organs and tissues. We examined the association between clinically obesity and SLD.

Method: This cross-sectional analysis included adults aged ≥18 years from the 2017–2018 National Health and Nutrition Examination Survey (NHANES). Obesity was defined as: BMI ≥ 40 kg/m^2; or BMI ≥30 kg/m^2 (≥27.5 kg/m^2 for Asian) with ≥ 1 adiposity abnormality; or ≥ 2 adiposity abnormalities regardless of BMI class. Clinical obesity was defined as obesity with ≥ 1 non-hepatic clinical complication (metabolic abnormality, sleep apnea, heart failure, chronic kidney disease, and activity-of-daily-living limitation); preclinical obesity indicated obesity without any of these complications. SLD was defined by a controlled attenuation parameter ≥285 dB/m and classified as MASLD, MetALD, or ALD based on the recent international consensus with alcohol intake corrected for underreporting. Advanced fibrosis (including cirrhosis) was defined by liver stiffness ≥12.0 kPa.

Results: Among 3,357 NHANES participants (mean age, 50.0 years; 46.1% male), weighted prevalence of SLD was 31.9% (MASLD 24.6%, MetALD 4.0%, ALD 3.3%) with 3.0% having advanced fibrosis. Using the new definitions, 30.0% had non-obesity, 17.5% preclinical obesity, and 52.5% clinical obesity. SLD prevalence increased across groups (no obesity: 3.0%, preclinical obesity: 26.2%, and clinical obesity: 50.3%, respectively), with parallel gradients for MASLD (1.7%, 21.3%, 38.8%), MetALD (0.7%, 2.5%, 6.4%), and ALD (0.5%, 2.3%, 5.1%). Advanced fibrosis prevalence similarly increased; 0.34%, 0.45%, and 6.67%. In multivariable models adjusted for demographic and lifestyle confounders, clinical obesity was strongly associated with SLD (OR 28.63, 95%CI 18.68–43.88) and advanced fibrosis (OR 10.09, 95%CI 2.53–40.25) compared with non-obesity, whereas preclinical obesity was only associated with SLD (OR 8.612, 95%CI 4.55–16.29). Results were unchanged after excluding participants with diabetes.

Conclusion: Adiposity-based clinical obesity identifies a high-risk phenotype strongly associated with SLD and hepatic fibrosis.

Incorporating clinical obesity frameworks may improve risk stratification.

SAT-054

Global burden and trends of primary liver cancer attributable to comorbid type 2 diabetes mellitus among people living with metabolic dysfunction-associated steatohepatitis: an observational trend study from 1990 to 2021

Xinyu Zhao[1,2], Chunfeng Mei[1], Jiatu Zhong[1], Shihao Zheng[1], Wenying Qi[1], Yong'an Ye[1]. [1]*Beijing University of Chinese Medicine, Beijing, China;* [2]*Dongzhimen Hospital, Beijing University of Chinese Medicine, Beijing, China*
Email: 20220931554@bucm.edu.cn

Background and aims: The synergistic interaction between metabolic dysfunction-associated steatohepatitis (MASH) and type 2 diabetes mellitus (T2DM) is an emerging driver of hepatocellular carcinoma (HCC). However, a comprehensive global assessment of the liver cancer burden specifically attributable to this comorbidity is lacking. This study aimed to quantify the global burden and temporal trends of primary liver cancer due to MASH-T2DM comorbidity from 1990 to 2021.
Method: Using Global Burden of Disease (GBD) 2021 data from 204 countries (1990–2021), we estimated liver cancer burden attributable to MASH-T2DM comorbidity. Population attributable fractions (PAFs) were calculated using Levin's formula. We analyzed age-standardized prevalence, disability-adjusted life years (DALYs), and mortality rates, stratified by region, sociodemographic index (SDI), sex, and age. Temporal trends were assessed using estimated annual percentage change (EAPC).
Results: In 2021, the global age-standardized prevalence and DALY rates were 13.6 (95% Uncertainty Interval [UI]: 2.2–36.4) and 257.1 (95% UI: 42.9–688.6) per 10,000,000 individuals, respectively. The highest burdens were observed in high-SDI regions, particularly High-income Asia Pacific and North America. The disease burden was approximately five-fold higher in individuals aged ≥ 60 years, and males exhibited a higher burden across most age groups. While EAPC point estimates were positive across all regions, wide uncertainty intervals precluded statistical significance, indicating substantial uncertainty in temporal trends.
Conclusion: MASH-T2DM comorbidity represents a distinct and escalating driver of the global liver cancer burden, characterized by a unique "affluence-aging" pattern that differs fundamentally from traditional viral etiologies. Our findings underscore an urgent need for public health strategies to pivot from a primary focus on infectious disease control toward integrated metabolic health management and risk-stratified surveillance, particularly in aging, high-income populations.

SAT-055

The burden of hepatocellular carcinoma in Oceania: an under-represented but high-risk population

Angela Zhu[1], Aparna Morgan[1], Nicholas Hannah[1], James Haridy[1], Ashok Raj[1], Neeraj Bhala[1]. [1]*Department of Gastroenterology and Hepatology, The Royal Melbourne Hospital, Melbourne, Australia*
Email: angzhu26@gmail.com

Background and aims: The global burden of hepatocellular carcinoma(HCC) and its mortality rate continue to rise despite advances in treatment. Contemporary reviews of HCC epidemiology often excludes data from Oceania, limiting representation of regions with distinct demographic profiles and risk factor distributions. There is a high prevalence of chronic hepatitis B(CHB) and increasing burden of metabolic dysfunction-associated steatotic liver disease (MASLD) among the Aboriginal and Torres Strait Islander peoples of Australia, Māori, Pasifika and migrant/refugee populations. We aim to summarise contemporary oceanic epidemiology of HCC and highlight implications for surveillance.
Method: We performed a literature review on epidemiological data based on cohort studies and clinical guidelines describing the prevalence, incidence and aetiology of HCC.
Results: Data derived from the Global Burden of Disease study reveals that Australia, New Zealand and Guam had the highest increase in incidence and mortality from liver cancer in Oceania between 1990 and 2021. Specifically, Australia and New Zealand have the the highest annual percentage increases in MASLD-related liver cancer at 3.27% and 2.01%. An estimated 5.7 million Australians lived with MASLD in 2020 and MASLD-associated HCC is projected to increase by 75% by 2030. Alarmingly, recent data indicates that 31% of MASLD-related HCC occurs without established cirrhosis. We also note higher incidences of non-cirrhotic HCC among Aboriginal and Torres Strait Islander peoples over 50 years old with CHB(0.36–0.9%). These data prompted the recent publication of clinical practice guideline by George et al. which addressed current gaps in HCC surveillance in this high-risk population. Over 70% of people living with CHB in Australia were born overseas. This diverse migrant population results in a broad HBV genotype distribution, including genotypes B and C among Asian migrants that are typically associated with increased oncogenic risk independent of cirrhosis. Similarly, HBV is the leading cause of HCC-related deaths in New Zealand(31.5%), and Māori people are 3.5 times more likely to die from HCC compared to non-Māori people. Data on HCC among Pasifika peoples remains limited and is largely derived from migrant cohorts.
Conclusion: Oceanic populations contribute important and distinct epidemiological insights into HCC risk. Addressing this gap in contemporary global syntheses is essential for eliminating geographic bias and supporting equitable guideline development.

Non-genetic determinants of hepatitis B surface antibody disappearance in Taiwan's vaccinated generations

Chun-Yi Chang[1,2], Chih-Jen Huang[2], Mei-Hung Pan[2], Ding-Lian Wang[2,3], Jaw-Ching Wu[1], Chien-Jen Chen[2], Hwai-I Yang[2]. [1]*Institute of Clinical Medicine, National Yang Ming Chiao Tung University, Taipei, Taiwan;* [2]*Genomic Research Center, Academia Sinica, Taipei, Taiwan;* [3]*Graduate Institute of Life Science, National Defense Medical University, Taipei, Taiwan*
Email: smilekey16@gmail.com

Background and aims: Chronic hepatitis B virus (HBV) is a major global public health challenge. Taiwan's universal neonatal HBV vaccination program, launched in 1986, has markedly reduced hepatitis B surface antigen (HBsAg) prevalence and liver cancer incidence. However, up to 60% of vaccinees lose protective hepatitis B surface antibody (anti-HBs) levels 15–18 years post-vaccination, raising concerns about long-term immunity and booster strategies. While host genetic factors have been implicated, the impact of measurable non-genetic determinants remains unclear. This study aimed to identify key non-genetic factors associated with anti-HBs seronegative and evaluate whether this loss confers differential risks of HBV infection and chronic carriage across vaccine types.
Method: We analyzed 6,586 Taiwan Biobank participants born after July 1, 1986, receiving neonatal HBV vaccination. Determinants of anti-HBs seronegative were evaluated among 6,247 anti-HBc-negative individuals. Demographic, anthropometric, biochemical, lifestyle, and vaccination-related factors were assessed. Multivariate logistic regression models estimated adjusted odds ratios (Adj-ORs) and 95% confidence intervals (CIs). The entire cohort was further stratified by vaccine type and anti-HBs serostatus to compare rates of chronic carriage (HBsAg+) and HBV infection (anti-HBc+).

Results: Among the 6,247 participants, 44.84% were anti-HBs seronegative. Four non-genetic factors were independently associated with antibody loss. Female sex was associated with a lower risk than male sex (Adj-OR = 0.76, 95%CI = 0.67–0.86). Obesity (BMI ≥ 30 kg/m^2) increased risk compared with normal BMI (Adj-OR = 1.40, 95%CI = 1.10–1.77). Current smokers had a higher risk (Adj-OR = 1.54, 95%CI = 1.29–1.85). Recipients of recombinant vaccine had a higher risk of anti-HBs seronegativity than plasma-derived vaccine recipients (Adj-OR = 1.41, 95%CI = 1.11–1.78). Despite better antibody persistence, plasma-derived vaccinees exhibited worse clinical outcomes after antibody loss. Chronic carriage (HBsAg+) was more frequent in the plasma-derived group than in the recombinant group (1.7% vs. 0.5%; Crude OR = 3.67, 95%CI = 1.70–7.93).
Conclusion: Sex, obesity, smoking, and vaccine type are significant non-genetic determinants of anti-HBs waning. Notably, recombinant vaccines confer superior long-term protection against chronic HBV carriage despite a higher rate of antibody loss. These findings support risk-stratified booster strategies to optimize long-term HBV prevention.

TOP-034

Impact of an EASL-guided screen-and-treat intervention for hepatitis B on HCC incidence in West Africa: results of a large-scale population-based study in The Gambia

Gibril Ndow[1], Erwan Vo Quang[1], Bakary Dibba[1], Damien Leith[1], Sainabou Drammeh[1], Gavin Cloherty[2], Stéphane Chevaliez[3], Sheikh Omar Bittaye[4], Kitabu Jammeh[1], Patrick Ingiliz[5], Vincent Leroy[5], Ousman Bah[1], Jean-Michel Pawlotsky[5], Amie Ceesay[1], Isabelle Chemin[6], Maimuna Mendy[1], Ramou Njie[1], Dalessandro Umberto[1], Mark R Thursz[7], Yusuke Shimakawa[8], Maud Lemoine[7]. *[1]MRCG@LSHTM, Fajara, Gambia; [2]Abbott company, United States, United States; [3]APHP, Creteil, France; [4]University of Gambia, Banjul, Gambia; [5]APHP Henri Mondor Hospital, Creteil, France; [6]INSERM, Lyon, France; [7]Imperial College London, Department of Metabolism, Digestion and Reproduction, London, United Kingdom; [8]Pasteur Institute, Paris, France*
Email: m.lemoine@imperial.ac.uk

Background and aims: Long-term outcomes of chronic hepatitis B virus infection (CHB) and the impact of antiviral therapy on reducing hepatocellular carcinoma (HCC) in Africa have been poorly documented.
Method: In 2011, the PROLIFICA programme established at the Medical Research Council Unit The Gambia a population-based cohort of CHB patients following a large-scale community screening intervention[1,2]. Following a liver assessment, participants were initiated on Tenofovir (TDF, 300 mg daily) based on the EASL treatment criteria. HCC surveillance was established using abdominal ultrasound and cirrhosis was defined by Fibroscan≥9.5 kPa[3]. The primary outcome was all-cause mortality stratified by TDF exposure. The secondary outcomes were liver-related deaths and HCC incidence compared to historical data2.
Results: Between 7 December 2011 and 28 October 2015, from 1,037 treatment-naïve participants, we analysed 898 CHB patients without HCC or HIV-HCV coinfections at enrolment. Participants were mainly males (516/898, 57%), median age 36 (32–46). During a median follow-up of 7.2 (6.2–9.8) years, 34/864 (3.9%) participants died of any cause giving an annual overall mortality rate at 4.9 (95%CI: 3.3–6.6) deaths/1,000 persons, comparable to the age-standardised mortality rate of the general Gambian population. Compared to untreated ineligible patients, non-cirrhotic treated patients had similar excellent survival (98%, 98%, 95% and 92% at 2, 4, 6 and 10 years, respectively) ($p = 0.26$) whilst eligible cirrhotic patients (94%, 89%, 77% and 58%) had lower survival ($p < 0.0001$). 6 patients died from liver-related events. No HCC occurred in untreated patients, 4 HCC were reported in treated patients, giving an overall incidence of 57.7 (14.4–115.4) per 100,000 person-year. All HCC occured in male cirrhotic patients despite good adherence to TDF, viral suppression and absence of HDV coinfection. Among men, HCC incidence was 101.5 (25.4–203.01) per 100,000 person-year, lower than a historical Gambian study before the introduction of antiviral therapy in the country[2] (183.5 (82.4–408.5) per 100 000 person-years).
Conclusion: This West African EASL criteria-driven screen-and-treat intervention study shows a reduction in HCC incidence, compared to historical data, with excellent clinical outcomes of non-cirrhotic patients, but highlights the importance of early detection of cirrhosis and strengthened HCC surveillance programmes.

A low-cost tool to assess HBV treatment eligibility: time to positivity of a point-of-care HBsAg test

Judit Romero[1,2], Asegedech Asmamaw[3,4], Nega Berhe[4,5], Ariadna Rando-Segura[6], Amanda Cohn[1], Xavier Major[7], Elena Vargas-Accarino[1,8], Adriana Palom[1,8], Juan Carlos Ruiz-Cobo[1,9,10], Mar Riveiro Barciela[1,8,9,10], Asgeir Johannessen[5,11], Maria Buti[1,8,9,10]. *[1]Research group of liver diseases, Vall Hebron Research Institute, Barcelona, Spain; [2]Department of Nursing and Health, University of Barcelona, Barcelona, Spain; [3]Department of Medical Laboratory Sciences, Addis Ababa University, Addis Ababa, Ethiopia; [4]Aklilu Lemma Institute of Health Research, Addis Ababa University, Addis Ababa, Ethiopia; [5]Department of Infectious Diseases, Vestfold Hospital, Tonsberg, Norway; [6]Liver Pathology Laboratory, Microbiology and Biochemistry Department, Vall d'Hebron Clinical Laboratories, Hospital Universitari Vall d'Hebron, Barcelona, Spain; [7]Programme on Addictions, HIV, Sexually Transmitted Infections and Viral Hepatitis. Email: judit.vico@vhir.org

Background and aims: Reaching the WHO hepatitis B elimination targets will require simplified, decentralized screening and care pathways that can be implemented at scale. In many low-resource settings, access to laboratory tests needed to assess treatment eligibility remains limited, creating major gaps in linkage to care. We evaluated whether the time to positivity of a low-cost point-of-care (POC) HBsAg rapid test could serve as a pragmatic proxy for serum HBsAg levels and support identification of inactive HBV carriers during screening.
Method: A multicentre prospective study was conducted between January and December 2025 in a hospital based hepatology clinic in Barcelona (Spain) and in community settings in Ethiopia, reflecting both high- and low-resource contexts. Individuals with current infection (HBsAg+), past infection (HBsAg –/anti-HBc+), and healthy controls were included. Serum HBsAg was quantified using Elecsys HBsAg II (Roche), and qualitative HBsAg testing was performed on capillary blood using POC rapid tests (Determine HBsAg 2, Abbott; LOD: 0.1 IU/mL; recommended reading time 15–20 minutes). Time to positivity was recorded as a simple, visually assessed parameter.
Results: A total of 585 patients were screened (255 in Spain and 270 in Ethiopia), 486 with current infection, 15 with past infection, and 24 healthy controls. Quantitative HBsAg results from the initial 236 individuals are included in the present analysis; 105 had HBsAg ≤1,000 IU/mL and 131 had levels >1,000 IU/mL. All HBsAg-positive individuals were correctly identified by the POC test. Mean (SD) time to positivity was 2.6 ± 2.4 minutes and correlated strongly and inversely with serum HBsAg levels (Pearson's $r = –0.726$, $p < 0.001$). A >2-minute cut-off identified low HBsAg levels (≤1,000 IU/mL) with 79% overall accuracy (sensitivity 75%, specificity 83%). A >3-minute cut-off increased specificity to 97% and positive predictive value to

93%, at the expense of sensitivity (53%). No false-positive results were observed among individuals with past infection or healthy controls.
Conclusion: A simple visual parameter—the time to positivity of an HBsAg rapid test—provides meaningful information on HBsAg levels. This approach could enable immediate identification of inactive HBV carriers during screening campaigns, reduce reliance on laboratory testing, and support decentralized hepatitis B care in resource-limited settings.

Email: fegarcia@ugr.es

Background and aims: Hepatitis C virus infection remains underdiagnosed in Spain despite the availability of curative direct-acting antivirals. Age-based screening represents a key opportunity to identify undiagnosed infections, but its implementation at national level requires diagnostic strategies that are both effective and economically sustainable. We assessed the population impact and cost-effectiveness of opportunistic age-based HCV screening using pooled HCV-RNA testing, using a regional elimination programme as a proof of concept to inform national policy decisions.
Method: HCV-RNA testing was performed using a pooling sample strategy. A validated lifetime Markov model of chronic HCV natural history was adapted to evaluate screening strategies in individuals 50–60 years. Three scenarios were analysed: pooled RNA testing vs no screening; pooled RNA testing vs standard testing based on anti-HCV antibody followed by RNA confirmation; and standard testing vs no screening. The model incorporated Spanish epidemiological data, sustained virologic response rates with direct-acting antivirals and official healthcare costs, from a healthcare system perspective over a lifetime horizon with 3% annual discounting.
Results: A total of 157,606 individuals were screened. The prevalence of HCV viremia was 0.14% (95% CI 0.12–0.16), significantly higher in males. Overall, 221 viraemic infections were identified. Compared with no screening, pooling increased short-term diagnostic costs by €181,716 but reduced lifetime costs related to advanced liver disease by €2,328,496, with marked reductions in decompensated cirrhosis (72%), hepatocellular carcinoma (64%), liver transplantation (69%) and liver-related mortality (67%). Pooled testing was a dominant strategy. Compared with standard testing, pooled testing achieved equivalent clinical effectiveness while reducing diagnostic costs, resulting in savings of €663 per diagnosed patient. Standard testing was cost-effective versus no screening, with incremental cost-effectiveness ratios well below Spanish willingness-to-pay thresholds.
Conclusion: Opportunistic age-based HCV screening in individuals 50–60 years has a major population-level impact and is cost-effective in Spain. Pooled RNA testing maximizes clinical benefit, minimizes costs and is a scalable diagnostic strategy. These findings provide robust evidence to support national implementation of age-based HCV screening as part of elimination policies, eitherpreferably, but not only, through pooling-based approaches.

FRI-003

A systematic review of digital health tools and early real-world experience with HepB&Me application in chronic hepatitis B to tackle the unmet clinical need

Almuthana Mohamed[1], Hamit Soyel[2], Mark Danta[3], Patrick Kennedy[1]. *[1]Blizard Institute, Barts and the London school of medicine and dentistry, Queen Mary University of London, London, United Kingdom; [2]School of Electronic Engineering and Computer Science, Queen Mary University of London, London, United Kingdom; [3]School of Clinical Medicine, St Vincent's Healthcare Clinical Campus, Faculty of Medicine and Health, UNSW Sydney, Darlinghurst, Sydney, Australia*
Email: almuthana700@gmail.com

Background and aims: Chronic hepatitis B (CHB) remains significantly underdiagnosed and undertreated, highlighting the need for accessible, trustworthy digital support for both individuals living with CHB and healthcare professionals (HCPs) with a prioritisation of personalised care. We aimed to conduct a systematic review of CHB-focused mobile tools and to summarise real-world experience with the HepB&Me application (app) to illustrate how identified gaps might be addressed through implementation.
Method: Using predefined eligibility criteria (apps or tools with publicly available, explicit HBV content for patients or HCPs), we systematically identified and screened tools through structured secondary research of app stores and web resources, supplemented by primary email interviews with clinicians. Two reviewers extracted predefined data categories: user audience, education, calculators or test result interpretation, signposting to trustworthy resources, clinical trial information, HBV reactivation content, data privacy statements, and medical device classification; disagreements were resolved through discussion. Findings were synthesised narratively. Concurrently, we incorporated data generated from HepB&Me (launched in Q1, 2025), including utilisation metrics and qualitative feedback from patient advocacy reviews.
Results: Sixteen CHB-related tools were identified. Common functions included education, calculators, and interpretation aids. The majority were free to use and not classified as medical devices. Only one specialised educational website addressed HBV reactivation; however, no app directed users to reliable external resources or presented clinical-trial details, identifying unmet content gaps. Early HepB&Me usage showed 89 monthly active users, including 27 healthcare professionals, with an average of 6 chatbot queries per day. Advocacy reviewers judged the content to be thorough but requested improvements in usability, offline access, and expanded language options, including Spanish and Hindi.
Conclusion: There remains a significant unmet need for signposting to credible information, awareness of clinical trials, and clear guidance on reactivation risk. HepB&Me demonstrates initial feasibility as a generative AI resource for Individuals living with CHB and HCP alike. Priorities include enhancing usability, providing offline functionality, expanding language options, ensuring secure authentication and regular updates. Further user-centred evaluations and outcomes research will be conducted.

SIMPLY-B pilot study: assessing hepatitis B treatment uptake in primary care clinics

Dina Moussa[1], Jack Wallace[1], Jacqui Richmond[1], Joseph Doyle[2], Long Nguyen[1], Douglas Boyle[3], Mark Stoove[1], Jason Asselin[1], Victoria Polkinghorne[1], Marvad Ahad[1], Susanne Glasgow[4], Kate New[4], Lena Sanci[3], Matt Penn[5], John Furler[5], Alexander Thompson[3], Margaret Hellard[1], Jessica Howell[1]. *[1]Burnet Institute, Melbourne, Australia; [2]Monash Health, Melbourne, Australia; [3]University of*

Melbourne, Melbourne, Australia; [4]St Vincent's Hospital, Melbourne, Australia; [5]North Richmond Community Health, Melbourne, Australia
Email: dina.moussa@burnet.edu.au

Background and aims: To increase hepatitis B management in primary care, we developed SIMPLY B, a novel hepatitis B electronic decision support tool that provides GPs with real-time management plans, automated specialist support and rapid access to Fibroscan. We evaluated the feasibility, acceptability and effectiveness of SIMPLY B for increasing hepatitis B management in primary care.
Method: This pilot intervention study was conducted in three urban primary care clinics in Melbourne between April 2023 to June 2025. Two clinics had SIMPLY B embedded in the electronic medical record, the other one clinic used an online link that GPs had to purposively access. Demographic and clinical data were extracted from the SIMPLY B database and described (N, %). Semi-structured qualitative interviews evaluating the acceptability of SIMPLY B were conducted with GPs.
Results: HBV management is feasible in primary care but remains hindered by structural, educational and systemic challenges. During the study, twelve of 106 patients (11%) with recorded chronic hepatitis B attended the clinics and all were enrolled in SIMPLY B. Most (58%) were female and ages ranged from 27–72 years. All received SIMPLY B-guided hepatitis B management by their GP in primary care: two patients commenced treatment, 6 commenced liver cancer surveillance and all continued monitoring in primary care without specialist referral. *SIMPLY B* demonstrated that GPs can effectively deliver evidence-based HBV care when supported by decision tools and specialist input. All patients enrolled received appropriate management, yet overall uptake was low. Barriers included limited consultation time, perceived complexity of HBV care, low prioritisation and inadequate integration of digital tools.
Conclusion: Future models of care should integrate HBV into existing chronic disease management frameworks, supported by education, incentives and embedded digital tools.

FRI-005
Monitoring of the cascade of care in patients with chronic HBV in primary care clinics in Australia

Dina Moussa[1], Jack Wallace[1], Jacqui Richmond[1], Joseph Doyle[2], Long Nguyen[1], Douglas Boyle[3], Mark Stoove[1], Jason Asselin[1], Victoria Polkinghorne[1], Marvad Ahad[1], Susanne Glasgow[4], Kate New[4], Lena Sanci[3], Matt Penn[5], John Furler[5], Alexander Thompson[3], Margaret Hellard[1], Jessica Howell[1]. *[1]Burnet Institute, Melbourne, Australia; [2]Monash Health, Melbourne, Australia; [3]University of Melbourne, Melbourne, Australia; [4]St Vincent's Hospital, Melbourne, Australia; [5]North Richmond Community Health, Melbourne, Australia*
Email: dina.moussa@burnet.edu.au

Background and aims: To achieve hepatitis B (HBV) elimination in Australia, a shift from hospital to community-based HBV care is needed. This study aimed to describe the prevalence of chronic HBV and uptake of the cascade of care in primary care patients in Victoria to determine the scope of HBV clinical management within primary care services.
Method: This prospective cohort study was conducted in 76 urban and regional primary care clinics across Victoria between 1/7/2020 to 30/6/2023. Anonymised socio-demographic, clinical and laboratory data from General Practice (GP) clinics' electronic medical records (EMR) were extracted via the PATRON primary care surveillance system. Descriptive analysis of the cohort of clinic clients with HBV was performed, including patient uptake of guideline-based testing, disease assessment and treatment.
Results: A total of 346,927 individuals attended appointments across the study period. Of these, 25,212 had records indicating HBV-related testing, and 20,056 individuals underwent a HBV surface antigen (HBsAg) test (5.8%). 491 (0.14%) individuals had evidence of current HBV infection defined HBsAg positive and/or HBeAg positive and/or HBV DNA positive. or HBV DNA testing. 469 attended the clinics during the study period, among whom 239 (51%) were female, the median age was 39 years and most were of Asian ethnicity. In the GP EMR, only 59 (13%) had evidence of at least one HBV DNA test and at least one ALT test ordered in primary care during the three years of follow up. Fourteen patients (3%) had record of being reviewed for HBV management by the clinic nurse or GP and 78 (17%) reviewed by a viral hepatitis specialist. Fifty-five (12%) of all eligible patients had attended at least one hepatocellular carcinoma (HCC) surveillance ultrasound (US) in primary care, 13 (24%) of whom were co-managed by a liver specialist. 92 (20%) were on treatment for HBV; 53 (58%) were on entecavir, 37 (40%) were on tenofovir and 2 (2%) were on tenofovir alafenamide. Of people receiving treatment, 23 (25%) had a record of linkage to specialist care.
Conclusion: Our data show that significant gaps in the cascade of care remain for people with chronic HBV in primary care settings, with a low proportion of patients having evidence of participating in all stages of the HBV cascade of care in general practice.

FRI-006
Reaching the unreachable: prison mobile outreach as a cornerstone of national HCV micro-elimination efforts in Croatia

Tatjana Reic[1], Adriana Vince[2,3], Magda Pletikosa Pavic[4], Maja Sremac[5], Iva Košuta[5], Vibor Šeša[5], Zdravko Andric[6], Ivona Reic[1], Ana Visic[1], Anna Mrzljak[3,5]. *[1]Croatian Society for the Liver Diseases "Hepatos", Split, Croatia; [2]Department of Virology, Zagreb University Hospital for Infectious Diseases, Zagreb, Croatia; [3]School of Medicine, University of Zagreb, Zagreb, Croatia; [4]Teaching Institute for Public Health Split - Dalmatia County, Split, Croatia; [5]Department of Hepatology, University Hospital Center Zagreb, Zagreb, Croatia; [6]County's General Hospital Pozega, Pozega, Croatia*
Email: tatjana@hepatos.hr

Background and aims: Hepatitis C virus (HCV) infection remains a major public health challenge in prisons, where the prevalence is substantially higher than in the general population. Early diagnosis and effective linkage to care are essential to achieve WHO 2030 elimination targets. Building on earlier positive outcomes, the Croatian Ministry of Justice is supporting this program as part of a national effort toward HCV micro-elimination in Croatian prisons aiming to raise health literacy, access to HCV testing, FibroScan® assessments, counseling, and treatment uptake.
Method: During 2025, the Society "Hepatos" joined by medical experts - hepatologists, ID specialists and epidemiologists conducted 17 mobile clinic activities across Croatian prisons. Data was collected on HCV testing, FibroScan® liver stiffness and CAP measurements, counseling and linkage-to-care. Liver fibrosis and steatosis were classified using established LSM and CAP thresholds appropriate for this population.
Results: A total of 591 prisoners were counseled and majority (N = 555) underwent FibroScan® exam, whereas 147 were tested for HCV. HCV testing was performed in individuals with known risk of exposition to infection. 23 prisoners were newly identified as HCV positive, while additional 12 prisoners previously knew of HCV infection and they were all linked to further specialist care. LSM results demonstrated considerable burden of liver disease: 26% were classified as F1 (5.6–7.0 kPa), 9% as F2 (7.1–9.5 kPa), 4% as F3 (9.6–14.5 kPa), 1% as F4 (≥14.6 kPa), while the rest had LSM within normal range (0–5.6 kPa). Furthermore, 19% of examined individuals exhibited CAP values ≥ 290 dB/m, indicating the high prevalence of moderate to severe hepatic steatosis.
Conclusion: The 2025 Croatian prison HCV micro-elimination program shows that persistent mobile outreach improves health awareness, early diagnosis, and linkage-to-care in a high-risk population. New and previously untreated HCV cases were identified and linked to care, and FibroScan® findings confirmed a notable burden of liver disease, supporting the integration of liver fibrosis and steatosis assessment into prison-based health programs. These results point out the importance of NGO sustained mobile services

and institutional support in advancing national HCV elimination goals.

FRI-007

Persistence of immune response and memory after infant hepatitis B vaccination: a systematic literature review

Bavithra Nathan[1], Volker Vetter[2], Maria Buti[3], Anna Maria Geretti[4], Pierre Van Damme[5], John Ward[6], Ike Iheanacho[7], Louis Lavoie[8], Frederik Verelst[2]. [1]*GSK, London, United Kingdom;* [2]*GSK, Wavre, Belgium;* [3]*Hospital Vall d'Hebrón, Barcelona, Spain;* [4]*Royal Free London NHS Trust, London, United Kingdom, University of Rome Tor Vergata, Rome, Italy;* [5]*University of Antwerp, Antwerp, Belgium;* [6]*Coalition for Global Hepatitis Elimination, Atlanta, United States;* [7]*Evidera, London, United Kingdom;* [8]*Evidera, Saint-Laurent, Canada*
Email: bavithra.x.nathan@gsk.com

Background and aims: Hepatitis B virus (HBV) infection can lead to serious long-term complications, including chronic disease, cirrhosis, and hepatocellular carcinoma. Since the 1990s, universal infant vaccination programs have dramatically reduced HBV incidence, but the duration of vaccine-induced immunity remains a key question for both policy and clinical practice. This systematic review summarizes existing evidence on the persistence of immune response and memory following infant HBV vaccination.
Method: Embase, MEDLINE, CENTRAL and grey literature were searched for studies published from Jan 2015 to Feb 2025 in immunocompetent individuals who completed primary HBV vaccination as infants (PROSPERO CRD420251068042). Studies reporting the proportion of individuals with antibody to HBV surface antigen (anti-HBs) ≥ 10 IU/L and anti-HBs titers at various time points after the primary series were included. The proportion with anti-HBs ≥ 10 IU/L was summarized as median % (range) across studies. Anti-HBs titers were summarized as median (interquartile range [IQR]; range) of the reported geometric mean titers. When a booster dose was administered, studies assessed anamnestic response 1 month later.
Results: We identified 110 studies and 461,616 participants who completed primary infant HBV vaccination. At 5–6 months after the primary series, the proportion with anti-HBs ≥ 10 IU/L was 92% (80–99), and median anti-HBs titer was 261 IU/L (IQR 194; range 29–558). At 1 year after the primary series, the proportion with anti-HBs ≥ 10 IU/L remained at 92% (66–100), but median anti-HBs titer decreased to 128 IU/L (IQR 171; range 19–200). The proportion with anti-HBs ≥ 10 IU/L progressively waned to 59% (42–76) at 5 ± 0.5 years, 54% (24–80) at 10 ± 1 years, and 37% (21–77) at ≥ 15 years. Similarly, median anti-HBs titer declined to 30 IU/L (IQR 14; range 16–38) at 5 ± 0.5 years, 30 IU/L (IQR 94; range 3–163) at 10 ± 1 years, and 7 IU/L (IQR 27; range 5–129) at ≥ 15 years. At the longest follow-up (29.5 years), the proportion with anti-HBs ≥ 10 IU/L was 39%. Of the primary series recipients with titers < 10 IU/L (at mean/median > 12 months after series completion), who received an additional dose of vaccine, 94% (79–100) achieved anti-HBs levels ≥ 10 IU/L.
Conclusion: Early protection after infant HBV vaccination is robust. Although anti-HBs titers decline over time, immune memory persists. Upon antigen re-exposure, anti-HBs titers rapidly restore.
Funding: GSK (VEO-001269).

Viral hepatitis B, C, and delta in Greenland: a national cross-sectional study

Carina Naustdal[1,2,3], Gerda Elisabeth Villadsen[4,5], Karsten Fleischer Rex[6,7], Henrik Krarup[7,8], Henning Grønbæk[4,5], Michael Lynge Pedersen[2,9], Rasmus Gantzel[2,4,5,10]. [1]*Section of Gastroenterology and Hepatology, Department of Medicine, Zealand University Hospital, Køge, Denmark;* [2]*Steno Diabetes Center Greenland, Nuuk, Greenland;* [3]*Queen Ingrid's Hospital, Center of Primary Health Care, Nuuk, Greenland;* [4]*Department of Hepatology and Gastroenterology, Aarhus University Hospital, Aarhus, Denmark;* [5]*Department of Clinical Medicine, Aarhus University, Aarhus, Denmark;* [6]*Department of Internal Medicine, Queen Ingrid's Hospital, Nuuk, Greenland;* [7]*Department of Clinical Medicine, Aalborg University, Aalborg, Denmark;* [8]*Department of Molecular Diagnostics, Aalborg University Hospital, Aalborg, Denmark;* [9]*Greenland Center for Health Research, Institute of Health and Nature, University of Greenland, Nuuk, Greenland;* [10]*Department of Medicine, Regional Hospital Gødstrup, Herning, Denmark*
Email: c.n.bagge@gmail.com

Background and aims: Viral hepatitis B infection is considered endemic in Greenland as in other Arctic areas. However, updated data are warranted after the implementation of screening, vaccination, and treatment programs during the past decades. We aimed to investigate the prevalence and disease characteristics of viral hepatitis B (HBV), C (HCV), and delta (HDV) in Greenland.
Method: We performed a cross-sectional nationwide study using data from the electronic medical records extracted from 2014–2023.
Results: We identified 299 patients with HBV- (positive of HBsAg) and 45 patients with HCV- (positive of HCV-Ab and/or HCV-RNA), corresponding to an overall low prevalence of 0.53% (95%-CI: 0.49–0.57%) and 0.08% (95%-CI: 0.06–0.11%), respectively. The prevalence of HDV co-infection (positive of HDV-Ab and/or HDV-RNA) among patients with HBV was 9.4%, of whom 82% were HDV-RNA positive, indicating ongoing infection. Most of these patients were middle-aged and male. Additionally, the occurrence of HBV and HCV was higher among women compared to men in the age category 20–39 years. The most recent liver biochemistry was within reference values among HBV-positive patients, while alanine and aspartate amino-transferase were slightly elevated among HCV-positive patients. A Fibrosis-4 score above 1.3 was observed in 28 (9%) with HBV, 2 (7%) of HBV-HDV positive patients, and 16 (36%) with HCV.
Conclusion: The prevalence of HBV infection through routine testing in the healthcare system was markedly lower than prevalences reported in previous population screening studies. Yet, HDV co-infection is common and warrants increased awareness. HCV is rare, but more of these patients have elevated liver enzymes and Fibrosis-4 score.

FRI-009

Re-engagement as a hepatitis b elimination strategy: a scoping review

Helen Nde[1], Brandon Eurich[1], Homie Razavi[1]. [1]*Center for Disease Analysis, Lafayette, CO, United States*
Email: hnde@cdafound.org

Background and aims: Loss to follow up (LTFU) limits care for people living with hepatitis B (PLWHBV) who are at higher risk for liver cancer-related mortality. Re-engagement reduces this risk and supports the World Health Organization's 65% mortality reduction target for PLWHBV. This study aims to assess the range and outcomes of re-engagement programs for LTFU PLWHBV implemented globally between 2015 and 2025.
Method: We searched PubMed for studies published between 2015 and 2025 which focused on identifying LTFU PLWHBV for re-engagement to care. Re-engagement was defined as attending a provider or laboratory appointment after outreach. We identified 4,702 potential studies and, after review to ensure outcomes were for LTFU cases only, included eleven.
Results: Seven countries and three WHO regions (EURO, PAHO, WPRO) were represented among the eleven studies. Median year of hepatitis B (HBV) diagnosis was 2017 and median study publication year was 2022. Ten out of eleven studies came from high income countries. Seven studies targeted the general population, three targeted immigrants and one targeted pregnant or post-partum women. Participant data came from medical record reviews in all studies except for two involving immigrants which used data sourced from registries. Six studies performed reviews to assess participant eligibility for outreach. Phone calls were the main means of outreach

occurring in seven studies. Spain (4,353), the Netherlands (3,240), and the United Kingdom (675) had the largest target populations. They also had the highest rates of outreach-ineligibility (72%, 82% and 79% respectively). Among the outreach-eligible, over 50% successful contact was recorded in six out of seven countries. Australia, Ireland, and Spain achieved 100% successful contact. The Netherlands (67%), the United Kingdom (48%) and French Guiana (42%) had the highest rates of contact failure. Median successful re-engagement was 52% and ranged from 2% in the Netherlands to 100% in Australia and Ireland. These results are analogous to preliminary outcomes from ongoing re-engagement programs for LTFU PLWHBV in the United States.

Conclusion: Results suggest re-engagement can support HBV elimination. However, available studies are not representative of the distribution of global HBV infections. Additionally, outreach ineligibility and contact failure indicate data management systems for PLWHBV must improve for both successful re-engagement and retention in care.

FRI-010-YI

Decentralised HBV, HCV, and HIV screening among migrant and refugee populations in Portugal and Spain: results from VH-COMSAVAC

Aina Nicolàs Olivé[1,2], Kiomi Barranco[1], Mariana Vicente[3,4], Laetitia[3], Luis Mendão[3,5,6], Inês Lopes Antunes[7], Francisco Antunes[8,9], Fábio Cota de Madeiros[8,10], Jeffrey Lazarus[1,11], Camila Picchio[1].

Email: aina.nicolas@isglobal.org

Background and aims: Migrants and refugees in Europe face increased risk of hepatitis B (HBV) and hepatitis C (HCV), yet structural and individual barriers limit access to testing and care. This study implemented decentralized approaches to offer HBV/HCV screening, HBV vaccination, and linkage to care among migrants and refugees in Portugal and Spain, while describing current infection patterns.

Method: From 11/22–12/25, the VH-COMSAVAC study offered decentralized HBV and HCV screening in Spain (Catalonia and Madrid) and Portugal (Lisbon) across non-clinical settings such as pop-up and mobile clinics, community and faith-based organizations, NGOs, and a Portuguese primary care centre. HIV screening was also offered in Portugal. Rapid HBsAg, anti-HCV and anti-HIV-1/2 tests were used, with expedited referral pathways to collaborating tertiary hospitals for participants with reactive results. Outreach services were facilitated by community health workers and intercultural mediators in Spain.

Results: A total of 1,337 individuals were screened, with an overall prevalence of 6.4% for HBsAg, 0.8% for anti-HCV, and 0.6% for anti-HIV-1/2. Participants were predominantly sub-Saharan Africans (74.2%), with a median age of 35 years (IQR 26–46), and 59.7% were recently arrived migrants (≤5 years). HBsAg+ and anti-HCV+ prevalences were similar in Portugal and Spain (7.6% vs 5.6%, $p = 0.145$, and 1.1% vs 0.6%, $p = 0.234$, respectively). Most HBsAg+ cases were among sub-Saharan African participants (96.5%), and 72.7% of anti-HCV+ participants were also among sub-Saharan Africans. HBsAg+ prevalence was significantly higher among men (8.5% vs 3.32%, $p < 0.001$) and recently arrived migrants (7.44% vs 3.73%, $p = 0.005$), while no statistical differences were observed among these groups for anti-HCV+ and anti-HIV-1/2+ prevalence ($p > 0.05$). In Spain, 71.1% of positive participants were linked to care, with legal barriers preventing linkage, whereas in Portugal 40.8% were linked, as many had been tested recently and have not yet attended follow-up care.

Conclusion: Migrants and refugees from high prevalence countries living in Portugal and Spain, carry a significant burden of viral hepatitis and HIV. Community-based and simplified screening models can improve access to screening and accelerate linkage to care by addressing linguistic, legal and administrative barriers. As a result, testing, diagnosis and care is increased among these underserved yet disproportionally affected communities.

10 year- experience from treatment as prevention for hepatitis C, a nationwide HCV elimination program in Iceland. Successes and new challenges

Sigurdur Olafsson[1], Anna Tomasdottir[2], Silja Olafsson[3], Valgerdur Runarsdottir[4], Ragnheidur Fridriksdottir[4], Agnar Bjarnason[2], Thorvardur J. Löve[1], Magnús Gottfredsson[1].
[1]Landspitali University Hospital, Faculty of Medicine, School of Health Sciences, University of Iceland, Reykjavik, Iceland; [2]Landspitali University Hospital, Reykjavik, Iceland; [3]Faculty of Medicine, School of Health Sciences, Reykjavik, Iceland; [4]SAA National Center for Addiction Medicine, Reykjavik, Iceland
Email: sigurdol@landspitali.is

Background and aims: The World Health Organization (WHO) set the goal of eliminating hepatitis C virus infection (HCV) as a major health threat by 2030. In 2016, a nationwide program, Treatment as Prevention for Hepatitis C (TraP HepC) was initiated in Iceland, offering treatment with direct acting antivirals (DAAs) without restrictions, including people who inject drugs (PWID). Screening and harm reduction was scaled up. During the first 3 years of the program > 95% of all diagnosed in the country received DAAs and the WHO service coverage targets were reached. The program has continued with emphasis on harm reduction, intense testing and outreach services. The aim was to analyse key outcomes from the TraP HepC program 2016–2025.

Method: Patient characteristics during the first three years of TraP HepC (1/2016–2/2019, period 1) were compared with data for 2021–2023 (period 2) and 2022–2024 (period 3) using nationwide clinical data. Prevalence of HCV among PWID was monitored.

Results: During period 1 (705 patients), mean age was 45, 89 (13%) were born outside Iceland. Ever injecting was reported by 84%, recent injection drug use (IDU) by 33%, 15% were homeless or living in a halfway house. Reinfections were 4.8% of new infections. Acute infections were 6% and 68% were treated at a university hospital. During period 2, the proportion of homeless/halfway-house residence had risen to 30%. Acute infections comprised 46%. During peroid 3, 43.6% were born outside Iceland, 29.6% were domestic new infections, 30.7% were reinfections and 28.5% were imported cases, diagnosed at immigration screening. The encounter site was university hospital 48.7%, outreach 20.7% and addiction treatment center 22.9%. Of all domestic infections 50.8% were reinfections and 95.1% had history of recent IDU. The prevalence of HCV among recently injecting prior to TraP HepC was 57%, decreased rapidly to 10.7% in 2018 and remained at 7–11% in 2019–2025.

Conclusion: Since initiation of TraP Hep C a dramatic change in the landscape of hepatitis C in Iceland has occurred. A rapid reduction in prevalence of HCV among PWID was observed in the first 3 years and has been maintaned. In spite of easy acess to harm reduction and DAAs, infections, especially reinfection rates remain high in a group of active IDU. Imported cases poses a further challenge to eliminaton efforts.

FRI-012

Low treatment rates observed in an analysis of the chronic hepatitis B care cascade at a tertiary medical center in a major metropolitan area in the US

Kevin Pak[1], Mei Leng[2], Steven-Huy Han[3]. [1]*Brooke Army Medical Center, Fort Sam Houston, United States;* [2]*David Geffen School of Medicine at UCLA, Los Angeles, United States;* [3]*Pfleger Liver Institute, Los Angeles, United States*
Email: kevin.pak528@gmail.com

Background and aims: Chronic hepatitis B (CHB) affects the lives of about 254 million people throughout the world and up to 1.89 million people in the US. The CHB care cascade describes the sequence of steps needed to diagnose and appropriately treat patients with CHB. Unfortunately, there remain major gaps in the care cascade in the US. Treatment rates in the US range from 30–60%. The aim of this study was to assess the CHB treatment rates at a tertiary medical system in Los Angeles.
Method: We conducted a retrospective analysis of all adult patients with CHB (positive HBsAg) across the entire UCLA database from 2013–2023. Of all HBsAg positive patients within this timeframe, we determined the number of patients who had an ALT and a HBV DNA level checked. We determined the number of patients with a HBV DNA level ≥ 2,000 IU/mL. Of the patients with a HBV DNA level ≥ 2,000 IU/mL, we determined the number of patients with an ALT > 60 U/L. From this pool, we determined the total number of patients on antiviral therapy with an indication for therapy per AASLD guidelines. We also identified patients with cirrhosis using ICD-9/10 codes and determined how many of these patients were started on treatment.
Results: Across all UCLA clinics from 2013–2023, there were a total of 3,384 patients with positive HBsAg. 3,320 patients had an ALT checked and 987 of these patients had an ALT > 60 U/L. Only 833 patients had a HBV DNA level checked and, of these, 252 patients had a HBV DNA level ≥2,000 IU/mL. 63 patients had an ALT > 60 U/L plus a HBV DNA ≥ 2,000 IU/mL. 511 patients had HBV-related cirrhosis. In total, 1,255 patients were on antiviral therapy (37.1%). 429 of 511 cirrhotic patients were on therapy (84%). 453 non-cirrhotic patients (54.8%) were on treatment within 6 months of being seen for the first time in the system.
Conclusion: From 2013–2023, the CHB care cascade at UCLA yielded a treatment rate of 37.1%, which is low but falls within the US range reported in prior studies. Treatment rates of cirrhosis patients were much higher (84.0%). While ALT was checked in 98.1% of patients, only 24.6% had a HBV DNA checked – a considerable gap which contributed to low treatment rates. Significantly more patients than were otherwise eligible received treatment. This can potentially be explained by a considerable number of patients being started on treatment prior to being referred and seen in the UCLA system and/or provider knowledge of treatment thresholds.

FRI-013

Prevalence and socioeconomics of hepatitis D virus coinfection in two Southern California counties

Kevin Pak[1], Mei Leng[2], Jeffrey Nguyen[3], Karine Moussa[3], Robert G. Gish[4], Steven-Huy Han[5], Paul Pockros[6]. [1]*Brooke Army Medical Center, Fort Sam Houston, United States;* [2]*David Geffen School of Medicine at UCLA, Los Angeles, United States;* [3]*Scripps Green Hospital, La Jolla, United States;* [4]*La Maestra Community Health Center, San Diego, United States;* [5]*Pfleger Liver Institute, Los Angeles, United States;* [6]*Scripps Clinic, La Jolla, United States*
Email: kevin.pak528@gmail.com

Background and aims: The global prevalence of Hepatitis D virus (HDV) is about 5%. There have been efforts to determine the HDV prevalence in the US; HDV is generally considered to be lower than that of other countries. HDV has been suggested to be more prevalent in lower socioeconomic status and immigrant individuals. Our aim was to determine the prevalence of HDV patients in three different healthcare systems based in San Diego (SD) County and Los Angeles (LA) County.
Method: We retrospectively reviewed the outpatient records of all adult chronic HBV patients screened for anti-HDV total antibody (HDV Ab) who were seen from 2010 to 2024 in the outpatient liver clinics at Scripps Clinic (SC) in La Jolla and La Maestra Clinic (LM) in SD, and from 2019 to 2023 in the Pfleger Liver Institute at UCLA. In patients with positive HDV Ab, the prevalence of detectable HDV RNA was then determined. We calculated the median household income by zip code for each service area, which was available through the US Census Bureau, to stratify all patients by socioeconomic status.
Results: At SC, 593 of 2,441 patients with CHB were screened for HDV. 14 patients tested positive for HDV Ab (2.4%). Two of the 14 patients with positive HDV Ab had detectable HDV RNA. At LM, 118 of 312 patients with CHB were screened for HDV. Three patients were positive for HDV Ab (2.5%). None had detectable HDV RNA. At UCLA, 234 of 267 HBV patients were screened for HDV. Ten patients had a positive HDV Ab (4.3%) and one patient had detectable RNA. Most patients screened at LM belonged to the lowest median income category ($75,281 per annum). Most patients screened at SC belonged to the middle median income group ($101,105 per annum). Most patients screened at UCLA belonged to the high ($117,023 per annum). There was no statistically significant difference in the prevalence of HDV Ab between cohorts of LM and SC, between SC and UCLA, and between LM and UCLA.
Conclusion: Of almost a thousand CHB patients who were screened for HDV, the prevalence of patients who tested positive for HDV Ab in three different healthcare systems between SD County and LA County ranged from 2.4–4.3%. There were no statistically significant differences of seropositivity rates among the three institutions. The screened patients from LM, SC, and UCLA were representative of low, middle, and high socioeconomic groups, respectively. This suggests that socioeconomic status may be less of a risk factor for HDV infection, particularly in this region of the country.

FRI-014

Advancing hepatitis C elimination in prisons: a state-specific modelling study of integrated harm-reduction and addiction interventions

Andrew Palmer[1,1,2], Aathavan Shanmuga Anandan[2], Matthew Carter[2], Ezaam Fraz[2], Paul Clark[1,2], Jason Connor[1,2], Gerald Holtmann[1,2], Naomi Runnegar[2], Geoffrey Playford[1,2], Jeremy Hayllar[3], Nick Scott[4], Farah Houdroge[4]. [1]*The University of Queensland Herston, Herston, Australia;* [2]*Princess Alexandra Hospital, Woolloongabba, Australia;* [3]*Biala Alcohol & Drug Service, Metro North, Brisbane, Australia;* [4]*Burnet Institute, Melbourne CBD, Australia*
Email: andrew.palmer@uq.edu.au

Background and aims: Australia has made major progress towards hepatitis C virus (HCV) elimination through direct-acting antivirals (DAA). However, ongoing transmission and injection-related infections (IRI) among people who inject drugs risk these gains. Prisons remain under-resourced environments where high-risk injecting persists, generating substantial downstream costs. While HCV testing and treatment are essential, treatment-focused approaches risk positioning DAA as the endpoint of care rather than as an entry point into harm-reduction and addiction treatment. We modelled the impact of integrated addiction interventions on HCV elimination, IRI, and health-system costs in Queensland (QLD) prisons.
Method: We developed a deterministic compartmental model calibrated to a large Australian prison system (QLD) using incarceration, epidemiological, and economic data. Prison inputs reflected QLD Corrective Services statistics, with 56% of people entering custody having a history of injecting drug use. HCV epidemiology was calibrated using QLD surveillance data. Hospital burden from IRI was informed by our own dataset describing 321 admissions over four years at a QLD hospital responsible for ~60% of prison-related IRI admissions statewide. We modelled three strategies across QLD

prisons from 2026–2030: prison needle and syringe programs (PNSP) alone, opioid agonist therapy (OAT) alone, and combined PNSP and OAT delivered as integrated care. Coverage increased to 10%, 30%, 50%, or 70%. Outcomes included HCV infections, incidence, IRI admissions, costs, and benefit–cost ratios (BCRs).
Results: Under status quo conditions, we projected 536 new HCV infections and 921 IRI-related hospital admissions between 2026 and 2030, with HCV incidence remaining at 2.6 per 100 person-years in 2030. At 50% coverage, PNSP alone averted 155 HCV infections and 154 IRI admissions (BCR 2.6), while OAT alone averted 55 HCV infections and 152 IRI admissions (BCR 1). Combined PNSP and OAT achieved the greatest impact, averting 188 HCV infections and 271 IRI admissions at 50% coverage and reducing incidence to 1.0 per 100 person-years (BCR 1.4). At 70% coverage, incidence declined to 0.5 per 100 person-years.
Conclusion: HCV elimination in prisons is unlikely to be achieved through DAA alone. Integrated harm-reduction and addiction care may improve HCV elimination, reduce IRI, and deliver net health-system benefits. Our findings have implications for others seeking to sustain HCV elimination gains.

FRI-015-YI
Predictors of hepatitis B infection and vaccination coverage in sub-Saharan Africa: case studies from Gabon and Mauritania using demographic and health survey data
Jodi Palmer[1], Jack Stone[1], Aaron G. Lim[1], Anna McNaughton[1], Kennedy Kipkoech[1]. [1]*University of Bristol, Bristol, United Kingdom*
Email: Uc24737@bristol.ac.uk

Background and aims: Hepatitis B virus (HBV) remains prevalent in sub-Saharan Africa (SSA), which accounted for approximately 63% of new HBV infections globally in 2022, largely driven by ongoing mother-to-child transmission (MTCT). The World Health Organisation (WHO) targets HBV elimination by 2030 via interventions including timely HBV birth dose (HepBD) and triple dose infant vaccination (HepB3), yet coverage remains low across SSA, where only 18% of newborns receive HepBD. Gabon, an upper-middle-income country with high urbanisation and health facilities, contrasts with Mauritania, a lower-middle-income country with largely rural populations. Whilst Gabon has not introduced HepBD, Mauritania adopted HepBD in 2013. This study estimates HBV prevalence, vaccination coverage, and predictors of vaccine uptake in both countries.
Method: We analysed Demographic and Health Survey (DHS) data from Gabon and Mauritania (2019–2021). Both included adult (≥15 yrs) hepatitis B surface antigen (HBsAg) prevalence and HepB3 coverage (0–59 mnths). Additionally, Mauritanian data included child/adolescent HBsAg prevalence (<15 yrs) and HepBD coverage (0–35 mnths). Weighted estimates and multivariable logistic regression analyses assessed demographic (age, sex), socio-economic (education, wealth), and healthcare-related (antenatal visits, facility delivery) predictors.
Results: Adult HBsAg prevalence was 5.4% in Gabon and 7.9% in Mauritania, and higher in men in both countries. Mauritania's child HBsAg prevalence was 1.2%, peaking at 10–14 years. HepB3 completion was suboptimal, with only 60.8% in Gabon and 61.7% in Mauritania receiving all three doses. In both countries, ≥4 antenatal visits and facility delivery strongly predicted completion of infant vaccination doses. In Mauritania, higher maternal education and wealth were associated with lower HBV prevalence and higher vaccine uptake. HepBD coverage in Mauritania was 73.3%, with lower uptake among those from poorer households, those delivered at home, and mothers reporting difficulty reaching health facilities.
Conclusion: HBV prevalence remains high in both countries, making elimination challenging. HepBD in Mauritania is likely contributing to reduced MTCT, but coverage remains uneven, reflecting persistent socioeconomic and health-system access barriers. Elimination strategies should target HepB3 completion across both settings, support Gabon's HepBD introduction, and enhance equitable delivery in Mauritania, particularly for infants born outside health facilities.

Email: mariabutiferret@gmail.com

Background and aims: Hepatitis D virus (HDV) infection remains underdiagnosed, and real-world data on screening and linkage to care are limited. We assessed the implementation of a double reflex HDV testing, linkage to care and treatment integrative program in all HBsAg-positive individuals in Catalonia.
Method: In this prospective multicenter study conducted from January 2024 to April 2025, all HBsAg-positive samples underwent reflex anti-HDV and HDV-RNA testing, with subsequent active linkage to care of individuals testing positive. Clinical data were extracted from electronic medical records. Patient characteristics, risk factors, and bulevirtide initiation were analyzed.
Results: Of 369,581 HBsAg determinations, 6100 were positive. Anti-HDV testing was completed in 5399 (89%), identifying 305 (5.6%) positive cases. HDV-RNA was assessed in 285 patients, with 86 (30%) viremic. Among 2945 first-time anti-HDV tests, 130 (4.4%) were positive and 26 (20%) viremic. Notably, 42% of positive patients had no recorded risk factors or elevated ALT. Prevalence varied by regions (2.3%–4.1%), and was highest in prisons, which also had a 14% HDV-RNA positivity rate. Viremic individuals were predominantly White, often from Eastern Europe, and more likely to have elevated ALT, cirrhosis, or previous pegIFN therapy. Newly diagnosed cases tended to be younger with milder disease. Among viremic individuals, 95% were linked to care and 43% initiated bulevirtide; while 57% remained untreated due to patient-related or reimbursement barriers. No incarcerated patients received bulevirtide, mainly because of complex social situations.

Conclusion: This large-scale public health intervention demonstrates that combining laboratory reflex testing with an active linkage-care strategy is feasible and very well accepted. Its favorable impact on patient care and public health has led to its integration into the Catalan Health System as standard practice. Although care engagement was high, treatment initiation remained limited by several barriers.

FRI-020

Epidemiological shift in hepatitis a seroprevalence among rural school children: insights from a community screening on viral hepatitis, nutrition, and early hepatic steatosis

Partha Sarathi Patra[1]. [1]*Bankura Sammilani Medical College And Hospital, Bankura, India*
Email: pratim.ptr@gmail.com

Background and aims: Amidst improving sanitation in rural India, the traditional high seroprevalence of hepatitis A virus (HAV) in children—historically exceeding 70% in school-aged groups—may be waning, potentially heightening outbreak risks in susceptible populations. This study sought to delineate current serological profiles for HAV, hepatitis B (HBV), and hepatitis C (HCV), alongside lifestyle behaviors, and noninvasive markers of hepatic steatosis in school children from a remote village, to inform targeted public health strategies.
Method: In a cross-sectional health screening initiative, 128 children (mean age 11.5 ± 1.5 years; 32.8% male) from three government schools underwent ELISA-based serological testing for anti-HAV IgG, HBsAg, and anti-HCV. Anthropometric assessments yielded body mass index (BMI) classifications adapted for pediatrics (<15 underweight; 15–22 normal; >22 overweight/obese). Questionnaires quantified daily outdoor play in minutes (<30 = A; 30–60 = B; 60–90 = C; >90 min = D) and daily mobile device use time in minutes (<30 = A; 30–60 = B; >60 = C), with values approximated for quantitative analysis. Hepatic fat was gauged via controlled attenuation parameter (CAP) using transient elastography (Fibro Touch). Data were summarized with means ± SD, percentages, and Spearman's correlations.
Results: Anti-HAV IgG seropositivity stood at 33.6% (43/128)—a strikingly low rate compared to prior national surveys reporting 75–85% in similar age cohorts—signaling a profound epidemiological transition. No HBV (HBsAg 0%) or HCV (anti-HCV 0%) cases emerged. Mean BMI was 18.9 ± 3.8 kg/m^2, revealing 18.0% underweight, 54.7% normal, and 27.3% overweight/obese children. CAP averaged 218.8 ± 34.9 dB/m, with 23.4% exhibiting mild steatosis (CAP >248 dB/m). Daily outdoor play averaged 59.8 min, contrasted by 31.2 min of mobile use; CAP correlated positively with screen time ($r = 0.54$, $p < 0.001$) and inversely with outdoor play time ($r = -0.74$, $p < 0.001$).
Conclusion: This screening unveils an unprecedented decline in HAV immunity among diverging from established high-endemic patterns and underscoring vulnerability to acute outbreaks. Coupled with absent chronic viral threats yet rising adiposity and steatosis—exacerbated by sedentary shifts—these revelations compel integration of HAV vaccination into India's national immunization schedule to safeguard this demographic. Broader adoption of school-based interventions promoting activity and nutrition could avert the nascent trajectory toward metabolic liver disease.

An optimized in-hospital management model enhances linkage to care for non-hepatology HBV-infected patients: interim analysis of Hot Wave Project 2.0

Chan Xie[1], Jia Chen[1], Qiumin Luo[1], Xin Song[1], Fangfang Wei[2], Zhongsi Hong[3], Liang Peng[1]. [1]*Third Affiliated Hospital of Sun Yat-sen University, Guangzhou, China;* [2]*Sixth Affiliated Hospital of Sun Yat-sen University, Guangzhou, China;* [3]*Fifth Affiliated Hospital of Sun Yat-sen University, Zhuhai, China*
Email: xchan@mail.sysu.edu.cn

Background and aims: A significant proportion of HBV-infected individuals in China remain undiagnosed or untreated. We aimed to evaluate whether an optimized in-hospital management model, emphasizing multi-disciplinary collaboration and patient education, improves linkage-to-care (LTC) and antiviral treatment (AVT) rates for HBsAg-positive patients identified in Non-hepatology departments.
Method: The "Hot Wave Project," initiated in 2022 at the Third Affiliated Hospital of Sun Yat-sen University (SYSU-3AH). Key interventions included collaboration between the Department of Hepatology and various clinical and administrative departments. The measures implemented were automated lab report alerts, establishment of dedicated HBV health clinics, varied patient education programs, and big data monitoring to facilitate professional consultation and treatment for HBV-infected patients. In April 2025, the model expanded to the Fifth Affiliated Hospital of SYSU (SYSU-5AH) and the Sixth Affiliated Hospital of SYSU (SYSU-6AH) as "Hot Wave Project 2.0,"featuring enhanced education plans, and call-back mechanisms. We compared data of HBsAg-positive patients from Non-hepatology departments between 2024 and January–September 2025 across these three centers.
Results: At SYSU-3AH, 15,201 HBsAg-positive patients were identified in 2024, with 9,065 receiving AVT (59.63%) and 2,716 referred to Hepatology (17.88%). From Jan–Sep 2025, among 13,686 identified patients, the AVT rate increased to 61.38% (8,140/13,686, $p = 0.002$), and the referral rate rose significantly to 27.72% (3,797/13,686, $p < 0.0001$). At SYSU-5AH, 6,044 and 4,311 patients were screened in 2024 and Jan–Sep 2025, respectively. The AVT rate improved from 20.14% (1,217/6,044) to 22.67% (978/4,311, $p = 0.002$), while the referral rate remained stable at 16.78% (1,014/6,044) versus 17.26% (744/4,311) ($p = 0.52$). At SYSU-6AH, the AVT rate increased significantly from 21.97% (1,121/5,103) to 35.40% (1,944/5,492) ($p < 0.0001$), and the referral rate improved from 2.12% (108/5,103) to 7.28% (400/5,492) ($p < 0.0001$).
Conclusion: The implementation of the Hot Wave Project 2.0 was associated with improved antiviral treatment uptake and referral rates for HBV patients in non-hepatology settings across multiple centers. The optimized referral system and education strategies demonstrate potential feasibility for expanding in-hospital HBV management coverage.

FRI-022

The impact of disability weights on the projected burden and prioritization of HBV in global health

Devin Razavi-Shearer[1], Chari Cohen[2], Jessica Hicks[3], Robert G. Gish[2], Catherine Freeland[2], Ivane Gamkrelidze[1], Samantha Hall[1], Kathryn Razavi-Shearer[1], Homie Razavi[1]. [1]*Center for Disease Analysis Foundation, Lafayette, United States;* [2]*Hepatitis B Foundation, Doylestown, United States;* [3]*World Hepatitis Alliance, Geneva, Switzerland*
Email: drazavishearer@cdafound.org

Background and aims: Disability-Adjusted Life Years (DALYs) help to prioritize health interventions, allocate resources, and guide policymakers to focus efforts where they're most needed. In Africa, there are an estimated 25.6 million people living with HIV, with 380,000 related deaths and 35.9 million DALYs being incurred. For malaria and tuberculosis (TB), the DALYs are estimated at 43.3 million and 17.8 million respectively. While HIV includes disability weights for every stage of the disease, traditionally HBV only has disability weights applied to severe and late-stage disease states. However, patient-focused and empirical evidence have shown that there is disability associated with living with HBV. We posit that the true impact of hepatitis B virus (HBV) is underprioritized based upon how HBV related DALYs are currently measured, leading to global de-prioritization. We utilized two different sets of utility weights, one from the Global Burden of Disease (GBD) and one from a recent Chinese study (Zhang et al, The Lancet Regional Health-Western

Pacific, 2023) to quantify the impact of different utility weights on the DALYs incurred in Africa.
Method: The Polaris Observatory's country specific PRoGReSs Models were utilized to create a regional model for Africa. These models included the impact of treatment, diagnosis, and prophylaxis programs. DALYs were calculated utilizing three different disability weights: GBD, Zhang 2023 with chronic HBV weights only applied to the diagnosed population, and Zhang 2023 with the disability weight for chronic HBV applied to the prevalent population.
Results: In Africa, it was estimated that there were 89.6 million people living with HBV and 361,000 deaths due to HBV. HBV-related DALYs increased from 6.9 million to 8.5 million to 27 million in 2025 depending on the utility weights.
Conclusion: Which disability weights are utilized and how they are applied has major ramifications for the DALYs associated with HBV and for where HBV lands in global health priorities. Currently, DALYs are low for HBV due to the DALY methodology being used. In Africa, HBV could be incurring higher number of DALYs than TB and only 8.9 million fewer than HIV. While further evidence would be useful, it is clear from multiple literature sources, and lived experience of HBV, that there needs to be disability weights applied to all stages of HBV disease to more accurately assess the burden, quality of life implications, and prioritization of HBV in Africa and globally.

FRI-023
Artificial intelligence-based hepatitis C screening: a real-world evidence analysis on Andalusian health database

Alberto Esteban Medina[1], Vanessa García-Fernández[2], Victor Manuel de la Oliva Roque[1], Carmen Lara-Romero[2,3], Carlos Loucera[1,4], Ana Lucena Valera[2,3], Joaquín Dopazo[1,4], Manuel Romero-Gómez[2,3,5]. *[1]Andalusian Platform for Computational Medicine, Andalusian public Foundation Progress and Health-FPS, Sevilla, Spain; [2]SeLiver Group. Instituto de Biomedicina de Sevilla (IBiS), Hospital Universitario Virgen del Rocío/CSIC/Universidad de Sevilla, Sevilla, Spain; [3]Servicio de Aparato Digestivo, Hospital Universitario Virgen del Rocío, Sevilla, Spain; [4]Institute of Biomedicine of Seville, IBIS, University Hospital Virgen del Rocio/CSIC/University of Sevilla, Sevilla, Spain; [5]Centro de Investigación Biomédica En Red De Enfermedades Hepáticas y Digestivas (CIBEREHD), Madrid, Spain*
Email: estebanm.alberto@gmail.com

Background and aims: The World Health Organization's (WHO) 2016–2021 strategy aimed to significantly reduce hepatitis C as a public health threat by achieving a 90% reduction in new infections, a 65% reduction in hepatitis C-related mortality, and treatment of 80% of detected cases by 2030. However, current approaches (Universal, by age group, or focused on patients at risk screenings) seem to be inefficient.
Method: Using Real World Data from the Andalusian Health Population Database (BPS) which contains electronic health records of more than 15 million patients, an AI-based predictive model was trained to identify undiagnosed hepatitis C cases. Several machine learning methods were assessed, with XGBoost (eXtreme Gradient Boosting) showing the most accurate results. For model training, we included 6,078 patients diagnosed with hepatitis C during the study period (2017–2022), along with a control group of 121,560 individuals with similar characteristics who tested negative for hepatitis C, developing PredictIA model.
Results: In a real-world scenario a sample of 200,000 random users of the Andalusian Public Health system were addressed with PredictIA model. Successful rate was 84% with a sensitivity of 0.15, significantly outperforming conventional screening strategies, which achieved no more than 0.007 sensitivity. A comparison of the predicted hepatitis C risk distribution across age groups with the actual diagnostic pattern revealed higher than expected potential detections outside conventional age-risk groups, mainly affecting women and individuals younger than 40 years. These cases would not have been identified through conventional screening. Among patients predicted to have hepatitis C infection, there were no significant differences in mean age or TSI category across probability groups: high (predicted probability >0.5; n = 213, 0.11%), moderate (predicted probability 0.1–0.5; n = 1,262, 0.63%), or low (predicted probability <0.1; n = 1,887, 0.94%).
Conclusion: The predictor developed constitutes a high precision, cost-effective screening model based on patient data already available in the health system, which clearly outperforms the conventional screening based on risk groups, by discovering one case every six selected individuals, while the conventional risk group strategy requires the screening of 143 individuals to find one case. This model will guide physicians in early detection and targeted testing, potentially advancing regional hepatitis C elimination efforts.

FRI-024
Prevalence of hepatitis B, and C in a cohort of transgender women living with HIV or on PrEP

Email: pabloryan@gmail.com

Background and aims: Transgender women (TGW), particularly those living with HIV or on pre-exposure prophylaxis (PrEP), may have unique risk factors for viral hepatitis. We aimed to assess the prevalence of hepatitis A, B, and C and liver enzyme abnormalities in this population.
Method: We conducted a cross-sectional analysis within a multicentre translational cohort of 185 transgender women in Madrid, Spain, involving HIV units, PrEP clinics, STI clinics, and gender identity clinics across different healthcare centres. After signing informed consent, demographic characteristics, risk behaviours, and medical history were collected. Serologic tests for hepatitis A (HAV), B (HBV), and C (HCV) were performed at baseline, with HCV RNA PCR testing if antibody positive. Liver transaminases (ALT, AST) were measured to evaluate liver injury. Prevalence of each viral hepatitis was calculated, and median liver enzyme levels were determined.
Results: Median age was 34 years (IQR 29–42); 90% were migrants (mainly Latin American) and 83% of Hispanic origin. Overall, 62% (114/185) were living with HIV and 38% were HIV-negative on PrEP. Receptive condomless anal intercourse was reported by 72.4%, and 74% had engaged in sex work in the previous six months. Injection drug use was uncommon (4%); alcohol use was reported by 55.9%, with problematic use in 11.3%. HCV seroprevalence was 1.1% (2/185), with one active infection (0.5%, RNA-positive). HBV infection was identified in two participants (1.1%), including one chronic HBsAg-positive case and one recent acute infection. No acute hepatitis A cases were observed during the previous 6 months. Liver enzymes

were mostly normal (median ALT 23 U/L; AST 25 U/L), although 15–16% had mild ALT elevation (>40 U/L). No cases of alcoholic or other chronic liver disease were identified; non-alcoholic fatty liver disease was observed in two participants (1.2%).
Conclusion: In our cohort, despite higher viral hepatitis prevalence than in the general population and substantial sexual risk behaviours, chronic hepatitis B and active hepatitis C prevalence remained low among transgender women in HIV/PrEP care.

FRI-025
The implementation of double reflex testing reveals a still relevant burden of HDV infection across Europe and represents a valuable strategy to increase HDV diagnosis at an earlier stage of liver disease

Email: rsalpini@gmail.com

Background and aims: Hepatitis D virus (HDV) causes the most severe viral hepatitis, however often remains underdiagnosed. Here, we investigate HDV screening and seroprevalence in a large set of HBsAg+ subjects and we report the characteristics of active HDV infection in Europe and the Middle-East before (2021–2023) and after (2024–2025) the implementation of double reflex testing (DRT, anti-HDV testing in all HBsAg+ subjects with unknown HDV serology and HDV-RNA if anti-HDV+ as per EASL guidelines).
Method: This multicenter study included 23927 HBsAg+ subjects from 21 hospitals in Europe (GB, CH, LU, DE, BE, SE, LT, ES, IT [N = 2], SI, HR, RO [N = 2], RS [N = 2], SK, BG) and the Middle East (IL, TR [N = 2]). The retrospective phase (2021–2023) evaluated 15170 HBsAg+ subjects while the prospective phase (2024–2025) implemented DRT in 8757.
Results: Subjects were 57.6% males, 92.3% HBeAg-negative, with median (IQR) age of 49 (39–61) years and only 29% under NUC-treatment. The rate of HDV screening strongly increased after DRT implementation from 58% to 94.5% (P < 0.001) (100% in 13 hospitals). HDV seroprevalence decreased after DRT implementation from 5.9% to 3.7% (P < 0.001). Notably, HDV-RNA testing raised from 80.7% to 94.7% (P < 0.001) while HDV-RNA positivity remained substantial (47% and 36.6%; P = 0.04), supporting a relevant circulation of active HDV infection. Overall, DRT increased anti-HDV detection by 36.5% (P < 0.001) and reduced the proportion of untested HDV-RNA cases to 5.4% compared to 19.3% (P < 0.01). Compared to 2021–2023, anti-HDV+ subjects diagnosed by DRT more frequently had ALT<40 U/l (66% vs 33.3%, P < 0.001) and a less advanced liver fibrosis (F0/F1 in 94% vs 33.8%, P < 0.001), supporting HDV detection in milder liver disease. In the 304 subjects with active infection, median (IQR) HDV-RNA was 5.5 (4.4–6.5) logIU/ml. Notably, compared to 2021–2023, subjects with active HDV infection detected by DRT had significantly lower HBsAg (2323 [1034–6109] vs 5158 [1740–11031] IU/ml), HBV-DNA (30 [0–2300] vs 131[16–2172] IU/ml), and ALT (46 [37–70] vs 79 [53–144] U/L) (P < 0.001 for all), supporting DRT as a valuable approach for an early HDV diagnosis, with lower cytolytic activity.
Conclusion: This study reveals a still relevant burden of HDV infection with an intense HDV replication across Europe. Implementing double reflex testing increases HDV case identification and enables diagnosis at earlier stages of liver disease, a critical step to strengthen linkage to care and reduce HDV-related morbidity and mortality.

FRI-026
Women's perspectives on care barriers in the setting of untreated HCV

Mai Sedki[1], Jennifer Price[1], Rena Fox[1]. [1]*University of California San Francisco, San Francisco, United States*
Email: rena.fox@ucsf.edu

Background and aims: Despite progress toward hepatitis C virus (HCV) elimination, many populations, particularly women, remain undiagnosed and untreated. Understanding patient experiences with HCV care is crucial to improving engagement. We conducted a mixed-methods study among women with untreated or incompletely diagnosed HCV to characterize prior care experiences, barriers to care, and patient-identified opportunities for improvement.
Method: Using electronic health record (EHR) at a large tertiary health system, we identified all women ≥18 years seen between 2020–2024 with either current HCV viremia or a reactive HCV antibody (Ab) without RNA testing. A navigator attempted phone contact, offered telehealth visits, and administered a structured

survey. The survey included Likert-scale assessments across seven domains of prior HCV care (testing, results, explanations, treatment offer, clinician time, courtesy and overall care) and free-response questions on barriers and suggested improvements. Quantitative data were summarized descriptively; and qualitative responses were coded thematically.
Results: The EHR query identified 248 eligible women; 130 were reached by phone, and 99 completed the survey (76%). Among respondents, mean age was 56.3 (15.9) years, 72% had public insurance, and participants were 61%White, 10%Latinx, and 7%Black. Forty-one percent were viremic, 34% were Ab-positive without RNA testing, only 8.1% had received antiviral therapy, and 12% had cirrhosis. Comorbidities included depression(26%), obesity(27%), and hypothyroidism(19%); only 16% had an established primary care provider. Survey responses revealed substantial dissatisfaction across the care cascade: 42% reported receiving no HCV care, and dissatisfaction rates were 41% for testing, 35% for receiving results, 40% for education, 46% for treatment offer, and 42% for clinician time. Over one-third reported barriers to care, with free responses emphasizing competing priorities, limited provider access, and fragmented follow-up.
Conclusion: Among women with untreated or incompletely diagnosed HCV who were reachable by phone, survey participation was high and revealed substantial gaps across the HCV care cascade. Structural and system-level barriers remain key drivers of disengagement, yet with dedicated efforts and flexible scheduling, we achieved high levels of patient engagement. Patient-identified priorities, including improved visit flexibility and clearer communication of results, may help advance progress toward HCV elimination.

FRI-027
Gaps between guidelines and clinical practice in hepatitis B virus reactivation prevention in non-hepatology immunosuppressive care
Hiroko Setoyama[1], Masatsugu Ohara[2], Satoru Kakizaki[3], Tatsuya Ide[4], Hirokazu Takahashi[5], Mizuki Endo[6], Tadashi Ikegami[7], Isao Hidaka[8], Yasuhito Tanaka[1], Masaaki Korenaga[9]. [1]*Department of Gastroenterology and Hepatology, Faculty of Life Sciences, Kumamoto University, Kumamoto, Japan;* [2]*Department of Gastroenterology and Hepatology, Hokkaido University, Sapporo, Japan;* [3]*National Hospital Organization Takasaki General Medical Center, Takasaki, Japan;* [4]*Kurume University, Kurume, Japan;* [5]*Saga University, Saga, Japan;* [6]*Oita University, Oita, Japan;* [7]*Tokyo Medical University Ibaraki Medical Center, Ibaraki, Japan;* [8]*Yamaguchi Saiseikai Hospital, Yamaguchi, Japan;* [9]*Research Center for Hepatitis and Immunology, National Center for Global Health and Medicine, Japan Institute for Health Security, Ichikawa, Japan*
Email: setoyama.h@me.com

Background and aims: Hepatitis B virus (HBV) reactivation is a potentially life-threatening but preventable complication of immunosuppressive therapy, for which HBV screening before treatment initiation is recommended by international guidelines. However, adherence to these recommendations remains inconsistent in non-hepatology settings. Orthopedic surgeons represent a group of physicians who frequently prescribe long-term corticosteroids and biologics associated with HBV reactivation risk, yet are not routinely involved in hepatitis care. This study assessed awareness of HBV reactivation prevention guidelines and adherence to recommended screening practices among orthopedic surgeons as non-hepatology prescribers.
Method: We conducted a multicenter cross-sectional survey as part of a national public health research program in Japan. An anonymous questionnaire was distributed to orthopedic surgeons practicing in eight prefectures. The survey assessed prescription of immunosuppressive therapies, awareness of HBV reactivation prevention guidelines, implementation of recommended HBV screening tests (hepatitis B surface antigen, hepatitis B surface antibody, and hepatitis B core antibody), and management of patients with positive screening results. Associations were analyzed using chi-square tests.
Results: A total of 567 orthopedic surgeons responded (response rate 28.8%). Among them, 294 (51.9%) reported prescribing immunosuppressive agents associated with a risk of HBV reactivation. Awareness of HBV reactivation prevention guidelines was reported by 120 physicians (40.8%). Complete HBV screening in accordance with guideline recommendations was performed by 136 physicians (51.1%) and was significantly more frequent among those aware of the guidelines than among those unaware ($p < 0.01$). Physicians in private practice demonstrated higher screening rates than hospital-based physicians ($p < 0.01$). Among respondents who encountered patients with positive screening results, 83.5% referred them to hepatology specialists.
Conclusion: Adherence to guideline-recommended HBV screening prior to immunosuppressive therapy in non-hepatology practice remains suboptimal, with limited guideline awareness identified as a key barrier. Given the high referral rate once infection is identified, enhanced guideline dissemination and systematic screening strategies may represent an effective public health approach to preventing HBV reactivation in non-hepatology immunosuppressive care, with potential applicability beyond Japan.

FRI-028
Real-world implementation of hepatocellular carcinoma surveillance after hepatitis C virus cure in Japan: a comparative analysis of performance indicators and a nationwide hospital-based database
Hiroko Setoyama[1], Shimakami Tetsuro[2], Yasue Takeuchi[3], Nobuharu Tamaki[4], Noriko Oza[5], Junko Tanaka[6], Yasuhito Tanaka[1], Tatsuya Kanto[7]. [1]*Department of Gastroenterology and Hepatology, Faculty of Life Sciences, Kumamoto University, Kumamoto, Japan;* [2]*Kanazawa University, Kanazawa, Japan;* [3]*Toranomon Hospital, Tokyo, Japan;* [4]*Musashino Red Cross Hospital, Musashino, Japan;* [5]*Karatsu Red Cross Hospital, Saga, Japan;* [6]*Hiroshima University, Hiroshima, Japan;* [7]*Research Center for Hepatitis and Immunology, National Center for Global Health and Medicine, Japan Institute for Health Security, Ichikawa, Japan*
Email: setoyama.h@me.com

Background and aims: According to international recommendations, patients with chronic hepatitis C virus (HCV) infection remain at risk of hepatocellular carcinoma (HCC) after achieving sustained virological response (SVR), and regular surveillance is recommended, particularly in those with advanced fibrosis or cirrhosis. However, real-world implementation of post-SVR HCC surveillance remains unclear. This study aimed to evaluate real-world patterns of post-SVR HCC surveillance and to compare them with reference standards of care derived from established clinical practice at designated regional core centers for liver disease management.
Method: We conducted a retrospective cohort study using a nationwide Japanese hospital-based administrative database (JMDC; 34,249,126 individuals). Patients with chronic HCV who achieved SVR after direct-acting antiviral therapy between 2014 and 2024 were included. Post-SVR HCC surveillance was assessed based on the frequency and interval of imaging examinations and tumor marker measurements. Reference surveillance was defined as imaging examinations performed at approximately 6-month intervals, with or without tumor marker testing, reflecting clinical practice in Japan. Real-world practice was compared with reference standards of care, defined as established post-SVR HCC surveillance practices based on predefined national hepatitis clinical indicators used in designated regional core centers serving as the hubs of regional liver disease care networks.
Results: A total of 19,186 patients who achieved SVR were included. During the first 6 months after SVR, imaging surveillance was not performed in 29.1% of patients and tumor marker measurements in 21.6%; during months 6–12 after SVR, the corresponding proportions

were 26.8% and 26.8%, respectively. Among patients undergoing surveillance, the median interval was approximately 180 days. Surveillance adherence was higher among patients with cirrhosis; however, only about 80% underwent any imaging surveillance within 1–3 years after SVR. In contrast, regional core centers demonstrated high adherence to these reference standards of care, with imaging surveillance performed in 98.6% of patients and tumor marker measurements in 97.8%.
Conclusion: These findings demonstrate a substantial gap between real-world surveillance practices after HCV cure and reference standards of care, particularly among patients with cirrhosis, highlighting the need for improved risk-based follow-up strategies.

FRI-029
Long term health and economic impact of a successful national hepatitis C elimination program: a model-based evaluation using real-world post-SVR outcomes
Gamal Shiha[1], Nabiel Mikhail[2], Ayman Hassan[3], Ahmed Farahat[4], Abdelhamid A Serwah[5], Reham Soliman[6]. *[1]Egyptian Liver Research Institute and Hospital, Gastroenterology and Hepatology Unit, Internal Medicine Department, Faculty of Medicine, Mansoura University, Shirbin, Mansoura, Egypt; [2]Egyptian Liver Research Institute and Hospital (ELRIAH), Biostatistics and Cancer Epidemiology Department, South Egypt Cancer Institute, Assiut University, Sherbin, El Mansoura, Egypt; [3]Egyptian Liver Research Institute and Hospital (ELRIAH), Medical Laboratories Department, Higher Technological Institute of Applied Health Sciences, Sherbin, Mansoura, Egypt; [4]Egyptian Liver Research Institute and Hospital (ELRIAH), Sherbin, El Mansoura, Egypt; [5]Internal Medicine Department, Suez Canal University, Suez, Egypt; [6]Egyptian Liver Research Institute and Hospital (ELRIAH), Technical institute of Nursing, Sherbin, El Mansoura, Egypt*
Email: g_shiha@hotmail.com

Background and aims: Direct-acting antivirals (DAAs) achieve sustained virological response (SVR) and substantially reduces hepatocellular carcinoma (HCC), hepatic decompensation, and liver-related mortality. While model-based analyses have projected the cost-effectiveness of hepatitis C elimination, empirical evidence quantifying its real-world long-term health and economic impact after nationwide implementation remains scarce. This study presents one of the first ex-post macroeconomic evaluations of a national HCV elimination program, using decade-long real-world post-SVR outcomes.
Method: We performed a model-based cost-consequence and health-economic evaluation from the healthcare payer perspective, considering direct medical costs only. Real-world post-SVR incidence rates for hepatocellular carcinoma (HCC), decompensated cirrhosis, and mortality were derived from a prospective cohort. Outcomes were extrapolated to the national treatment population using a 10-year analytic horizon (2015–2025). A counterfactual scenario was built using published natural history estimates for untreated HCV. Mortality benefit was monetised using value-of-life-years-gained, valuing each life-year at one GDP per capita. Sensitivity analysis and discounting were applied. Conservative and high-impact scenarios were explored. Analyses followed CHEERS 2022 guidelines.
Results: Without DAA therapy, five million chronically infected individuals would have been expected to develop 0.24–0.84 million HCC cases and 0.58–1.05 million decompensation events over ten years. Incorporating real post-SVR outcomes, national treatment markedly reduced advanced liver disease. Estimated healthcare savings from prevented complications reached 70–350 billion Egyptian pounds (EGP). Mortality reduction yielded 2.0–5.0 million life-years gained, valued at 200–500 billion EGP. Total economic benefit was therefore 270–850 billion EGP over 2015–2025.
Conclusion: Our findings confirm that hepatitis C elimination is not only a major public health success but also one of the most economically rewarding health interventions implemented in national programs. By translating real-world, decade-long post-SVR clinical outcomes into absolute numbers of events prevented, lives saved, and money preserved, this analysis quantify the realised return on national investment.

Synergistic effect of diabetes and hypertension on the risk of liver disease progression in hepatitis B virus infection
Laura E. Telep[1], Lesley Patmore[2], Lai San Hong[3], Amanda Singer[1], Leland J. Yee[1], Catherine (Carrie) Frenette[1], Milan J. Sonneveld[2]. *[1]Gilead Sciences, Foster City, United States; [2]Erasmus University Medica Center, Department of Gastroenterology and Hepatology, Rotterdam, Netherlands; [3]Redsen Limited, Tring, United Kingdom*
Email: laura.telep@gilead.com

Background and aims: Recent studies have reported an association between metabolic comorbidities (MCs) and adverse liver outcomes among individuals with hepatitis B virus (HBV) infection. The extent to which MCs interact to confer additional risk remains unclear. We compared the risk of liver-related events (LREs; compensated and decompensated cirrhosis, hepatocellular carcinoma, liver transplant) among individuals with HBV infection who have evidence of hypertension (HTN), diabetes mellitus (DM), obesity (OBS), or hyperlipidemia (HLD) individually, and in combination, to individuals with HBV and no evidence of MCs to better understand the combined risk associated with metabolic conditions.
Method: This observational study used US administrative claims data (HealthVerity Marketplace™; Oct 2015–Aug2025) from adults (18+ years) with chronic HBV infection (index date set to first inpatient or first of two outpatient HBV claims). Patients were excluded if there was evidence of LREs or other forms of chronic liver disease, or human immunodeficiency virus infection, prior to index. MCs were identified using all available data on or before index date. Incidence of an LRE during follow-up was compared among those with individual MCs vs. no MC and among pairs of MCs vs. no MC. Overlap-weight adjusted hazard ratios (HRs) were estimated, and unadjusted relative risk ratio (RRR) and relative excess risk due to interaction (RERI) were calculated to quantify multiplicative and additive interaction.
Results: Six pairs of MCs were studied: DM/HTN, DM/OBS, DM/HLD, HTN/OBS, HTN/HLD, and OBS/HLD. While most pairs indicated some interaction on both multiplicative and additive scales, DM/HTN together showed a pronounced synergistic effect; the joint risk of LREs was (HR[95%CI]: 1.49 [1.33–1.67]) and the individual associations of DM and HTN were: DM HR; 1.07 [0.88–1.29]); HTN HR; 1.16 [1.05–1.28]). The RRR was 1.73 (95%CI: 1.41–2.12) which indicates a risk 73% higher than expected if the DM and HTN were independent, and the RERI was 0.95 (95% CI: 0.70–1.20) where a value > 0 represents excess risk.
Conclusion: In this study of individuals with HBV and MCs in US claims data, we observed a synergistic effect where individuals with both DM and HTN had a greater risk of LREs than individuals with either DM only or HTN only. Our findings highlight the need to monitor and appropriately manage HBV patients for these comorbidities.

FRI-031
Predictors of advanced liver disease events among individuals with hepatitis delta infection in a large United States administrative claims dataset: a machine learning analysis
Laura E. Telep[1], Lai San Hong[2], Bo Zhao[1], Ziwei Yin[1], Jordan Guillot[3], Amanda Singer[1], Robert Wong[4]. *[1]Gilead Sciences, Foster City, United States; [2]Redsen Limited, Tring, United Kingdom; [3]University of California, San Francisco, Bakar Computational Health Sciences Institute, San Francisco, United States; [4]Stanford University Medical Center, Division of Gastroenterology and Hepatology, Palo Alto, United States*
Email: laura.telep@gilead.com

Background and aims: Hepatitis delta virus (HDV) is the most aggressive form of viral hepatitis and is associated with rapid progression to adverse liver outcomes. Early detection and risk-

stratification can help target patients for closer monitoring and urgent treatment. This study aimed to develop a machine learning (ML) model to predict liver-related events (LRE)—a composite of cirrhosis, hepatocellular carcinoma, and liver transplant—within 5 years among adults with HDV infection in the United States (US).

Method: Using HealthVerity (HV), a large US claims dataset, we identified adults (18+) with 1 in-patient or 2 out-patient claims for HDV (Oct 2015–Sep 2025) and no LRE prior to the first HDV claim (index date). The cohort was stratified by those who developed an LRE vs. not during follow-up. The R package automl trained a model with an 80/20 train/test split and 5-fold cross validation using demographic, dispensing, and comorbidity data from 6 months pre-index to 5 years post-index. The probability threshold that maximized the F1 score (harmonic mean of precision and recall) predicted individuals who would develop an LRE. The model with the greatest area under the precision-recall curve (AUPRC) relative to baseline LRE prevalence was selected. Features contributing most to prediction were identified as potential LRE risk factors.

Results: Among n = 8,955 individuals with HDV (45% male, mean age 45 years), the stacked ensemble model demonstrated the highest performance, yielding an F1 score of 0.61 at a prediction threshold of 0.26—individuals with a predicted LRE risk ≥26% were classified as positive. Precision was 55%, recall was 69%, and AUPRC was 0.63, representing an 11.6-fold improvement over LRE prevalence (5.4%). Overall accuracy was 95%. These metrics indicate that 55% of predicted positives were true cases, and 69% of actual LRE cases were identified. Features most predictive of LRE included hepatitis C virus (HCV) infection, hypertension, acute renal insufficiency, and demographic factors such as age and sex.

Conclusion: The ML model achieved an AUPRC of 0.63 with 95% accuracy in predicting LRE within 5 years in a real-world HDV cohort. HCV, hypertension, and renal insufficiency emerged as key predictors. Continued refinement and evaluating predictors of individual LRE outcomes will provide valuable tools to help clinicians identify HDV patients at highest risk for advanced liver disease, enabling earlier intervention, closer monitoring, and more informed treatment decisions.

FRI-035

Community-based dried blood spot testing reveals substantial progress towards hepatitis C virus elimination in people who inject drugs in Catalonia

Department of Psychobiology and Methodology in Health Sciences. Universitat Autònoma de Barcelona (UAB), Bellaterra, Spain
Email: emartro@igtp.cat

Background and aims: As part of the Plan for the Prevention and Control of Hepatitis C in Catalonia, the REDAN study, a periodical bio-behavioural survey, monitors HCV and HIV epidemics since 2008 in people who inject drugs (PWID) accessing harm reduction centres (HRCs). Previously, serological markers were determined in oral fluid samples. For the first time in REDAN, dried blood spot (DBS) collection was implemented for serological and molecular testing in 2024. The objectives were to estimate HCV seroprevalence and viremic prevalence, and describe the HCV care cascade in comparison with previous data to assess progress towards the WHO 2030 elimination targets.

Method: A cross-sectional study was conducted among PWID (injection within the previous 6 months) accessing 15 HRCs in Catalonia (October 2024–February 2025). Participants completed an epidemiological questionnaire. 287 DBS samples were collected and tested for HCV-Ab and HIV-Ag/Ab (DiaSorin), and for HCV-RNA (Abbott Molecular). The HCV care cascade was estimated on the total PWID population accessing HRCs in Catalonia (N = 2080) by combining DBS results with self-reported data. Proportions were compared to DBS results from the HepC*detect* II study (2016–17) in 4 HRCs.

Results: Overall, 15.3% of participants were females, 46.5% were migrants, 23% were homeless and 37% reported sharing injection equipment. HCV seroprevalence declined from 79.8% to 54.6% and viremic prevalence from 58.5% to 19.2%. HIV co-infection increased from 25.7% to 48.1% of viremic HCV cases. Regarding the HCV cascade of care, treatment uptake and cure markedly increased (from 31.9% to 76.2% and 17.7% to 57.4%, respectively). All these differences were statistically significant ($p < 0.01$). Among those ever treated, 24.7% were currently viremic.

Conclusion: HCV infection among PWID attending HRCs in Catalonia has significantly decreased over the last 7 years, highlighting the impact of micro-elimination test-and-treat strategies implemented, and demonstrating progress towards HCV elimination by substantially closing the treatment gap (76.2% vs 80% WHO elimination target). However, the proportion of viremic cases among previously treated individuals, together with injecting risk behaviours, underscores the need for sustained monitoring for reinfection. DBS-based HCV and HIV testing provides a valuable tool for community-based surveillance, supporting its sustained use and potential extension to other vulnerable populations.

FRI-036

Identifying and re-engaging hidden hepatitis C cases through registry linkage in primary care: a population-based intervention in Catalonia

Elena Torrell-Pedreira[1], Sandra Manzanares[1], Renata Briseño[1,2], Xavier Major[1], Ariadna Mas[3], Elisabet Balló[4], Rafael Ruiz[3], Jordi Casabona[5], Joan Colom[1], Luisa Conejos[1]. *[1]August Pi i Sunyer Biomedical Research Institute, Subdirectorate General of Addictions, STIs, HIV and Viral Hepatitis, Public Health Agency of Catalonia, Barcelona, Spain; [2]August Pi i Sunyer Biomedical Research Institute (IDIBAPS), Barcelona, Spain; [3]Subdirectorate for Health Planning and Research, Government of Catalonia, Barcelona, Spain; [4]Primary Care Services Information System, Catalan Institute of Health (Catsalut), Department of Health, Catalonia, Barcelona, Spain; [5]Centre for Epidemiological Studies on Sexually Transmitted Infections and HIV/AIDS of Catalonia (CEEISCAT), Barcelona, Spain*
Email: elena.torrell@gencat.cat

Background and aims: Achieving hepatitis C virus (HCV) elimination by 2030 requires closing gaps in the cascade of care, particularly among individuals diagnosed but not linked to treatment. In settings with comprehensive health information systems, administrative data linkage offers an opportunity to systematically identify these hidden cases. We evaluated a population-based pilot strategy using healthcare registry linkage to identify and re-engage untreated HCV cases through primary care in Barcelona, Catalonia.

Method: A cross-sectional linkage was performed between the Minimum Basic Data Set (CMBD) of the Catalan Health Service and the Registry of Patients Treated (RPT) to identify individuals with a recorded diagnosis for chronic or unspecified hepatitis C and no registered treatment as of December 31st, 2021. Lists of potentially untreated cases were integrated into the electronic health records of general practitioners (GPs) in 52 primary care teams in Barcelona. Between 2022 and 2024, physicians reviewed each case, classified clinical status, and implemented appropriate actions. Treatment initiation was assessed through a second linkage with the RPT as of December 31, 2024. An ongoing evaluation includes a repeated linkage to compare patient lists before and after the intervention and a sociodemographic characterization of treated cases to identify factors associated with successful linkage to care.
Results: Among 5,948 identified cases with a HCV diagnostic and no recorded treatment, (84.8% were reviewed by their GPs. Clinically relevant status requiring action were identified in 24% (n = 1.212) of reviewed cases, including untreated HCV infection (49%), unconfirmed HCV infection (44%), and previously treated but uncured infection (6%). Clinical actions were documented in 11% (n = 602)of reviewed cases, including referral to hepatology, HCV diagnostic testing, or referral for rescue treatment. Overall, 151 individuals initiated antiviral therapy, representing 3.0% of reviewed cases. Additionally, 25% of cases initially classified as active HCV infection were corrected or removed from the administrative registry.
Conclusion: Linking administrative diagnostic and treatment registries with primary care clinical management enables systematic identification, diagnostic validation, and treatment initiation among hidden HCV cases at scale. The model demonstrates the value of primary care–led, population-based approaches and is being expanded across Catalonia to support HCV elimination goals.

FRI-037

Cross-sectional testing for diagnosing asymptomatic BBV (Blood Borne Virus: HIV, HBV, HCV) infection; HBV infection is being eliminated in Japan

Haruka Uemura[1], Daisuke Mizushima[1], Daisuke Shiojiri[2], Akira Kawashima[1], Eri Inoue[1], Naokatsu Ando[1], Takato Nakamoto[1], Yasuaki Yanagawa[1], Takahiro Aoki[1], Katsuji Teruya[1], Hiroyuki Gatanaga[1]. *[1]Japan Institute for Health and Security, Tokyo, Japan; [2]Personal Health Clinic, Tokyo, Japan*
Email: uemura.h@jihs.go.jp

Background and aims: To eliminate BBV (Blood Borne Virus: HIV, HBV and HCV) infection as a public health threat, it is important to diagnose asymptomatic BBV infection. To diagnose BBV infections often overlooked in routine clinical practice, we conducted cross-sectional BBV screening at HIV and STI (Sexually Transmitted Infection) clinics.
Method: We evaluated the number of BBV diagnoses made during routine care over a 3-month period at each medical institution attended by three high-risk groups for STIs in Japan (HIV-positive individuals, HIV-negative men who have sex with men: MSM, and HIV-negative women visiting STI clinics). Over the subsequent 2-month period, we tested individuals who provided consent for HBs antigen (HBs-Ag), HBs antibody (HBs-Ab), HBc antibody, HCV antibody and HIV antigen/antibody. Medical records were retrospectively reviewed to compare the HBs antigen positivity rate at the initial visit by calendar year.
Results: During the routine care period, 662 HIV-positive individuals, 783 HIV-negative MSM, and 762 HIV-negative women visited each clinic, and no new BBV infections were diagnosed. During the cross-sectional testing period, 370 HIV-positive individuals (HIV group), 693 HIV-negative MSM (MSM group), and 150 women (women group) participated in the study. Among them, 3 new HCV infections were diagnosed in the HIV group, one new HBV infections and one new HIV infection were diagnosed in the MSM group, and no BBV were diagnosed in the women group. Among the HIV and MSM groups, 188 cases (50.8%) and 355 cases (51.2%) were HBs-Ab negative, and of these, 183 and 186 cases were taking regimens containing nucleoside analogues for HIV antiviral therapy (ART) or prophylaxis (PrEP: pre-exposure prophylaxis) respectively. Patients not taking nucleoside analogs and considered high-risk for HBV infection accounted for 5 (1.4%) in the HIV-infected group and 169 (24.4%) in the MSM group. The HBs-Ag positivity rate at initial visit in the HIV group showed a decreasing trend at 11.0%, 8.4%, 8.0%, 6.8%, 5.3% and 5.3% in 1997–2001, 2002–2006, 2007–2011, 2012–2016, 2017–2021 and 2022–2025, respectively.
Conclusion: The prevalence of BBV infection was low among high-risk groups for STIs in Japan, but cross-sectional testing identified several new BBV cases. In Japan, HBV infection among HIV-infected individuals has been decreasing over time over the past 30 years. The use of nucleoside analogues for ART in HIV patients and for PrEP in HIV-risk populations is expected to further reduce HBV infection.

FRI-038

European emergency department screening shows progress toward HCV elimination

Email: mariabutiferret@gmail.com

Background and aims: Curative direct-acting antivirals (DAAs) for HCV became available in 2016. In the same year, the World Health Organization set the goal of eliminating viral hepatitis as a public health threat by 2030. We analysed trends in HCV-RNA and HBsAg prevalence over time using data generated through systematic

emergency department (ED) testing initiatives, in order to assess their utility for monitoring progress toward viral hepatitis elimination in Europe.
Method: We reviewed published European ED HCV and HBV testing studies between 2005 and 2025. We calculated temporal trends in the proportion of HCV-RNA-positive among those individuals testing HCV-antibody positive (Ab+) (RNA+/Ab+) and recorded the prevalence of HBsAg+. Studies including fewer than 30 Ab+ or HBsAg+ individuals were excluded. For studies spanning multiple years, we contacted study authors. Where available, data were grouped by year.
Results: 16 ED screening studies were included (9 from England, 4 from Spain, 2 from Ireland, and 1 from Germany), conducted between 2008 and 2024. In total 1,851,715 adults were screened for HCV Ab, 25,903 were HCV Ab+, and of those 4,243 HCV-RNA+. Data from several years were available from Spain, England and Ireland. Over the study period, we observed a statistically significant decrease in the proportion of viraemic HCV infection (RNA+/Ab+). The proportion of active infection across Europe decreased from 72%, carried out in earlier years prior to DAA availability to 9% in the most recent ones in 2023 (broad DAA access since 2018), ($R^2 = 0.64$; beta = –4.6; $p < 0.001$). 10 studies reported HBV screening data, 1,426,843 were screened, and 10,491 HBsAg+. In contrast to HCV, the proportion of HBsAg-positive patients among those screened remained largely stable over the period, ranging from 0.47% to 0.55%.
Conclusion: The decline in viremic cases among HCV-Ab+ individuals identified through ED testing across Europe likely reflects the impact of broad DAA access driven by HCV elimination initiatives. In contrast, HBV prevalence remains stable. This simple approach, using routinely available HCV RNA and antibody data, enables monitoring of time trends and site comparisons.

FRI-039
Why screen hepatitis C alone? Integrated hepatitis B and hepatitis C screening reduces liver related complication and is cost effective: a model-based cost effectiveness analysis
Sai Praveen Jonnalagadda[1], Feng Tian[1], William WL Wong[1]. [1]*School of Pharmacy, University of Waterloo, Kitchener, Canada*
Email: wwlwong@uwaterloo.ca

Background and aims: One-time hepatitis C screening has expanded in many jurisdictions to link undiagnosed individuals to curative direct acting antivirals. Hepatitis B, despite its global burden and risk of progressive liver disease, is often overlooked even though suppressive therapy reduces complications. Integrating hepatitis B into hepatitis C screening can leverage shared populations, unified testing, streamlined care navigation, detection of coinfection, and prevention of hepatitis B reactivation during antiviral therapy. This study evaluates the cost effectiveness of offering a single lifetime screen for both hepatitis B and hepatitis C compared with hepatitis C only screening.
Method: We developed a multi disease agent based model to represent hepatitis B and hepatitis C epidemics in Ontario, Canada. The model simulates transmission within and between networks of people who inject drugs, men who have sex with men, and heterosexual populations, and tracks diagnosis, linkage to care, treatment, and disease progression. Two strategies were compared: hepatitis C screening alone and combined hepatitis B and hepatitis C screening, using a cost utility framework. Simulations included the entire Ontario population, stratified by age, sex, and risk behaviors. Parameters were derived from peer reviewed studies and Ontario health administrative data. The economic evaluation was conducted from the Ontario Health payer perspective for 2025 to 2050, with costs and utilities discounted at 1.5% annually. Outcomes included advanced liver disease and liver related deaths prevented, quality adjusted life years (QALYs), total costs, and incremental cost effectiveness ratios (ICERs).
Results: The model reproduced historical trends in chronic hepatitis B and C, cirrhosis, and hepatocellular carcinoma. Combined screening reduced decompensated cirrhosis and hepatocellular carcinoma incidence by 19% and 13%, respectively, and lowered liver related deaths by 13%. Compared with hepatitis C screening alone, combined screening increased costs by 29.5 million dollars but yielded 2,759 additional QALYs, resulting in an ICER of $10,693/QALY, well below the conventional $50,000/QALY threshold.
Conclusion: This is the first study to apply a dynamic multi disease agent based model to evaluate combined hepatitis B and hepatitis C screening in Ontario. Findings support integrated screening and linkage to care to identify undiagnosed individuals, improve outcomes, guide policy, and advance elimination targets.

FRI-040
Adaptive and simplified model of relinking HCV-Ab positive patients to care in China: a real-world study from Yunnan province
Changhui Wu[1], Chunmei Li[1], Mei Li[2], Ruiling Hui[3], Ruiling Liu[4], Fei Wang[5], Qiong Yang[6], Shuangying Duan[7], Huaiyan Fan[8], Huiyong Su[9], Changxian Lu[10], Shun Feng[11], Wei Yue[12], Yuhua Shi[13], Hui Li[1], Jia Wei[1]. [1]*The Affiliated Hospital of Yunnan University, Kunming, China;* [2]*The People's Hospital of Fuyuan County, Qujing, China;* [3]*Qujing central hospital of Yunnan Province, Qujing, China;* [4]*Xuanwei No.1 Hospital, Xuanwei, China;* [5]*The People's Hospital of Kaiyuan City, Kaiyuan, China;* [6]*Dehong Hospital of Traditional Chinese Medicine, Dehong, China;* [7]*Tengchong People's Hospital, Tengchong, China;* [8]*Zhaotong First People's Hospital, Zhaotong, China;* [9]*Dali Prefecture People's Hospital, Dali, China;* [10]*The People's Hospital of Lincang, Lincang, China;* [11]*Puer People's Hospital, Puer, China;* [12]*The First People's Hospital of Yunnan Province, Kunming, China;* [13]*Yunnan Center for Disease Control and Prevention, Kunming, China*
Email: weijia@ynu.edu.cn

Background and aims: To develop an adaptive, simplified relinking model for HCV antibody-positive individuals and improve hepatitis C diagnosis and treatment rates in China.
Method: This study was conducted in two phases.
Retrospective Phase: Collaborating with Centers for Disease Control and Prevention (CDC), we retrospectively analyzed patients who had HCV infection between 2004 and 2021. Demographic and clinical disparities between treated and untreated cohorts were compared to construct a predictive model. Prospective Phase: Since 2024, with the provincial CDC, we launched educational campaigns across all prefectures, focusing on enhancing patient education among priority populations. By optimizing patient relinking strategies, we facilitated the re-engagement of HCV antibody-positive but untreated patients across the province. Changes in HCV RNA screening rate, HCV RNA positivity rate, and treatment initiation rate were recorded.
Results: A total of 5,506 HCV antibody-positive and/or HCV RNA-positive patients were enrolled in the retrospective phase. Statistical modeling revealed that the proportion of patients declining treatment was significantly higher among the following subgroups: young individuals (<30 years old), urban residents, unmarried subjects, those with no history of needle sharing, and individuals with limited HCV-related knowledge. The established model achieved a sensitivity of 85%. Since 2024, targeted health education programs and green referral pathways have been implemented for the key populations through collaboration between 11 prefectures and local CDCs. Using the optimized relink paradigm, 5,063 HCV antibody(+) patients were successfully contacted. Of these, 90% (4,535/5,063) underwent further HCV RNA testing, and 51% (2,249/4,535) were HCV RNA(+). Till December 2025, 85% (1,914/2,249) of patients had initiated antiviral therapy with Sofosbuvir/Velpatasvir (SOF/VEL) or Ledipasvir/Sofosbuvir (LDV/SOF), with ongoing efforts to recall the remaining patients. Compared with 2022, both HCV RNA screening rate (from 15% to 90%) and treatment rate (from 8% to 85%) were highly increased.
Conclusion: The predictive model identified key patient subgroups associated with low treatment uptake that differed from previously

recognized populations, clarifying the underlying causes of suboptimal treatment rates. The optimized recall strategy significantly improved diagnosis and treatment rates, facilitating province-level HCV elimination.

FRI-045

Mapping the global network of viral hepatitis A, B, C and E: unveiling disease-specific epidemic architectures through complex network analysis

Yanhui Yang[1], Yanpei Mai[2], Yuxi Shi[2], Suzhen Jiang[1], Xin Wen[2], Tianyi Xue[2], Qinshuo Wang[2], Yafen Liu[3], Huiying Rao[1], Zixing Wang[1]. *[1]Peking University Hepatology Institute, Beijing, China; [2]Peking University Hepatology Institute, Peking University Health Science Center, Beijing, China; [3]Peking University Hepatology Institute, Peking University People's Hospital Department of Infectious Diseases, Beijing, China*
Email: wangzixing@pkuph.edu.cn

Background and aims: The global burden of viral hepatitis remains a formidable public health challenge, with HBV and HCV alone accounting for 1.3 million deaths annually. Traditional surveillance fails to capture the complex interconnectedness driving these epidemics. This study employs complex network theory to uncover the fundamental architectural patterns governing the global persistence and diffusion of Hepatitis A, B, C, and E.
Method: We constructed static and dynamic networks using Global Burden of Disease data from 1990 to 2021. Static networks comprised high-incidence countries (top 50%) as nodes, connected by edges determined by a high Spearman correlation coefficient (>0.9) in incidence rates. Dynamic networks employed 10-year sliding windows with 1-year steps based on this foundation to capture temporal evolution. Key metrics were calculated to quantify structural characteristics: density (measuring overall connection tightness), efficiency (reflecting global transmission capacity), clustering coefficient (indicating local interconnection strength) and modularity (measuring the degree of network division into separate communities). Degree centrality was employed to identify network hub nations.
Results: We identified distinct network architectures for hepatitis subtypes. Hepatitis B exhibited a dense, integrated network with increasing connectivity and declining modularity, forming a unified component with emerging communities. Hepatitis A demonstrated high connectivity with strong local clustering, but fragmented progressively, maintaining low modularity. In contrast, hepatitis C presented a sparse and fragmented architecture with the highest modularity and five connected components, showing accelerating structural polarization despite gradual density increases. Hepatitis E maintained a stable hybrid structure with increasing modularity. Analysis of degree centrality identified Comoros as a critical hub consistently maintaining strong correlations with 40–91 high-epidemic countries across all four diseases networks. Equatorial Guinea, Eritrea, Benin, Sao Tome and Principe, and Lao PDR also emerged as pivotal hubs across three disease networks.
Conclusion: This study identifies disease-specific network structures requiring tailored strategies for global elimination. For highly integrated networks like HBV, we suggest coordinated sentinel systems in hub nations to track progress. For fragmented networks like HCV, hub nations reveal cluster-specific patterns, informing targeted interventions.

FRI-046

RE-LIVE study (Re-Linkage to Pan-Viral hepatitis): interim results from a multicenter observational study on care engagement in chronic viral hepatitis

Jaehyun Yoon[1], Young-Sun Lee[2], Yang Jae Yoo[2], Yu Rim Lee[3], Seul Ki Han[4]. *[1]Chonnam national university hospital, College of medicine, Gwangju, Korea, Rep. of South; [2]Korea university hospital, Seoul, Korea, Rep. of South; [3]Kyungpook national university hostpial, Daegu, Korea, Rep. of South; [4]Wonju Yonsei University Hospital, Wonju, Korea, Rep. of South*
Email: zenmake14@gmail.com

Background and aims: Despite highly effective antiviral therapies, linkage to care remains a key barrier to the global elimination of viral hepatitis. A considerable proportion of individuals with chronic viral hepatitis remain undiagnosed, and untreated, sustaining the burden of disease and transmission. This study aimed to evaluate systematic re-linkage strategies to re-engage these individuals in the continuum of care, with the goal of improving clinical outcomes and contributing to public health objectives.
Method: A retrospective chart review was conducted at four tertiary academic hospitals in Korea to identify candidates for antiviral treatment. HBV eligibility included (i) non-cirrhotic patients with HBV DNA >2,000 IU/mL and fibrosis stage ≥2, and (ii) cirrhotic patients with any detectable HBV DNA. For HCV, partially diagnosed-but-untreated (DBU) cases were defined as anti-HCV antibody positive with missing HCV RNA data; completely DBU cases were HCV RNA positive without prior antiviral therapy. HBV patients eligible for HDV screening underwent HDV PCR. All identified patients were re-contacted via text or phone for re-evaluation and potential treatment linkage.
Results: Among 2,810 patient charts reviewed, 33 HBV and 127 HCV patients were enrolled in the call-back program. Among HBV patients, 21.2% (7) responded and agreed to further evaluation; 6.1% (2) initiated antiviral therapy, while 78.8% (26) did not respond to call-back. Of 92 partial HCV DBU cases, 13.0% (12) agreed to evaluation, 3.3% (3) had prior treatment, 3.3% (3) sought care elsewhere, 2.2% (2) refused, and 78.3% (72) did not respond. Among them, 2.2% (2) initiated treatment. Among 35 complete DBU cases, 2.9% (1) agreed to evaluation, 2.9% (1) sought care elsewhere, 5.7% (2) refused, and 88.6% (31) did not respond; only 2.9% (1) initiated treatment. HDV RT-PCR was performed in 618 chronic HBV patients; 0.1% (1) tested positive but declined further management. In total, 3.1% (5) of 160 patients identified through the call-back program initiated antiviral therapy.
Conclusion: Although effective antiviral treatments and expanded eligibility criteria are now available, many patients with viral hepatitis remain disconnected from care. Our re-linkage efforts showed limited success in bringing patients back into the treatment pathway. These findings emphasize the need for continued, practical strategies to improve access to care and support national and global goals for viral hepatitis elimination.

FRI-047

Data for action - Informing viral hepatitis and HIV public health interventions through high resolution geo-mapping of migrant populations

Jamie Zagorski[1], Murad Ruf[2], Helen Hammond[2], Victoria Livingstone[2], Nigel Breakwell[3]. *[1]Gilead Sciences, Foster City, United States; [2]Gilead Sciences Europe, Uxbridge, United Kingdom; [3]DOT I/O Health, Manor House, 21 Soho Square, London, W1D 3QP, London, United Kingdom*
Email: jamie.zagorski@gilead.com

Background and aims: Healthcare-planning requires detailed knowledge of health profiles and location of people. This need is particularly great during sudden large-scale population migration, with associated increased risk of communicable diseases, including blood-borne viruses (BBV). Most likely significant is the forced displacement of Ukrainians due to the Russian invasion. Given the substantial estimated burden of HCV: 1,263,530, HBV: 507,063, and HIV: 244,877 in Ukraine, mass migration will also impact on local BBV epidemiology. We set out to explore a novel methodology to estimate the small-area migrant population distribution and its potential for local HIV, HBV and HCV prevalence impacts.

Method: We developed a hybrid model combining national statistics, non-governmental organisation data, scientific literature review in multiple languages, and local expert opinion. From this we synthesised population data of the magnitude and registered geo-location of Ukrainian forced migrant populations pre and post the Russian invasion, in the EU at a national and sub-national level. BBV prevalence rates in Ukrainian, sourced from published official reports were proportionally applied to the sub-national migrant populations estimates in our model. We generated high resolution, small area heatmaps using the data. An international expert steering committee reviewed our methodology and proposed a focused analysis in the Krakow region as example.
Results: Seven countries accounted for 49.7% (3,077,770) of the Ukrainian migrant population in 2024 (Austria, Czechia, Germany, Italy, Netherlands, Poland and Slovakia). Applying our extrapolation, we estimate up to HCV: 2,410, HBV: 1,004, and HIV: 442 additional infections in these countries.
Granular analysis in the Krakow region, using governmental data up to June 2025 identified a 79% increase in the Ukrainian-born population since 2021; equating to nearly 100,000 Ukrainians, which make up 4.27% of the Krakow metropolitan area. We estimate up to a total of 2,585 additional BBV infections in local UKR migrants (HCV: 1,621, HBV: 675, HIV: 298).
Conclusion: We believe, our innovative methodology synthesising routine data sources allows precise small-area estimates of size and geo-location of migrant populations potentially at risk for BBV infection. This promising novel methodology can contribute to informing development of targeted, tailored novel BBV care pathways including mobilisation of local community-based support to advance local BBV elimination efforts.

WED-003

Impact of a national hepatocellular carcinoma surveillance program on tumor staging: geographic disparities and temporal trend in post-hcv elimination Egypt

Wael Abdel-Razek[1], Mohamed AbdAllah[2], Mohamed Hassany[3], Gamal Esmat[4], Imam Waked[1]. *[1]Department of Hepatology and Gastroenterology, National Liver Institute, Menoufia University, Menoufia, Egypt; [2]Medical Research and Clinical Studies Institute, National Research Center, Giza, Egypt; [3]National Hepatology and Tropical Medicine Research Institute, Ministry of Health and Population, Cairo, Egypt; [4]Endemic Medicine Department, Faculty of Medicine, Cairo University, Cairo, Egypt*
Email: wabdelrazek@liver-eg.org

Background and aims: Following Egypt's successful hepatitis C virus (HCV) elimination efforts, the liver disease burden is shifting toward hepatocellular carcinoma (HCC). We evaluated the effectiveness of the national HCC surveillance program launched in 2022 across Egyptian states, assessing its impact on BCLC staging and identifying demographic and geographic disparities.
Method: We conducted a retrospective multicenter analysis of 6,362 HCC patients diagnosed between 2022 and 2025 across 25 Egyptian states. Patients were stratified into two cohorts: regular surveillance vs. incidental diagnosis (no surveillance). The primary endpoint was BCLC stage distribution (0/A, B, C, D). Secondary endpoints included temporal trends and geographic heterogeneity in staging outcomes.
Results: The study included 6,362 patients (66.4% male, mean age 63.9 ± 8.1 years). Only 19.9% (n = 1,267) were diagnosed under surveillance, while 80.1% (n = 5,095) had no prior surveillance. Surveillance was significantly associated with earlier detection ($p < 0.001$). Patients under surveillance showed higher rates of potentially curative/intermediate stages compared to the non-surveillance group (BCLC 0/A: 11.7% vs. 8.6%; BCLC B: 25.6% vs. 19.3%). Conversely, advanced/terminal disease (BCLC C/D) was prevalent in the non-surveillance group (72.1% vs. 62.8%). The surveillance cohort had a higher male proportion (71.4% vs. 65.1%, $p < 0.001$) with no age difference ($p = 1.000$). Significant heterogeneity was observed across states ($p < 0.001$ for total distribution). In high-burden Kafr El-Sheikh (north, Nile delta), surveillance yielded robust early detection rate (40.0% BCLC 0/A vs. 18.8% in non-surveillance, $p = 0.002$). In contrast, Minia (south) showed low rates of very early detection even within surveillance (1.6% BCLC 0/A). While the proportion of patients diagnosed under surveillance remained stable (17.5–21.5%), absolute annual HCC cases declined from 1,903 in 2022 to 1,309 in 2025 ($p < 0.001$).
Conclusion: In this national cohort, HCC surveillance is associated with significant stage migration toward early-stage disease amenable to curative therapy. However, surveillance coverage remains low, and many surveillance patients still present with advanced disease. The marked geographic disparities highlight the urgent need for standardized, quality-controlled protocols and targeted interventions to consolidate the gains of Egypt's HCV elimination program. The declining overall trend might represent the impact of the HCV elimination program.

WED-004

Introduction of a hepatitis C testing prompt for primary care LFTs with raised ALT leads to increased testing and diagnosis

Stephen Barclay[1], Julie Craik[1], Rory Gunson[2], Maurizio Panarelli[1], Daniel Carter[1], Erica Peters[1]. *[1]NHS Greater Glasgow & Clyde, Glasgow, United Kingdom; [2]West of Scotland Specialist Virology Centre, Glasgow, United Kingdom*
Email: stephen.barclay2@nhs.scot

Background and aims: A raised ALT should lead to consideration of hepatitis C (HCV) testing, however adherence to this is inconsistent, with previous work suggesting undiagnosed cases amongst those with raised ALT on primary care blood tests. We sought to establish whether adding an HCV testing prompt to primary care LFT results with an ALT above the upper limit of normal (ULN) improved HCV testing and diagnosis.
Method: Biochemistry laboratory systems identified samples with ALT above ULN sent from 65 primary care practices in north-east Glasgow, Scotland, for two 6-month time periods: No Prompt (NP); July 24 to Jan 25, and following a four-week break, With Prompt (WP); Feb 25 to Aug 25. Virology laboratory systems identified samples sent from the same practices between July 24 and October 25. Numbers of HCV tests and (reflex) HCV RNA positive results were obtained for both NP and WP periods, plus the subsequent four weeks (7-month period) to allow time for a test to take place. Finally, linkage using a unique patient identifier, captured the proportion of patients in each period who subsequently underwent HCV testing within 90 days of a positive HCV test.
Results: 6453 and 6391 raised ALT samples were sent in NP and WP, respectively. During WP, HCV tests rose from 1093 to 1803 (64.95% increase) and RNA positives from 9 to 17 (88.88% increased). WP demonstrated significantly more patients received HCV testing within 3 months of a raised ALT (1847 (28.9%) vs 616 (9.55%), $p < 0.0001$).
Conclusion: Introduction of a HCV prompt to primary care LFT results with a raised ALT led to increased HCV testing and rates of HCV diagnosis. Further work is required to ascertain the proportion untested who have had previously received HCV testing, and the characteristics of those identified via this approach. In addition the durability of increased testing following permanent introduction of a prompt requires further evaluation.

WED-005

Symptom burden and health-related quality of life in chronic HBV–HDV infection: real-life evidence from the ANRS HD EP01 HEPDELTA cohort

Camelia Protopopescu[1], Vincent Di Beo[1], Helene Fontaine[2], Morgane Bureau[1], Marta Lotto[1], Gwenaëlle Maradan[3], Marc Bourlière[1], Garance Bessaudou[4], Claire Fougerou-Leurent[4], Christelle Tual[4], Fatoumata Coulibaly[5], Fabien Zoulim[6], Miroslava Subic-Levrero[6], Patrizia Carrieri[1]. *[1]Aix Marseille Univ, Inserm, IRD, SESSTIM, Sciences Economiques & Sociales de la Santé & Traitement de l'Information Médicale, ISSPAM, Marseille, France; [2]Université de Paris-Cité, Hôpital Beaujon, AP-HP Assistance Publique - Hôpitaux de Paris, INSERM UMR1149, Paris, France; [3]ORS PACA, Observatoire Régional de la Santé Provence-Alpes-Côte d'Azur, Marseille, France; [4]CHU Rennes, Inserm, CIC 1414, Rennes, France; [5]ANRS MIE, PariSanté Campus, 2 rue d'Oradour sur Glane, Paris, France; [6]Hepatology Department, Hospices Civils de Lyon, INSERM U1052-CRCL; Université Claude Bernard Lyon 1, Lyon, France*
Email: camelia.protopopescu@inserm.fr

Background and aims: People living with chronic HBV–HDV infection experience substantial symptom burden and impaired health-related quality of life (HRQoL). However, the respective impact of self-reported symptoms, antiviral treatments, and liver disease on physical and mental HRQoL remains insufficiently documented in real-life settings. We aimed to assess these associations to provide guidance on patient care and treatment strategies.
Method: We analyzed data from adults with chronic HBV–HDV infection enrolled in the ANRS HD EP01 HEPDELTA cohort, with or without specific treatment for HDV. HRQoL was assessed using the Short Form-12 (SF-12v2), providing the physical (PCS) and mental (MCS) component summary scores (study outcomes). Twenty-five distinct self-reported bothersome symptoms and exposure to current or past HBV and HDV antiviral treatments were assessed. Associations between each symptom, HBV/HDV treatment status, and physical and mental HRQoL were evaluated using multivariable linear mixed models adjusted for liver steatosis, advanced fibrosis (i.e., FIB-4 > 3.25), and socio-behavioral variables.
Results: The study included 250 patients (68% male, median age [IQR] = 43 [35–50]) accounting for 444 visits. At baseline, 54% were receiving bulevirtide. Median [IQR] HRQoL scores were 45.4 [38.2–51.8] for PCS and 47.1 [38.6–56.0] for MCS. The most prevalent self-reported bothersome symptoms were sleep disorders (43%), headaches (39%), joint pain (39%), and shortness of breath (31%). After multivariable adjustment, most symptoms were associated with lower HRQoL scores, with generally a higher effect on MCS than on PCS. The symptoms with the highest effects were shortness of breath (coefficient [95% CI]: −4.1 [−5.9, −2.2]) for PCS, and appetite loss (−6.7 [−9.0, −4.4]), memory problems (−6.7 [−9.2, −4.2]), and concentration difficulties (−6.6 [−8.8, −4.3]) for MCS. In most of the models, female sex, tobacco smoking, steatosis, and advanced fibrosis were independently associated with lower PCS, whereas housing instability was associated with lower MCS. HBV/HDV treatment status was not associated with either PCS or MCS.
Conclusion: In this cohort of patients with HBV–HDV infection, most self-reported symptoms were strongly associated with impaired physical and mental HRQoL, whereas antiviral treatment showed less impact. These findings highlight the importance of symptom monitoring in the management of HBV–HDV infection, to improve patient-centered outcomes and indirectly improve retention in care.

WED-006

Implementation of the ReLink-C strategy in hospitals in Spain (ReLink-C Observatory Spain)

Gonzalez Santiago[17], Sonia Albertos Rubio[18], Carolina Freyre[19], Andreu Sansó[20], Carmen Vinaixa[21], Eva María Rodriguez Marcos[22], Rafael Manuel Alejandre Altamirano[23], Laisy Zacarias Martínez[24], Rocío Aller[25], Sandra Blanco Cano[26], Cristina Gonzalez De Adalid[26], Nataly Espinoza-Cámac[27], Raquel Domínguez-Hernández[27], Marta Casado-Martin[1]. *[1]Hospital Universitario Torrecárdenas, Almería, Spain; [2]Hospital Universitario La Paz, Madrid, Spain; [3]Hospital Universitari Vall d'Hebron, Barcelona, Spain; [4]Hospital del Mar, Barcelona, Spain; [5]Hospital Universitario Puerta de Hierro Majadahonda, Madrid, Spain; [6]Hospital Universitario 12 de Octubre, Madrid, Spain; [7]Hospital Universitari Joan XXIII de Tarragona, Tarragona, Spain; [8]Hospital Universitario Puerta del Mar, Cádiz, Spain; [9]Complexo Hospitalario Universitario de Santiago, A Coruña, Spain; [10]Hospital Universitario Regional de Málaga, Málaga, Spain; [11]Hospital Universitario de Jerez de La Frontera, Cádiz, Spain; [12]Hospital Universitario Juan Ramón Jiménez, Huelva, Spain; [13]Hospital de Sagunto, Valencia, Spain; [14]Hospital Clínico Universitario Lozano Blesa, Zaragoza, Spain; [15]Complejo Hospitalario Universitario Badajoz, Badajoz, Spain; [16]Hospital Universitario Reina Sofía, Córdoba, Spain; [17]Hospital Universitario de Salamanca (Complejo Asistencial de Salamanca), Salamanca, Spain; [18]Hospital Residencia Sant Camil - Consorci Sanitari Alt Pendés - Garraf, Barcelona, Spain; [19]Hospital Universitario de Puerto Real, Cádiz, Spain; [20]Hospital de Manacor, Baleares, Spain; [21]Hospital Universitari i Politècnic La Fe, Valencia, Spain; [22]Hospital Lluís Alcanyís de Xàtiva, Valencia, Spain; [23]Hospital Infanta Margarita, Córdoba, Spain; [24]Hospital del Vendrell, Tarragona, Spain; [25]Hospital Clínico Universitario de Valladolid, Valladolid, Spain; [26]Gilead España, Madrid, Spain; [27]Pharmacoeconomics & Outcomes Research Iberia (PORIB), Madrid, Spain*
Email: anjo134@gmail.com

Background and aims: Among the actions implemented to achieve the elimination of hepatitis C virus (HCV) infection, the ReLink-C strategy identifies and relinks patients with a complete or partial HCV diagnosis who have been lost to clinical follow-up and show no evidence of infection cure, linking them back to the healthcare system. The objective was to describe the outcomes of implementing the ReLink-C strategy in Spanish hospitals.
Method: An observational, retrospective, cross-sectional, multicentre study was conducted through data collection in hospitals using an online questionnaire. An information flow was designed with mandatory and optional variables, including patients with a complete diagnosis (anti-HCV serology positive with RNA-HCV confirmation) and patients with a partial diagnosis (anti-HCV serology positive without HCV RNA determination). From all centres participating in the ReLink-C strategy, those whose data availability aligned with the established flow and met the defined criteria for data collection were selected.
Results: Information from 25 hospitals participating in the ReLink-C strategy was included. A total of 20,409 anti-HCV serology tests (15,188 complete diagnoses and 5,221 partial diagnoses) were reviewed, and 3,508 patients with HCV (1,973 from complete diagnoses and 1,535 from partial diagnoses) were identified as lost to follow-up. Of these, 1,992 patients were successfully located, and 824 initiated treatments with direct-acting antivirals (577 from complete diagnoses and 247 from partial diagnoses). The recovery rate of patients who started treatment among those lost to follow-up was 23%.

Conclusion: The results obtained confirm the effectiveness of the ReLink-C strategy in identifying, relinking, and treat to access to HCV patients lost in the system, reinforcing its value as a reference model to achieve the goal of hepatitis C elimination in Spain.

WED-007

Viral hepatitis in the community of Shenzhen city, China: current status and elimination challenges — a large scale screening study

Deliang Huang[1], Zhibin Zhu[1], Jun Chen[1]. [1]*The Third People's Hospital of Shenzhen, National Clinical Research Center for Infectious Diseases, Shenzhen, China*
Email: huangdeliang2020@163.com

Background and aims: Aligned with the WHO strategic objective to eliminate viral hepatitis as a public health threat by 2030, this study was conducted to evaluate the current epidemiological profile of virus hepatitis infections within community populations in Shenzhen, China, and to identify key barriers to achieving the elimination target.
Method: A large-scale, cross-sectional community screening was performed across 95 community health centers spanning all 10 districts of Shenzhen from September 2023 to July 2025. Participants were tested for hepatitis B surface antigen (HBsAg), hepatitis B surface antibody (HBsAb), and hepatitis C antibody (anti-HCV). Epidemiological and demographic data were collected concurrently.
Results: Among 96,170 individuals screened, 51,168 and 45,540 were assessed for hepatitis B and C, respectively. The overall HBsAg seroprevalence was 4.32%, showing a clear age gradient: the highest infection rate was observed in individuals aged 30–60 years, while the rate among those under 15 years was 0.32%. Alarmingly, only 9.69% of HBsAg-positive individuals were aware of their infection status. Furthermore, 78.23% of HBsAg-positive persons reported an unknown family history of hepatitis B, and 80.04% were unaware of any family history of cirrhosis or hepatocellular carcinoma. The proportion of the immune population (HBsAb positive) was 28.40%, whereas the susceptible population (both HBsAg and HBsAb negative) reached 66.27%. Among susceptible individuals, 90.77% had an unclear vaccination history. The anti-HCV seroprevalence was 0.28%, with a marked age clustering showing the highest rate (0.54%) among adults aged over 60 years.
Conclusion: While Shenzhen has demonstrated substantial success in hepatitis B prevention, particularly in pediatric vaccination coverage, significant challenges persist. These include a profound diagnosis gap, a large immunity gap among adults, and critically low disease risk awareness in key populations. To accelerate progress towards the 2030 elimination goal, future efforts must prioritize the development of innovative, proactive community screening models, implement robust adult catch-up vaccination programs, and establish an integrated continuum of care encompassing screening, diagnosis, treatment, and long-term management. This study provides crucial empirical evidence to inform targeted elimination strategies in Shenzhen and similar urban settings across China.

WED-008

Perspectives of people living with hepatitis B towards long-acting antivirals: a global study

Chari Cohen[1], Yasmin Ibrahim[1], Karine Dube[2], David Thomas[3]. [1]*Hepatitis B Foundation, Doylestown, United States;* [2]*University of California San Diego, La Jolla, United States;* [3]*Johns Hopkins University, Baltimore, United States*
Email: chari.cohen@hepb.org

Background and aims: There are multiple barriers to long-term oral antiviral therapy for chronic hepatitis B (CHB). Long-acting antivirals (LAAs) could help improve treatment uptake and adherence. As research for LAAs advances, we need to understand how people living with hepatitis B (PLWHB) perceive these new treatment modalities. The goal of this study was to assess perspectives and preferences towards potential LAA treatment modalities among PLWHB globally.
Method: We implemented an online cross-sectional survey with 49 multiple choice and Likert scale questions for PLWHB (self-report) who were ≥18 years old. The survey included 4 sections: demographics, current treatment experiences, challenges with current treatment, and preferences for three long-acting routes: injectables, implants, and microneedle patches. The survey was launched globally and open for 16 weeks in English, Spanish, Mandarin, Arabic and Tagalog; and distributed to email listservs, e-newsletters, social media channels, and partner organizations. This study was supported by the NIH (LEAP, R24AI118397) and the Hepatitis B Foundation.
Results: A total of 1,074 PLWHB responded (93% in English), with 653 completing ≥75% of survey questions. Respondents were from 81 countries; 70% identified as male; with 55% between age of 26–45. Among respondents, 66% were in care for CHB and 54% were on treatment; 58% had treatment-related challenges, and 13% missed a dose at least once weekly. Further, 81% would consider an injection, 55% would consider an implant, and 50% would consider a microneedle patch for CHB treatment, if these modalities worked as well as pills. In a direct comparison, 57% preferred an injection to pills, 44% preferred an implant to pills, and 34% preferred a microneedle patch to pills. Respondents ranked fewer side effects, higher efficacy, and easier adherence as the top potential benefits of LAAs. Top concerns included potential decreased efficacy, stronger/longer side effects, pain (insertion/removal of implant), needing to receive treatment at a clinic, and visibility to others (implant/patch) as top concerns.
Conclusion: This first-ever study assessing preferences among PLWHB shows that there is strong interest in LAAs to treat CHB, especially for long-acting injectables. Additional studies are needed to document and explore perceptions and challenges towards LAAs, particularly as we explore these as an option to overcome challenges with pill uptake, adherence, and access.

WED-009

Modeling the potential effect of long-acting injectables of DAA treatment to reach HCV elimination among persons who inject drugs

Eric Tatara[1], Louis Shekhtman[2], Marian Major[3], Scott Cotler[2], Basmattee Boodram[4], Jonathan Ozik[1], Harel Dahari[2]. [1]*Consortium for Advanced Science and Engineering, University of Chicago, Decision and Infrastructure Sciences, Argonne National Laboratory, Chicago, United States;* [2]*Program for Experimental and Theoretical Modeling, Division of Hepatology, Department of Medicine, Loyola University Chicago, Maywood, IL, United States;* [3]*Division of Viral Products, Center for Biologics Evaluation and Research, Food and Drug Administration, Silver Spring, MD, United States;* [4]*Division of Community Health Sciences, School of Public Health, University of Illinois at Chicago, Chicago, United States*
Email: harel.dahari@gmail.com

Background and aims: Access, adherence and cost remain barriers to global elimination of hepatitis C virus (HCV) with direct-acting antivirals (DAA). Re-formulation of DAA to an injectable form to produce sustained concentrations for 24 weeks could not only cure hepatitis C virus (HCV) but also protect persons who inject drugs (PWID) from repeat infections by suppressing viral replication for 24 weeks with a single dose. Since PWID are at high risk for acquiring and transmitting HCV, we aimed to study the effects of a 24-week long-acting DAA treatment among PWID to reach HCV micro-elimination in metropolitan Chicago, IL, USA.
Method: We used our advanced Hepatitis C Elimination in PWID (HepCEP) agent-based modeling [doi.org/10.1101/2025.07.25.25332212] in which HCV transmission probability is determined using a mathematical model of HCV RNA titers among needle/syringe-sharing donors [PMID: 29997251]. DAA treatment enrollment is modelled as (unbiased) random sampling of infected PWID using an annual target enrollment rate of 7.5% of the total PWID

population in Chicago and the surrounding area (32,000 individuals) to reach HCV elimination. Access to long-acting DAA was simulated for 10 years. We compared the mean frequencies (using stochastic model replicates) of reinfection and number of unique treatment courses between potential long-acting DAAs and ultra-short 4-week duration DAA-based treatment [e.g., PMID: 40347964].
Results: The model predicts reaching HCV elimination with a long-acting DAA that provides cure and 24 weeks of protection from repeat infections during a 10-year treatment period results in fewer total infections (3,377, 95%CI: 3,298–3,456) compared to a 4-week DAA-based treatment duration (6,200, 95%CI: 5,960–6,441). Moreover, treatment duration of 24 weeks (15,946 treatments) versus 4 weeks (19,325 treatments) would result in need for 3,379 fewer treatments.
Conclusion: Our modeling results predict that a 24-week long-acting DAA treatment would result in a reduced number of HCV infections compared to 4-week ultra short DAA-based treatment over a 10-year period to reach HCV micro-elimination in metropolitan Chicago due to greater duration of protection from repeat infections and further transmission.

WED-010
HCV screening and linkage to care in the 1969–1989 birth-cohort population: the Bergamo experience
Liliana Dell'Oro[1], Alessandro Loglio[1,2], Loredana Rota[2], Luca Ongis[2], Carlos Eduardo Paz Domínguez[1], Elisa Farina[2], Davide Isabella[1], Luisa Pasulo[2], Giulia Bombardieri[3], Stefania Borlini[3], Marco Arosio[4], Stefano Fagiuoli[1,2], Mauro Viganò[1,2]. *[1]Department of Medicine and Surgery, University of Milano-Bicocca, Milan, Italy; [2]Gastroenterology, Hepatology and Transplantation Division, ASST Papa Giovanni XXIII, Bergamo, Italy; [3]Healthcare Directorate, ASST Papa Giovanni XXIII, Bergamo, Italy; [4]Microbiology and Virology Laboratory, ASST Papa Giovanni XXIII, Bergamo, Italy*
Email: l.delloro2@campus.unimib.it

Background and aims: The Italian Ministry of Health has promoted a national screening program for Hepatitis C Virus (HCV) infections targeting individuals born between 1969–1989 who have never taken Direct Antiviral Agents (DAAs). Aim was to evaluate the effectiveness of this age-based screening in the referral area of ASST Papa Giovanni XXIII, Bergamo, with a focus on adherence, HCV antibodies (HCVab) positivity, HCV-RNA positivity, linkage to care, DAA introduction and achievement of sustained virological response (SVR).
Method: All individuals born between 1969 and 1989 who underwent HCV screening from May 2022 to June 2025 across four healthcare settings (hospital inpatient wards, outpatient blood collection centers, active screening invitation letter, and physician-initiated testing) were included. HCVab positive subjects were invited to undergo a confirmatory HCV-RNA test, hepatology consultation and ultimately DAAs initiation.
Results: Among 23,577 screened individuals [15,594 responding to invitation letters, 4,913 during hospitalization, 2,014 via physician prescription, and 986 during blood collection], 308 (1.3%) tested positive for HCVab [0.8%, 3%, 0.9%, and 1.8% for each respective cohort]: 58% male, 48 (33–55) years-old, 17% of foreign origin. Overall, 49 (0.2%) patients had detectable serum HCV-RNA [0.07%, 0.67%, 1.04%, and 0.2%, respectively], while 259 individuals were HCV-RNA negative, of whom 51% had never received antiviral treatment. Notably, 200 (65%) HCVab positive subjects were already aware of their status, with 186 actively followed-up. Among the 49 HCV-RNA positive individuals [55% already known to have the infection], 24 (49%) started DAA reaching an SVR in 18, while the remaining 6 were non-compliant patients. The remaining 25 HCV-RNA positive patients (predominantly active drug users) never started DAAs due to non-adherence to follow-up visits.
Conclusion: The impact of this screening program on the 1969–1989 birth-cohort population is low, thus suggesting an extension to advanced age groups and the implementation of more effective linkage-to-care strategies.

WED-011
Anti-HDV reflex testing among HBsAg positive individuals in the Netherlands
Esmee Fath el Bab[1], Annemiek Van der Eijk[1], Lesley Patmore[1], Jolanda Kreeft - Voermans[1], Thijs van der Laar[2], Hans Zaaijer[2], Annelies Riezebos-Brilman[3,4], Harry L.A. Janssen[1,5], Khoa Thai[6], Milan J. Sonneveld[1]. *[1]Erasmus MC, University Medical Center, Rotterdam, Netherlands; [2]Sanquin Research, Amsterdam, Netherlands; [3]Diagnostiek voor U, Eindhoven, Netherlands; [4]Laboratory for Medical Microbiology and Public Health, Hengelo, Netherlands; [5]Toronto Center for Liver Disease, Toronto General Hospital, University of Toronto, Toronto, Canada; [6]Star-shl Medical Diagnostics Center, Rotterdam, Netherlands*
Email: e.fathelbab@erasmusmc.nl

Background and aims: Hepatitis delta virus (HDV) is the most severe form of viral hepatitis and carries a high risk of liver-related complications. Universal anti-HDV reflex testing in all HBsAg positive individuals is recommended according to the EASL guidelines. Nevertheless, HDV remains underdiagnosed, primarily due to limited awareness. This study aims to access the diagnostic yield of reflex anti-HDV testing in HBsAg positive samples obtained from blood donor screening, general practice and a tertiary hospital in the Netherlands.
Method: Anti-HDV reflex testing was conducted in HBsAg positive samples collected in 2024–2025 from laboratories serving general practice (general practitioners and maternity care (n = 249)), the laboratory responsible for Dutch blood donor screening (n = 218) and a virology laboratory of a tertiary hospital in the Netherlands (n = 283). Anti-HDV positive samples were subsequently tested for HDV RNA. Positive results were communicated to the primary caregiver and appropriate linkage to care was established.
Results: Reflex testing was successfully conducted in 99.3% (n = 745) of 750 HBsAg positive individuals in the study period. Among these, 244 (32.8%) originated from general practice, 218 (29.3%) from blood donor screening and 283 (38.0%) from the hospital. The overall prevalence of anti-HDV was 6.7% (n = 50), with a prevalence of 4.1% in general practice (n = 10), 2.3% in blood donor screening (n = 5) and 12.4% in the hospital (n = 35). HDV RNA testing was performed in all anti-HDV positive samples. HDV RNA was detectable in 54.0% (n = 27), including 6 cases (60%) from general practice, 1 (20%) from blood donor screening and 20 (57.1%) from the hospital. HDV RNA was detectable in 2.5% of HBsAg positive samples obtained from general practitioners, in 0.5% of samples obtained from blood donors and in 7.1% of hospital samples.
Conclusion: Reflex anti-HDV testing in both primary and secondary care settings in the Netherlands proved feasible and effective. The high prevalence in samples obtained from general practitioners suggests that universal screening for HDV is warranted in HBsAg positive individuals.

WED-012
Advancing elimination targets for viral hepatitis and human immunodeficiency virus in Poland: estimating the cost-effectiveness of emergency department opt-out testing for blood-borne viruses
Robert Flisiak[1], Justyna Kowalska[2,3], Andrzej Fal[4], Magdalena Rosinka[5,6], Laurel Bates[7], Hairuo He[7], Erik Robinson[7], Elisabeth Adams[7], James Jarrett[8], Murad Ruf[9]. *[1]Department of infectious diseases and hepatology, Medical University of Białystok, Białystok, Poland; [2]Infectious diseases observational research unit, Medical University of Warsaw, Warsaw, Poland; [3]Hospital for Infectious Diseases, Warsaw, Poland; [4]Collegium Medicum, Warsaw faculty of medicine, Cardinal Stefan Wyszynski University, Warsaw, Poland;*

[5]Department of infectious disease epidemiology and surveillance, National Institute of Public Health PZH-National Research Institute, Warsaw, Poland; [6]Digital Medicine Centre, Maria Skłodowska-Curie National Institute of Oncology, National Institute of Oncology, Warsaw, Poland; [7]Aquarius Population Health, London, United Kingdom; [8]Global HEOR, Gilead Sciences, London, United Kingdom; [9]Medical Department, Gilead Sciences Europe Ltd, London, United Kingdom
Email: robert.flisiak1@gmail.com

Background and aims: In Poland, blood-borne virus (BBV) diagnosis rates fall below global elimination goals. Additionally, forced migration since 2022 into Poland has rapidly increased the number of people living with HIV and viral hepatitis (HBV and HCV). Currently, there is no systematic screening for BBVs in general medical settings. International evidence suggests BBV opt-out testing (OOT) in urban emergency departments (ED) is effective, particularly in diagnosing infections in people who do not access traditional, largely client-initiated testing options. We assessed the potential health and economic value of ED BBV OOT in high-prevalence areas in Poland.
Method: We developed a hybrid cost-effectiveness model to compare outcomes between BBV OOT and no testing in the ED as the standard of care. A decision tree simulated the testing and linkage to care (LTC) for ED attendees requiring blood tests who do not opt out; a Markov model projected long-term outcomes. Polish surveillance data and published literature were used to inform the model where available, supplemented with international literature and expert opinion. We used a public payer perspective over a lifetime. Primary outcomes were the number of new diagnoses, number LTC, quality-adjusted life years (QALYs), and costs (discounted at 5% per annum). Scenarios varied prevalence and LTC rates.
Results: Our model suggests OOT could result in 128 new BBV diagnoses per 10 000 ED attendees (72 HBV; 27 HCV; 28 HIV) and 95 individuals linked or re-linked to care (66 HBV; 10 HCV; 19 HIV). Combined BBV testing was cost-effective over a lifetime horizon, with an incremental cost per QALY gained of PLN 61 614 (€14 563). Individually in isolation, cost-effectiveness ranged from 7 851 (€1 856) per QALY gained (HCV) to 124 905 (€29 523) (HIV). The intervention remained cost-effective with scenarios decreasing HIV and HCV prevalences to 0.1%. Successful LTC post-diagnosis was the primary driver of long-term cost effectiveness.
Conclusion: Combined ED BBV opt-out testing targeted to high-prevalence areas in Poland could be cost-effective, identifying viral hepatitis and HIV infections and improving health outcomes. The intervention remained cost-effective under several stress-test scenarios. Results are likely underestimates as the benefits of potential transmissions averted through diagnosis and care were not assessed. We recommend further evidence-informed national dialogue on systematic testing strategies to address un/late diagnoses and maximise LTC.

WED-013
Addiction medicine involvement is associated with improved hepatitis C and viral hepatitis screening among hospitalised incarcerated patients who inject drugs

Ezaam Fraz[1], Leda Kasas[1], Matthew Carter[1], Jeremy Yeo[1], Aathavan Shanmuga Anandan[1], Jason Connor[1], Geoffrey Playford[1], Naomi Runnegar[1], Jeremy Hayllar[2], Gerald Holtmann[1], Paul Clark[1], Andrew Palmer[1]. [1]Princess Alexandra Hospital, Woolloongabba, Australia; [2]Metro North Mental Health Alcohol & Drug Service, Brisbane, Australia
Email: ezaam.fraz@health.qld.gov.au

Background and aims: Incarcerated people who inject drugs experience a high burden of hepatitis C virus (HCV) infection and face substantial structural barriers to blood-borne virus (BBV) screening and continuity of care. Hospitalisation represents a high-yield opportunity to identify undiagnosed BBV infection and engage hard-to-reach populations. We examined the association between inpatient addiction medicine unit (AMU) involvement and BBV screening, engagement, and short-term outcomes among incarcerated patients admitted with injection-related infections (IRI).
Method: We examined 391 incarcerated people transferred to a quaternary hospital secure unit (serving 60% of the state prison population) in Brisbane, Australia, between 01/07/19 and 30/06/25. Primary outcomes were HCV RNA testing during admission and complete BBV screening (defined as HCV RNA testing, hepatitis B surface antigen testing (HbSAg), and HIV serology). Secondary outcomes were self-discharge, 30-day readmission, and linkage to HCV care. Associations with AMU involvement were examined using multivariable logistic regression adjusted for age, First Nations status, sex, and length of stay.
Results: The cohort was predominantly male, with a median age of 32 years (IQR 28–38) and median length of stay of 5 days (IQR 3–14). BBV screening during admission was incomplete: HCV RNA and HIV testing were performed in 58.8% of admissions, HbSAg in 62.4%, and only 49.6% completed all three tests. AMU involvement was associated with higher odds of HCV RNA and HIV testing (OR 3.60, 95% CI 2.32–5.59; $p < 0.001$), HbSAg testing (OR 4.11, 95% CI 2.60–6.50; $p < 0.001$), and completion of the BBV composite (OR 3.9, 95% CI 2.5–6.0; $p < 0.001$). AMU involvement was associated with lower odds of self-discharge (OR 0.46, 95% CI 0.23–0.91; $p = 0.026$) and 30-day readmission (OR 0.47, 95% CI 0.24–0.92; $p = 0.028$). Findings were robust to sensitivity analyses adjusting for clinical complexity. AMU involvement was not associated with improved downstream linkage to HCV care.
Conclusion: AMU involvement was associated with improved BBV screening and engagement, underscoring the importance of addressing upstream drivers of liver disease. In this cohort, the dominant barrier in the HCV care cascade was case identification. These findings support viral hepatitis elimination strategies that prioritise AMU involvement and closer alignment between hepatology and AMU across comparable custodial and hospital systems.

WED-014
A multivariable model of spontaneous hepatitis C virus clearance: increasing realism of simulated data

Keshav Gandhi[1,2], Eric Tatara[3,4], Jonathan Ozik[3,4], Basmattee Boodram[5], Scott Cotler[1], Marian Major[6], Harel Dahari[1], Alexander Gutfraind[1,2]. [1]Program for Experimental and Theoretical Modeling, Division of Hepatology, Department of Medicine, Loyola University Chicago, Maywood, IL, United States; [2]Division of Epidemiology and Biostatistics, School of Public Health, University of Illinois at Chicago, Chicago, IL, United States; [3]Consortium for Advanced Science and Engineering, University of Chicago, Chicago, IL, United States; [4]Decision and Infrastructure Sciences, Argonne National Laboratory, Argonne, IL, United States; [5]Division of Community Health Sciences, School of Public Health, University of Illinois at Chicago, Chicago, IL, United States; [6]Division of Viral Products, Center for Biologics Evaluation and Research, Food and Drug Administration, Silver Spring, MD, United States
Email: krg3@uic.edu

Background and aims: Approximately 20–35% of hepatitis C virus (HCV)-naïve individuals clear acute HCV infection. While spontaneous clearance rates vary by age, sex, and interferon lambda-4 (IFNL4) rs12979860 genotype, HCV elimination (PMID: 35271634) and vaccine trial (PMID: 39777292) simulations have used fixed clearance probabilities stratified only by sex (female: 0.35; male: 0.12). We aim to develop a literature-informed logistic regression model to more precisely estimate spontaneous HCV clearance in elimination and vaccine simulations.
Method: We performed a literature search of studies that estimate spontaneous viral clearance and could be used to construct a logistic regression model, emphasizing systematic reviews and meta-analyses where possible. First, a baseline clearance probability was generated before modification by age, sex, or IFNL4 rs12979860

genotype (PMID: 16364080). Age effects were derived from published odds ratios (ORs) comparing the clearance probability greater than or equal to 45 years versus less than 45 years (PMID: 29345844). Sex effects used relative risks (RRs) for female people who inject drugs converted to ORs (PMID: 38633576). CC versus non-CC rs12979860 genotype identities were assigned probabilistically using allele frequencies specific to race/ethnicity (PMIDs: 19684573, 20399780, 22612303), with the clearance-favorable CC genotype modeled using spontaneous viral clearance ORs (PMID: 34216268). Confidence intervals (CIs) from these sources were used to define normal distributions on log-odds scales, from which trial-specific coefficients were sampled.
Results: We developed a clearance model with predictors of age, sex, and IFNL4 rs12979860 genotype. Age, sex, and IFNL4 rs12979860 genotype have a clearance OR of 0.52 [95% CI 0.64–0.97], RR of 1.58 [95% CI 1.40–1.79], and OR of 2.75 [95% CI 2.23–3.38], respectively. The adjusted model indicates that while median [Q1, Q3] naïve male clearance probabilities (0.12 [0.09, 0.16]) were close to the fixed clearance rate of 0.12, naïve female clearance probabilities shifted from a fixed probability of 0.35 to a median of 0.20 [0.15, 0.26].
Conclusion: We developed a new modular, literature-informed logistic regression model of spontaneous HCV clearance incorporating age, sex, and IFNL4 genotype to improve the accuracy of HCV elimination and vaccine trial simulations.

WED-015

Assessing the economic value of bulevirtide for chronic hepatitis delta in Romania: combining real-world patient data with a markov state-transition model

Liana Gheorghe[1,2], Speranta Iacob[1,2], Mihaela Ghioca[1], Mirela Chitul[1], Anca Trifan[3,4], Laura Huiban[3,4], Daniela Larisa Sandulescu[5], Ionut Gheonea[5], Corina Radu[6,7], Bogdan Procopet[6], Roxana Sirli[8], Corina Pop[2,9], Nicoleta Tiuca[2,9], Bogdan Ungureanu[5], Adina Turcu-Stiolica[5]. *[1]Fundeni Clinical Institute, Bucharest, Romania; [2]Carol Davila University Of Medicine And Pharmacy, Bucharest, Romania; [3]Spitalul Clinic Județean de Urgență Sfântul Spiridon Iași, Iași, Romania; [4]Universitatea de Medicină și Farmacie 'Grigore T. Popa' Iași, Iași, Romania; [5]Universitatea de Medicina și Farmacie Craiova, Craiova, Romania; [6]Iuliu Haţieganu University of Medicine and Pharmacy, Cluj-Napoca, Romania; [7]Iuliu Hatieganu University of Medicine and Pharmacy, Cluj Napoca, Romania; [8]Universitatea de Medicină și Farmacie Victor Babeș, Timișoara, Romania; [9]Spitalul Universitar de Urgență București, București, Romania*
Email: drlgheorghe@gmail.com

Background and aims: Chronic hepatitis Delta (CHD) is the most severe form of viral hepatitis, contributing significantly to cirrhosis, hepatocellular carcinoma (HCC), and liver-related mortality in the absence of effective therapy. In Romania, HBV/HDV-related cirrhosis and HCC remain leading causes for liver transplantation (LT), unlike Western Europe where ALD and MASLD predominate. This unique epidemiology increases the potential impact of therapies that delay decompensation and reduce LT need. Bulevirtide (BLV), recently approved for compensated CHD, was evaluated for cost-utility and budget impact versus Best Supportive Care (BSC) in Romania, using local real-world evidence (RWE).
Method: A Markov cohort state-transition model was adapted to the Romanian healthcare setting from the perspective of the public payer (CNAS). Unlike models relying on hypothetical cohorts, baseline characteristics and transition probabilities were derived from a retrospective real-world cohort of 175 Romanian patients treated with BLV (69.7% with cirrhosis/F4 at baseline). The model adopted a lifetime horizon for cost-utility and a 5-year horizon for budget impact analysis (BIA), discounting outcomes at 3%. Efficacy was defined by a combined endpoint of HDV RNA undetectability or >2 log decline with ALT normalization.
Results: Treatment with BLV resulted in a substantial survival gain, extending discounted life expectancy by 3.36 years (10.52 LYs for BLV vs. 7.16 LYs for BSC). Patients gained 3.08 discounted Quality-Adjusted Life Years (QALYs) compared to BSC. Clinically, BLV effectively halted disease progression, averting 1,188 cases of decompensated cirrhosis, 822 cases of HCC, and 87 liver transplants over the cohort's lifetime. The Incremental Cost-Effectiveness Ratio (ICER) was 918,829 RON/QALY. Probabilistic sensitivity analysis confirmed clinical benefits in 100% of iterations. The BIA demonstrated a negligible burden on the national insurance fund, with the incremental Per Member Per Month (PMPM) cost reaching only 0.024 RON by Year 5.
Conclusion: BLV acts as a disease-modifying therapy, preventing progression to liver failure and LT in real-world CHD. Although the ICER is high, it generates significant survival and quality-of-life gains by preventing expensive end-stage liver complications and the need for LT. With minimal budget impact, BLV represents a high value option for this unmet need population.

WED-019

Multicenter automated strategy for opportunistic screening of viral hepatitis in primary care based on hypertransaminasemia and the FIB-4 index (ProHCYL study)

Jesús M. González-Santiago[1], Noa Villar[1], Laura Sancha[1], Rosario Rico Jimenez[1], Pilar Delgado[2], Fernando Hernandez Pacho[2], Soledad Sonsoles Muñoz Hernaz[2], Laura Fueyo[3], Ana M Roldan[3], Marta Calvo[4], Laura Herrera[4], Daniel Monge[4], Ruth Saez[5], Cristina Fernández Marcos[5], Alberto Mir Subias[6], Susana García-De Cruz[6], Laura Perez Citores[7], Ana Isabel Garcia Sanchez[7], Laura Milian[8], Olivia Nuevo[8], Ruben Perez Fernandez[8], Luis Hernandez[3], Ana Haro[1], Angel Vega[1], Fernando Geijo[1], David Cembrero[1], Pilar Tajada[4]. *[1]Complejo Asistencial Universitario de Salamanca Biomedical Research Institute of Salamanca (IBSAL), Salamanca, Spain; [2]Complejo Asistencial de Ávila, Ávila, Spain; [3]Hospital Santos Reyes, Aranda de Duero, Spain; [4]Complejo Asistencial de Segovia, Segovia, Spain; [5]Complejo Asistencial Universitario de Burgos, Burgos, Spain; [6]Complejo Asistencial de Soria, Soria, Spain; [7]Complejo Asistencial de Palencia, Palencia, Spain; [8]Hospital Universitario del Bierzo, Ponferrada, Spain*
Email: jmgsdigestivo@gmail.com

Background and aims: The integration of automated screening algorithms linked to Primary Care (PC), combining the detection of hypertransaminasemia with the FIB-4 index, may optimize the identification of hidden cases and accelerate progress toward viral hepatitis elimination. This study evaluate the feasibility of a pilot program for opportunistic and decentralized screening of viral hepatitis (HBV, HCV, HDV) in asymptomatic individuals attending PC.
Method: A prospective study was conducted (June–September 2025) in eight healthcare areas of Castilla y León (Spain). Patients aged 30–80 years with a request for routine blood testing in PC were included. Individuals with elevated alanine aminotransferase (ALT) levels and no prior hepatitis serology recorded in the lab information system underwent calculation of the FIB-4. In cases with FIB-4 >1.3 (<65 years) or >2.0 (≥65 years), viral hepatitis serology was automatically added without additional blood extraction. Samples positive for anti-HCV or HBsAg were confirmed by HCV RNA testing and anti-HDV antibodies, respectively. Diagnosed patients were individually assessed and referred to hospital-based care when indicated.
Results: A total of 189,594 blood tests from PC were processed, of which 6,331 (3.34%) showed hypertransaminasemia. FIB-4 was automatically calculated in these cases, and 958 patients (15.1%) exceeded the predefined cut-off values and underwent serological screening. Fifty-two previously undiagnosed viral hepatitis infections were identified (5.43% of those screened): 38 HBV infections (73.1%; including 2 HBeAg-negative chronic hepatitis cases, 4 inactive carriers, and 26 resolved infections) and 14 HCV infections (26.9%; 12 active and 2 resolved). Anti-HCV seroprevalence was 1.49%, and active HCV infection prevalence was 1.25%, both markedly higher than estimates for the general population (0.85% and 0.22%, respectively). The number needed to screen (NNS) to detect one

case of active HCV infection was approximately 80 among patients with elevated FIB-4, highlighting the efficiency of the sequential screening strategy in reducing unnecessary testing.
Conclusion: Automated opportunistic screening based on FIB-4 in PC identifies a prevalence of active HCV infection up to six times higher than that estimated in the general population. These results support the continuation and scaling-up of this pilot program as an operationally feasible tool to increase the diagnostic yield of viral hepatitis and advance toward WHO's elimination targets by 2030.

WED-020-YI
Evaluation of sex-based differences on hepatitis B, C and D viruses' disease burden and cascade of care in Italy
Samantha Hall[1], Loreta Kondili[2,3], Maria Giovanna Quaranta[2], Luigina Ferrigno[2], Ivane Gamkrelidze[1], Danielle Leavelle[1], Andrei Osmani[1,4], Devin Razavi-Shearer[1], Homie Razavi[1]. *[1]Center for Disease Analysis Foundation, Lafayette, United States; [2]Istituto Superior di Sanita, Rome, Italy; [3]Saint Camillus International University of Health Sciences, Rome, Italy; [4]Luiss Guido Carli University, Rome, Italy*
Email: shall@cdafound.org

Background and aims: Sex-based differences shape the epidemiology, clinical presentation, and outcomes of chronic viral hepatitis, yet they remain insufficiently incorporated into disease burden estimates and care strategies.
Method: We analysed anonymized data from the Italian PITER cohorts of patients in care for hepatitis B, C, and D viruses (HBV, HCV, HDV) to characterise sex-specific differences in demographics, virology, fibrosis severity, and treatment outcomes. Sex-stratified parameters derived from this well-characterised, nationally representative cohort were integrated into validated Markov disease progression models to estimate the sex-specific hepatitis burden in Italy.
Results: Among 6,265 individuals with chronic HBV, males presented with more advanced fibrosis and were nearly twice as likely to initiate treatment, despite females exhibiting higher baseline viremia. In HCV infection, treatment success was high in both sexes; however, males more advanced fibrosis at treatment initiation and lower odds of achieving sustainted virological response. No overall sex-based differences were observed for HDV, likely reflecting limited sample size; however, recent analyses of the same cohort indicate greater disease severity among younger women with HDV, a pattern distinct from HBV and HCV. Modelled national estimates showed a higher prevalence of HBV, viremic HCV infection, and advanced fibrosis among males, while overall HCV prevalence was similar by sex. Forecasted 2025–2030 liver-related death (LRD) ratios (male:female) were 3.5, 1.0, and 7.2 for HBV, HCV, and HDV, respectively, with comparable ratios for decompensated cirrhosis, hepatocellular carcinoma, and cirrhosis. While disease burden was projected to decline for HCV, remain relatively stable for HBV, and increase for HDV. HCV was projected to account for most LRDs (18,000 cases between 2025–2030), followed by HBV (7,700) and HDV (660).
Conclusion: Sex-based differences across viral hepatitis infections are heterogeneous and disease-specific, with implications extending beyond binary comparisons. Incorporating sex-specific real-world data from representative cohorts of patients in care is essential to refine burden estimates and to support sex-informed early diagnosis, treatment eligibility, and outcome monitoring within hepatitis elimination strategies.

WED-021
Hepatitis D testing patterns and prevalence in Australia: a retrospective statewide cohort study
Jessica Howell[1], Lauren Brotherton[2], Samuel Hui[3], Rohit Sawhney[4], Ammar Majeed[5], Siddharth Sood[6], Avik Majumdar[7], Zina Valaydon[8], Ashok Raj[9], Amanda Wade[10], Jack Wallace[11], Jacqui Richmond[11], Anouk Dev[12], Alexander Thompson[1]. *[1]St Vincent's Hospital Melbourne, University of Melbourne, Fitzroy, Australia; [2]St Vincent's Hospital Melbourne, Peter MacCallum Cancer Centre, University of Melbourne, Fitzroy, Australia; [3]Monash Health, Clayton, Australia; [4]Eastern Health, Monash University, Box Hill, Australia; [5]Alfred Health, Monash University, Melbourne, Australia; [6]Northern Health, University of Melbourne, Epping, Australia; [7]Austin Health, University of Melbourne, Heidelberg, Australia; [8]Western Health, University of Melbourne, Footscray, Australia; [9]The Royal Melbourne Hospital, University of Melbourne, Parkville, Australia; [10]Burnet Institute, Barwon Health, Melbourne CBD, Australia; [11]Burnet Institute, Melbourne CBD, Australia; [12]Monash Health, Monash University, Clayton, Australia*
Email: jessica.howell@svha.org.au

Background and aims: Hepatitis D (HDV) coinfection with hepatitis B (HBV) is the most serious form of viral hepatitis and is associated with a threefold higher risk of cirrhosis and hepatocellular carcinoma. We aimed to describe changing hepatitis D testing patterns and disease prevalence in Victoria state, Australia (~40,000 people with confirmed HBV in 2023).[1]
Method: This retrospective observational cohort study included every adult aged >18 years who underwent anti-HDV antibody testing and HDV PCR testing in Victoria between January 1, 2010 and December 31, 2023. Testing numbers and proportion positive were described overall and stratified by year, age category and sex. Associations with anti-HDV positive status were assessed by chi square test and Mantel-Haenszel odds ratios calculated.
Results: 11,361 anti-HDV antibody tests were ordered in 10,048 adults in Victoria during the study period. Over half (56%) were male and mean age was 42.2 ± 14.7 years. 500 anti-HDV antibody tests were positive and 50 had equivocal results, with a total of 498 anti-HDV antibody tests confirmed positive (4.3%) in 365 adults (3.6%). Of these, 210 adults (42%) who were anti-HDV Ab positive underwent HDV PCR testing and 72 (34%) were HDV RNA positive, consistent with active infection. 24 (33%) of HDV PCR positive adults had more than one PCR test during the study period. Of those who underwent HDV PCR testing, 48 (10%) did not have a HDV PCR test after their first positive anti-HDV antibody test, but after a repeat anti-HDV antibody test. The proportion of anti-HDV tests that were positive remained stable between 2.0–3.9% per annum during the study period. The proportion of HDV PCR tests that were positive also did not change significantly over time, ranging from a nadir of 1 (10%) in 2016 to a peak of 12 (36%) in 2018 (c^2 p = 0.232). Individuals who were anti-HDV antibody positive had higher odds of being male (67%; OR 1.55, 95% CI 1.24–1.94) but had a similar mean age (44.2 ± 12.5 years vs 44.3 ± 14.7 years, p = 0.95) compared to those who were anti-HDV antibody negative.
Conclusion: HDV-HBV coinfection is uncommon in Australia, with 1% of people with HBV tested having evidence of active HDV infection. However, major gaps in testing persist, with less than half of those who tested anti-HDV antibody positive having a HDV PCR test. Policy changes such as reflex HDV PCR testing for those who test anti-HDV antibody positive would significantly improve the HDV cascade of care.

WED-022
Assessing liver health literacy and screening uptake behaviors in an immigrant/visible minority community in Canada
Md Irfan Hyder[1], Mark Swain[1], Folake Arinde[1], Nashit Chowdhury[1], Nafiza Rahman[1], Carla Coffin[1], Mayur Brahmania[1], Tanvir C Turin[1].
[1]University of Calgary, Calgary, Canada
Email: mdirfan.hyder@ucalgary.ca

Background and aims: South Asians, including people of Bangladeshi origin, experience a disproportionate burden of chronic liver disease such as viral hepatitis and steatotic liver disease, yet awareness of liver health and preventive screening uptake remain suboptimal. Hence, Bangladeshi Canadians represent an important population to examine liver health literacy, screening uptake, perceived barriers and motivators, and associated factors.

Method: We conducted a bilingual (English/Bangla) cross-sectional survey, online and on paper, among Bangladeshi Canadian adults (n = 966) employing non-probability convenience sampling. The survey captured key demographics, general liver health knowledge, screening history & barriers, preferred screening locations, and information sources. Literacy was assessed using a nine-item exploratory scale (0–9) co-designed with community members and content experts. Adjusted negative binomial regression was used to model the knowledge score as a function of key sociodemographic characteristics, examining how scores varied across groups.
Results: Overall, 27% of participants were previously recommended to have hepatitis testing, and 23% had ever been tested for hepatitis B or C. Among respondents with no prior testing, the most reported barriers were lack of doctor's recommendation (75%), low awareness of screening (22%), and low perceived risk (21%), while unwillingness to undergo testing was uncommon (9%). Participants' preferred sources of liver health information were healthcare providers (75%), family members (30%) and friends (28%). The nine-item liver knowledge scale showed acceptable internal consistency (Cronbach's alpha = 0.76; mean score 3.8 ± 2.4). Women had 15% higher expected liver-knowledge scores than men ($p = 0.004$). Compared with participants with high school education or less, those with a diploma or bachelor's degree and those with a graduate degree had 23% ($p = 0.020$) and 34% ($p = 0.001$) higher expected scores, respectively. Temporary residents had 30% higher expected scores than citizens or permanent residents ($p = 0.002$).
Conclusion: In this large, community-based sample of Bangladeshi immigrants, both liver health knowledge and screening uptake were low, despite a high willingness to be screened and expressed trust in healthcare providers. Together, these findings underscore an important opportunity to develop targeted, culturally responsive interventions to strengthen liver disease prevention and promote earlier detection in high-risk immigrant communities.

WED-023

Hepatitis B and C viruses drive the burden of transfusion-transmissible infections in Karamoja Uganda

Jerry Ictho[1], Peter Lochoro[1], Dorothy Kyeyune[2], James Lemukol[3], Lilly Achayo[4], Godfrey Esiru[1], Brenda Nakafeero[5], Joseph Katetemere[1], Gilbert Sunday[2], Ahmed Bumba[6], Peter Lokwang[7], Sara Battistella[8], Francesca Tognon[1], Giovanni Putoto[1], Francesco Paolo Russo[8].
[1]Doctors with Africa Cuamm, Kampala, Uganda; [2]Uganda Blood Transfusion Services, Kampala, Uganda; [3]Moroto District Local Government, Moroto, Uganda; [4]Moroto Municipal Council, Moroto, Uganda; [5]Independent Statistician, Kampala, Uganda; [6]Mbale Regional Blood Bank, Mbale, Uganda; [7]Nabilatuk District Local Government, Nabilatuk, Uganda; [8]University of Padova, Padua, Italy
Email: j.ictho@cuamm.org

Background and aims: Transfusion-transmissible infections (TTIs) pose major challenges to blood safety, particularly in low-resource settings like northeastern Uganda. The aim of the study was to assess the prevalence of TTIs and associated factors among potential blood donors in the Karamoja subregion.
Method: We conducted a community-based, cross-sectional mixed-methods study involving 475 participants aged 18–60 years, selected using multistage cluster sampling from nine districts in Karamoja. Structured interviews and blood sample testing for HIV, HBV, HCV, and syphilis were performed. Modified Poisson regression with robust standard errors was used to identify factors associated with TTIs. In-depth interviews and focus group discussions explored perceptions and barriers to blood donation. Qualitative data were thematically analyzed.
Results: The prevalence of at least one TTI was 26.5% (95% CI: 22.7–30.7), with HCV (11.7%) and HBV (7.0%) being most common. Males had a significantly higher risk of TTIs (adjusted prevalence ratio [APR] 1.70, 95% CI 1.20–2.42). Older age, low education, and lack of prior blood donation were associated with higher infection rates. Qualitative findings revealed deep-rooted fears, cultural taboos, and mistrust of health services as barriers to donation. Health system limitations, including poor outreach and lack of testing capacity, further constrained safe blood availability.
Conclusion: Karamoja faces a dual challenge of high TTI prevalence and low blood donation rates. Interventions must be gender-responsive, culturally sensitive, and health-system strengthening to improve blood safety and accessibility. The high burden of viral hepatitis, particularly HBV and HCV, represents a critical public health concern and underscores the urgent need to enhance prevention, screening, and linkage-to-care strategies alongside efforts to promote safe and sustainable blood donation. Our findings provide the first community-based evidence to guide targeted public health strategies in pastoralist and underserved populations.

Hepatitis C virus reinfection after successful treatment with direct acting antiviral therapy in Canada

Naveed Janjua[1], Stanley Wong[1], Dahn Jeong[1], Jean Damascene Makuza[1], Prince Adu[1], Amanda Yu[1], Héctor Alexander Velásquez García[1], Sofia Bartlett[1]. *[1]BC Centre for Disease Control, University of British Columbia, UBC Centre for Disease Control, Vancouver, Canada*
Email: naveed.janjua@bccdc.ca

Background and aims: Preventing hepatitis C virus (HCV) reinfection following successful treatment with direct-acting antiviral (DAA) therapy among people who inject drugs(PWID) remains a key component of the HCV elimination strategy. We estimated HCV reinfection rates following DAA treatment in a population-based cohort in British Columbia (BC), Canada.
Method: We analyzed data from the IDEALS (Integrated Data for Enhanced SurveillAnce and EpidemioLogy of STBBI+TB) Platform, which includes all people tested for HCV in BC. We followed individuals with HCV infection treated with DAAs who achieved sustained virologic response (SVR) and had ≥1 subsequent HCV RNA measurement until Nov 18, 2025. Reinfection was defined as a positive RNA measurement after SVR. Injection drug use(IDU) was identified using a validated algorithm based on physician diagnosis and hospitalization codes, categorized as none, recent (IDU- related visits <3 years), and past. Crude reinfection rates per 100 person-years(PY) were calculated and Cox proportional hazards modelling was performed to identify factors associated with reinfection.
Results: Among 9,058 eligible individuals achieving SVR, the majority were male(n = 5,971, 66.0%), born 1945–64 (n = 5,137, 56.7%, median age: 56 years); 32% persons with recent IDU(n = 2,903), and 13% persons with past IDU(n = 1,148). We identified 257 HCV reinfections during 22,861.06 PY of follow-up, yielding a reinfection rate of 1.12/100 PY. Reinfection rates were higher among persons with recent IDU(n = 188, 2.37/100 PY) than persons with past IDU(n = 26, 0.77/100 PY) and persons with no IDU(n = 43, 0.37/100 PY). Cumulative incidence curves showed significantly higher and steeper increase in incidence among persons with recent IDU over time. Among persons with recent IDU, reinfection rates were highest among those <30 years of age(4.0/100 PY). In a multivariable model for persons with recent IDU, younger age (age <30 years adjusted hazards ratio(AHR): 2.05, 95%CI:1.26–3.33 (ref:50–59 yrs), and opioid use (AHR: 2.03, 95%CI:1.22–3.36) were associated with higher reinfection risk.
Conclusion: In this population-based cohort, HCV reinfection rates after DAA therapy were highest among persons with recent IDU, especially among younger PWID and who use opioids. Scale-up of HCV treatment with addiction management among persons with recent IDU, especially identifying and supporting unique needs of younger PWID, would be critical in preventing reinfection and HCV elimination.

WED-025-YI

Changing epidemiology of hepatitis A in India: trends converging with Europe

Ayush Jasrotia[1], Premashis Kar[1], Pabitra Sahu[1], Reshma Reshma[1], Nikhil Nagre[1], Amit Anand[1], Abhijit Bhalke[1]. [1]*Max Super Speciality Hospital, Vaishali, Ghaziabad, Uttar Pradesh 201010, India*
Email: ayushjasrotia1103@gmail.com

Background and aims: India was historically highly endemic for hepatitis A virus (HAV), with near-universal childhood exposure. Improvements in sanitation and socioeconomic conditions may delay primary infection, increasing susceptibility in adolescents and adults. We synthesised Indian evidence on age-specific HAV seroprevalence, surveillance and outbreaks, and compared India's trajectory with the European epidemiological transition.
Method: A PRISMA-aligned systematic review (1990–2025) identified Indian population-based serosurveys reporting anti-HAV immunoglobulin G or total antibodies, along with national and state surveillance data and outbreak investigations. Random-effects proportions using the Freeman–Tukey transformation were estimated by age band (0–5, 6–10, 11–15, 16–25, 26–40 and > 40 years). Surveillance and molecular data were narratively compared with European outbreak experience.
Results: Fourteen serosurveys including approximately 25,000 participants demonstrated a consistent age shift. An urban Delhi study (2000) reported lower immunity in individuals younger than 35 years (57%) compared with those older than 35 years (92%). A multicity survey (2011–2012) showed 37.5% overall seroprevalence and 50.3% in children aged 6–10 years, with marked socioeconomic and sanitation gradients. A national survey conducted in 2021 among individuals aged 6–30 years ($n \approx 15{,}000$) reported seroprevalence of 74.7%, 85.2% and 96.9% in the 6–10, 11–15 and 16–30 year age groups respectively, consistent with intermediate endemicity. National surveillance data (2014–2017) detected HAV immunoglobulin M in 12.6% of tested samples, predominantly in individuals aged 19 years or younger. Recent community outbreaks in Kerala (genotype IIIA) primarily affected young adults. European outbreaks between 2016 and 2018, mainly involving men who have sex with men, demonstrated similar post-transition adult susceptibility.
Conclusion: India's hepatitis A epidemiology now mirrors Europe's earlier transition, characterised by declining childhood exposure, increasing adult susceptibility and recurrent young-adult outbreaks. These findings support routine childhood vaccination in transitioning regions, adolescent catch-up in urban settings, targeted immunisation of high-risk groups and strengthened molecular surveillance.

WED-026

Mother-to-child is the dominating route of HBV transmission in the post vaccination era: a community based study in Ethiopia

Nega Berhe[1], Dawit Brhane[2], Humed Yaid[3], Fufa Hunduma[1], Bethlehem Gebregziabher[1], Lasse Rossvoll[4], Kristian Malme[4], Hailemichael Desalegn[5], Shevanthi Nayagam[6], Asgeir Johannessen[4]. [1]*Addis Ababa University, Addis Ababa, Ethiopia;* [2]*Dubti General Hospital, Semera, Ethiopia;* [3]*Mohamed Akile Comprehensive Hospital, Afar, Ethiopia;* [4]*Sykehuset i Vestfold Tønsberg, Tønsberg, Norway;* [5]*St.paul's Hospital Millennium Medical College, Addis Ababa, Ethiopia;* [6]*Imperial College London, London, United Kingdom*
Email: johannessen.asgeir@gmail.com

Background and aims: The Afar region in Ethiopia is reported to have high burden of HBV and HDV infection despite introduction of the childhood HBV vaccine in 2007. Previous studies, however, were limited by small size and unrepresentative sampling, and it is unknown whether HBV transmission is perpetuated by mother-to-child transmission or through early horizontal transmission such as traditional invasive practices. We aimed to estimate community prevalence of HBV and HDV, vaccination coverage among children under 5 years, and HBV distribution patterns within families.
Method: A cross-sectional serosurvey was conducted from February to April 2025 in the Afar region. In addition, mothers with their children under 5 years were randomly selected to assess HBV infection status, vaccination coverage, and intrafamilial HBV distribution patterns. All participants were tested for HBsAg with a point-of-care kit (Determine HBsAg2, Abbott Diagnostics; LOD 0.1 IU/ml). HDV antibodies were assessed in HBsAg positive subjects using a commercial ELISA assay (Dia.Pro Diagnostic).
Results: Overall HBV prevalence among 3,112 study participants (51.9% females; median age 30 years) was 8.1% (95% CI 7.1–9.1), with the lowest prevalence in children under 5 years (1.0%; 95% CI 0.4–3.0) and highest in adults 18–35 years (11.8%; 95% CI 10.3–13.4). HDV co-infection was detected in 90/250 (36.0%; 95% CI 30.3–42.1) of HBsAg positive individuals and was common across all age groups: 4/8 (50.0%) in children under 10 years and 16/47 (34.0%) in adults over 45 years.
Among 364 mothers, 31 (8.5%; 95% CI 6.1–11.8) were HBsAg-positive. None of their children under 5 years had received birth-dose HBV vaccine, but the majority (78.0%) had at least 2 doses of childhood HBV vaccine. Of children born to HBsAg positive mothers, 5/31 (16.1%; 95% CI 7.1–32.6) were HBsAg positive, compared to 0/333 (0%; 95% CI 0.0–1.1) of children born to HBsAg negative mothers ($p < 0.001$).
Conclusion: HBV and HDV are endemic in Afar, and the prevalence among children under 5 years is far from the WHO elimination target of <0.1%. Childhood HBV infection occurred exclusively among those born to HBV infected mothers, suggesting that mother-to-child rather than traditional practices is the predominant route of transmission. The highest HBV prevalence was seen among individuals of reproductive age, underscoring the need for birth-dose vaccination and strengthened routine childhood immunization in Ethiopia.

WED-027

National hepatitis B virus (HBV) screening pilot using rapid HBV antibody tests in Kazakhstan

Kulpash Kaliaskarova[1], Samantha Hall[2], Danielle Leavelle[2], Kulkayeva Gulnara Utepergenovna[1], Alma Aubakirova[3], Marzhan Zhanasbayeva[1], Alan Bijiyev[1], Nataliya Satlikova[1], Shakhlo Yusupalieva[4], Homie Razavi[2]. [1]*National Research Oncology Center, Astana, Kazakhstan;* [2]*Center for Disease Analysis Foundation, Lafayette, United States;* [3]*National Research Center for Health Development, Astana, Kazakhstan;* [4]*Center for Disease Analysis Foundation, Tashkent, Uzbekistan*
Email: kulpash.kaliaskarova@gmail.com

Background and aims: Hepatitis B virus (HBV) infection remains a major public health challenge in Kazakhstan, affecting an estimated 443,000 individuals. Despite the availability of free testing and treatment, fewer than 17% of cases were diagnosed by 2024. Current screening programs target only high-risk groups, pregnant women, and surgical patients, leaving many undiagnosed. This gap undermines Kazakhstan's progress toward the World Health Organization's (WHO) 2030 elimination target. This pilot evaluated the effectiveness of large-scale adult population screening in urban and rural polyclinics. The findings aim to inform the development of a national program to improve diagnosis, treatment, and public health outcomes to meet WHO elimination goals.
Method: Convenience sampling was employed to recruit adults attending polyclinics in five regions: East Kazakhstan, Abay, Turkistan, Karaganda, and Shymkent. A total of 100,024 individuals were screened for HBsAg antibodies using rapid diagnostic tests, with data recorded in an electronic registry. Prevalence was analyzed by age, sex, birth region, and clinic region. Poisson regression identified factors contributing to variability in HBV prevalence.
Results: HBV prevalence, adjusted for age and sex, was estimated to be 0.79% (0.74–0.86%). Males had higher prevalence (1.45% (1.32–1.56%)) than females (0.49% (0.44–0.55%)). Prevalence peaked at 1.51% (1.28–1.77%) for those aged 35–39. The highest prevalence was

observed among individuals born outside Kazakhstan, reaching 4.88% (1.60–12.56%). Among clinic regions, Turkistan had the highest prevalence of 1.38% (1.26–1.51%). Regression analyses indicated higher adjusted prevalence in individuals born outside of Kazakhstan, while younger age groups had significantly lower prevalence compared with those aged 40–44 ($p < 0.01$).
Conclusion: This pilot program demonstrated the feasibility of large-scale HBV screening and identified significant variability in prevalence by age, sex, and geography. Males, individuals aged 35–39, and those born outside Kazakhstan showed elevated prevalence, highlighting the need for targeted interventions. However, expanding the program to all regions and high-risk groups is critical for a comprehensive assessment of HBV prevalence. Development of a national screening strategy will be essential for Kazakhstan to meet WHO elimination targets and reduce the public health burden of HBV.

WED-028
Experience from the first two years of a peer support programme for people living with hepatitis B in north central London
Joy Ko[1], Indrajit Ghosh[1], Emily Martyn[2], Angieszka Kemper[1], Fernando Monterio[1], Richard Gilson[1,3], Mustapha Hacine Bacha[4], Mark Leonard[4], Mark Longman[4], Binta Sultan[1,3], Philippa C Matthews[1,2], Stuart Flanagan[1,3]. *[1]Central & North West London NHS Foundation Trust, Mortimer Market Centre, London, United Kingdom; [2]Francis Crick Institute, London, United Kingdom; [3]University College London, Institute of Global Health, London, United Kingdom; [4]Nhs University College Hospital, London, United Kingdom*
Email: joy.ko@nhs.net

Background and aims: There is increasing focus on peer support for people living with Hepatitis B (PLWHB), in order to improve linkage to care and treatment, enhance long-term well-being, improve health outcomes, and support progress towards international elimination goals for viral hepatitis.
Method: Our service is provided by a primary care NHS trust which runs a clinic at the Mortimer Market Centre. This trust has extensive experience in providing peer support for people living with different health challenges, and appointed the UK's first paid peer support worker (PSW) for PLWHB in 2023. This role is delivered through a combination of approaches, including individual face-to-face or telephone consultations, family meetings, and small group sessions. Referrals are made by Health Advisors and clinicians, and the PSW reaches out to all those with a recent HBV diagnosis. Translation services are provided if required. We present data on the first two years of peer support provision, from November 2023, to describe the role and workload, and to provide evidence for ongoing resourcing and expansion.
Results: 105 adults were referred to the peer support service (77 M:28 F), median age 35 years (range 18–83 years). At the time of referral, 30% were in temporary accommodation. Twenty languages were spoken, with 56% speaking English, and the commonest other languages being Mandarian, Pashto and Arabic. At the time of referral, 15% were receiving HBV treatment. 29% did not attend an offered PSW appointment (10% could not be reached, 8% were contacted and declined, and 11% had left the area). Priority topics included support with a new HBV diagnosis, discussion about starting treatment, support to share information with a partner or family members, tackling stigma and discrimination, and social issues such as migration status and housing. Our PSW also met with partners and families to tackle questions and concerns, and to support education, testing and vaccination.
Conclusion: Our PSW for PLWHB in central London provides support for adults from a diverse range of countries with complex social needs. Not all those who are referred to the service can be reached, highlighting a vulnerable population for whom additional resources are needed. We highlight peer support as a successful approach to providing information, addressing concerns and engaging individuals and their families.

WED-029
Population-based hepatitis C screening and elimination program in Lithuania: may it affect the incidence of hepatocellular carcinoma?
Limas Kupcinskas[1], Alexis Voeller[2], Artur Kozlov[3], Homie Razavi[2], Jurate Sabaliene[3], John Ward[4], Janina Petkeviciene[1], Juozas Kupcinskas[1]. *[1]Lithuanian University of Health Sciences, Kaunas, Lithuania; [2]Center for Disease Analysis Foundation, Lafayette, United States; [3]National Health Insurance Fund under the Ministry of Health, Vilnius, Lithuania; [4]Coalition for Global Hepatitis Elimination, Decatur, United States*
Email: l.kupcinskas@gmail.com

Background and aims: Liver cancer is the 15th most common type of cancer in Lithuania (2022) and almost 50% of cases of hepatocellular carcinoma (HCC) were caused by the hepatitis C virus (HCV). The Lithuanian HCV screening programme started in 2022. HCV antibody testing by general practitioners (GP) was performed: 1) for people born 1945–1994 (once in a lifetime) and 2) for those who inject drugs (PWID) or HIV+ (annual testing). The aim of the study was to assess results of the first 39 months of the programme, evaluate different scenarios to achieve WHO 2030 targets and effect on HCC incidence.
Method: GP invited people to perform a serum ant-HCV test. Anti-HCV positive patients (pt) were referred to a gastroenterologist or infectologist for HCV RNA testing, and if result positive, direct-acting antiviral (DAA) was prescribed. Information about pt was obtained from National Health Insurance Fund. The Markov disease progression model elaborated CDA Foundation was used to assess HCV elimination progress. The data from the 2022–2023 screening were used as inputs. Three scenarios were developed: the 'Base' scenario - return to pre-screening program level in 2023 and 2 scenarios with different extents of treatment.
Results: in 2022, about 1.8 million people born 1945–1994 lived in Lithuania. Between May 5, 2022 and July 31, 2025 from this population 1419059 (81%) were tested for HCV antibodies. Positive test were found in 1.3% of cases. In the risk group, 18695 PWID and HIV+ people were screened, of whom 29.4% were seropositive. Viremia was detected in 52,8%. During 39-month period 3 times more HCV pt were treated with DAA than during the same period before starting of the program (8321 vs 2690). The Markov disease progression model to assess HCV elimination progress showed the following: Scenario 1: if the same number of pt are treated as before the screening, the WHO targets will not be reached. Scenario 2: treating 70% of infected patients will meet most but not all WHO targets. Scenario 3: by treating all infected patients by 2030, the WHO target will be met by saving 150 lives and preventing 90 new cases of decompensated cirrhosis and 120 cases of HCC.
Conclusion: In country with moderate HCV seroprevalence, a population-based screening program can be feasible, screening 81% (more than 1,4 million) of the target population during the first 39 program months. In case of realization of the Scenario 3 we could expect to achieve WHO targets by 2030 and diminish HCC incidence in Lithuania.

WED-030
Epidemiological landscape of hepatitis E in South Korea: analysis of national surveillance data (2020–2023)
Chang Hun Lee[1], Hwa Young Choi[2], Won-Mook Choi[3], Byeong Geun Song[4], Moran Ki[2], Sook-Hyang Jeong[5], In Hee Kim[1]. *[1]Department of Internal Medicine, Research Institute of Clinical Medicine of Jeonbuk National University-Biomedical Research Institute of Jeonbuk National University Hospital, Jeonbuk National University Medical School, Jeonju, Korea, Rep. of South; [2]Department of Public Health and AI, Graduate School of Cancer Science and Policy, National Cancer Center, Goyang, Korea, Rep. of South; [3]Department of*

Gastroenterology, Liver Center, Asan Medical Center, University of Ulsan College of Medicine, Seoul, Korea, Rep. of South; [4]Department of Medicine, Samsung Medical Center, Sungkyunkwan University School of Medicine, Seoul, Korea, Rep. of South; [5]Department of Internal Medicine, Seoul National University Bundang Hospital, Seoul National University College of Medicine, Seongnam, Korea, Rep. of South
Email: ihkimmd@jbnu.ac.kr

Background and aims: Hepatitis E virus (HEV) infection was designated as a mandatory reportable disease in South Korea in July 2020 by the Korea Disease Control and Prevention Agency (KDCA). This study aimed to analyze national infectious disease surveillance data to evaluate temporal trends and epidemiological characteristics of reported hepatitis E cases.
Method: We analyzed all confirmed HEV cases reported to the KDCA from July 2020 to December 2023. Reporting trends, demographic distributions (age, sex, and region), and clinical characteristics were assessed using epidemiological investigation forms and laboratory data.
Results: After excluding duplicate reports, a total of 1,768 hepatitis E cases were identified. The annual reporting rate increased from 0.95 per 100,000 population (n = 493) in 2021 to 1.09 per 100,000 (n = 562) in 2023. A significant male predominance was observed (58.1% vs. 41.9%, $p < 0.001$). Reported cases increased progressively with age, from 35 cases in children aged 0 to 9 years to 327 cases in those aged 60 to 69 years ($p < 0.001$). No distinct seasonal pattern was identified. Regionally, the highest reporting rate was observed in Gangwon province. Symptomatic cases accounted for 62.8% of all reports and were more frequent in younger age groups, with no significant difference by sex. Among 1,542 cases with completed epidemiological investigation forms, liver function test results were available for 1,434 cases. Elevated aminotransferase levels (aspartate aminotransferase or alanine aminotransferase $\geq$ 40 U/L) were observed in 82.5% of symptomatic cases and 51.7% of asymptomatic cases.
Conclusion: Reported hepatitis E cases in South Korea have increased since the implementation of mandatory national surveillance in 2020, with higher reporting rates among men and older age groups. These findings provide insights into the epidemiological burden of hepatitis E in South Korea based on national infectious disease surveillance data.

WED-031
Global prevalence of HIV-HBV co-infection in pregnancy: a systematic review to inform elimination of mother-to-child transmission

Leona Leipold[1], Francesca Bladt[1], Rageshri Dhairyawan[2,3], Stamatina Iliodromiti[4], Upkar Gill[1,5]. *[1]Centre for Immunobiology & Infection, The Blizard Institute, Barts and The London Faculty of Medicine & Dentistry, Queen Mary University of London, London, United Kingdom; [2]SHARE Collaborative, Blizard Institute, Barts and The London Faculty of Medicine & Dentistry, Queen Mary University of London, London, United Kingdom; [3]Department of Infection and Immunity, Barts Health NHS Trust, London, United Kingdom; [4]Women's Health Research Unit, Wolfson Institute of Population Health, Queen Mary University London, London, United Kingdom; [5]Department of Hepatology, Barts Health NHS Trust, London, United Kingdom*
Email: u.gill@qmul.ac.uk

Background and aims: HIV-HBV co-infection in pregnancy remains a critical but under-characterised challenge for the World Health Organization (WHO) goal of triple elimination of mother-to-child transmission (MTCT) of HIV, hepatitis B virus (HBV), and syphilis. While antenatal HIV and HBV screening is widely implemented, the global burden of maternal co-infection and its implications for pregnancy and birth outcomes remain poorly synthesised.
Method: We conducted a systematic review of published studies reporting HIV-HBV co-infection in pregnant populations across multiple regions. Studies reporting prevalence and/or maternal, obstetric, or birth outcomes were included. Data were extracted on study design, geographic region, period, population characteristics, and diagnostic methods.
Results: A total of 165 studies were included, encompassing ~2.33 million pregnant individuals globally. Studies were geographically skewed, with ~68% originating from the WHO African Region, and relatively sparse representation from Europe, the Americas, and Asia-Pacific regions. Reported HIV-HBV co-infection prevalence varied widely by setting and population. In general antenatal populations, prevalence ranged from near 0% in several settings to high historical outliers (e.g. ~28.9% in a 1992 Tanzanian cohort). Among HIV-positive pregnant cohorts, higher co-infection rates were consistently observed, frequently in the 5–15% range, with some European and African cohorts reporting substantially higher prevalence (e.g. ~39.2% in a Romanian HIV-positive cohort). Maternal, obstetric, and neonatal outcomes were poorly reported, with a minority of studies presenting outcome data alongside prevalence estimates. Considerable heterogeneity was observed in diagnostic methods and reporting, with HIV and HBV testing strategies often unstated. Several countries appear to collect antenatal HIV and HBV data through unlinked surveillance systems, limiting reliable co-infection estimates and trend analysis.
Conclusion: Despite a large global evidence base, data on HIV-HBV co-infection in pregnancy remain imbalanced, methodologically inconsistent, and outcome-sparse. Co-infection prevalence can be substantial in specific antenatal settings, particularly among HIV-positive pregnant populations. These findings support the need for integrated antenatal HBV/HIV testing, improved diagnostic reporting standards, and linked surveillance systems to better inform MTCT prevention strategies and guide elimination efforts.

WED-035
Global drug utilization and expenditure of essential medicines forecasting future viral hepatitis elimination: a multinational drug use study

Jiaqi Wang[1], Lung Yi Loey Mak[1], Kathy Leung[1], Esther Wai Yin Chan[1], Po-Lin Chan[2], Yasser Abdallah[3], Won-Mook Choi[4], Adrian Gadano[5], Yasuhito Tanaka[6], Alexander Nersesov[7], Xiaodong Guan[8], Ajay Kumar Duseja[9], Ian Chi Kei Wong[10], William CM Wong[1], Young-Suk Lim[4], Man-Fung Yuen[1], Mindie Nguyen[11], Xue Li[1], Wai-Kay Seto[1]. *[1]The University of Hong Kong, Pok Fu Lam, Hong Kong; [2]World Health Organization South-east Asia Regional Office, New Delhi, India; [3]Minia University, Minia, Egypt; [4]Asan Medical Center, University of Ulsan College of Medicine, Seoul, Korea, Rep. of South; [5]Sección Hepatología, Hospital Italiano, Buenos Aires, Argentina, Buenos Aires, Argentina; [6]Department of Gastroenterology and Hepatology, Faculty of Life Sciences, Kumamoto University, Japan, Kumamoto, Japan; [7]Department of Gastroenterology, Kazakh National Medical University, Almaty, Kazakhstan, Almaty, Kazakhstan; [8]Department of Pharmacy Administration and Clinical Pharmacy, School of Pharmaceutical Sciences, Peking University, Beijing, China, Beijing, China; [9]Department of Hepatology, Post Graduate Institute of Medical Education & Research, Chandigarh, India, Chandigarh, India; [10]Aston Pharmacy School, Aston University, Birmingham, UK, Birmingham, United Kingdom; [11]Division of Gastroenterology and Hepatology, Stanford University Medical Center, Palo Alto, California, USA, Palo Alto, United States*
Email: loeymak@gmail.com

Background and aims: The World Health Organization (WHO)'s 2030 viral hepatitis elimination goals aim to reduce related deaths by 65%. Treatment uptake of antiviral medications for chronic hepatitis B (CHB) and chronic hepatitis C (CHC) remains low. We aimed to examine the actual utilization of these antiviral drugs on a global scale, describing drug consumption and expenditure trends over the past decade & make projections in viral hepatitis-related mortality towards year 2030.
Method: We used data from the IQVIA Multinational Integrated Data Analysis System database to analyze the trends in actual utilization of the WHO Model Lists of Essential Medicines (EML) in CHB & CHC from

2015 to 2023 & evaluated economic inequality in medication utilization. We estimated the association between these trends with CHB- & CHC-related incidence & mortality using data from the Global Burden of Diseases & Polaris Observatory, by fitting into generalized linear mixed models, alongside economic & health system metrics. Projections on disease-related mortality were generated towards year 2030.

Results: Among 68 & 61 countries with WHO EML data available on CHB & CHC, respectively, utilization of EML drugs for CHB has increased with time that was largely contributed by the Western Pacific region & high-income countries. For CHC, utilization of EML has peaked around 2017 & subsequently declined with time & concentrated in low-middle-income countries, largely driven by utilization in Egypt (14.3 per 1000 population). Inequality in EML drug usage was observed, with CHC favouring lower Gross National Income (GNI) levels but in CHB favouring higher GNI levels. Most countries demonstrated modest decline in age-standardized incidence and/or mortality rates, but mortality reduction was outpaced in CHB. By 2030, the greatest forecasted mortality reductions for CHB & CHC would be 59.4% in Korea & 55.8% in Kazakhstan respectively. For high-disease burden countries, mortality will decline modestly or even increase till 2030 (−13.7% to +97.1%; & −51.2% to +151% respectively).

Conclusion: Global utilization patterns of essential medicines for CHB & CHC have evolved over the past decade with residual inequality. Most countries showed modest decline in incidence and/or mortality but the mortality reductions were delayed. No countries are projected to approach the goal of mortality reduction by 2030, & expansion of treatment access in the next 5 years would be a critical priority.

WED-036

Incidence of HIV among people living with chronic hepatitis B: 10-year results from a large cohort in Ethiopia

Kristian Malme[1,2], Hailemichael Dessalegn[3,4], Nega Berhe[1,5], Eyerusalem Mamo[4], Tsehay Solomon[4], Asgeir Johannessen[1,6].

Email: krismalme@hotmail.com

Background and aims: Although tenofovir disoproxil fumarate (TDF) monotherapy is safe and effective for long-term treatment of people living with chronic hepatitis B (PLWHB), its use in settings with a moderate/high prevalence of human immunodeficiency virus (HIV) warrants caution, as TDF monotherapy may lead to HIV resistance among co-infected individuals. The aim of this study was to assess HIV incidence, with and without antiviral therapy, in a well-characterized cohort of PLWHB in Addis Ababa, Ethiopia, where the background HIV prevalence in the adult population is 3.1%.

Method: This was a longitudinal cohort study of HIV-negative HBsAg-positive adults (>/ = 18 years) enrolled in a treatment center in Addis Ababa in 2015 and followed up until 2025. HIV testing was conducted at baseline and repeated every 3–6 months among treated, and less frequently among untreated, individuals using HIV antibody/antigen rapid diagnostic tests. HIV incidence rates were calculated using person-time of observation.

Results: The total number of person-years was 6611 (median follow-up time 4.95 years). Among 1303 participants enrolled (mean age 34 years, 59% male, 21% liver cirrhosis, 22.5% TDF treated during the study period), 1 case of HIV was detected after inclusion, resulting in an HIV incidence of 0.015 per 100 person years [95% CI 0.001–0.084]. HIV incidence was 0.05 per 100 person years [95% CI 0.001–0.30] among treated persons and 0.00 per 100 person years among untreated [95% CI 0.00–0.0.8]. The sole participant who tested HIV positive at month 3 was later shown, through HIV immunoblot retesting of the baseline screening sample, to have been HIV positive at inclusion, consistent with infection during the HIV serological window phase.

Conclusion: In settings with high HIV prevalence, TDF therapy can be safely administered in hepatitis B programs but should be accompanied by repeated HIV testing.

WED-037

Re-linkage to care for HDV positive patients as part of an unique pan-re-linking program in Italy

Alessandra Mangia[1], Valeria Piazzolla[1], Antonio Napolitano[1], Adelia Aquilano[2], Luca L'erario[3], Angelo L'erario[4], Mattia Lopez[5], Laura Lange[6], Maria Squillante[1], Rosanna Santoro[7], Laura Solito[8].
[1]IRCCS Casa Sollievo della Sofferenza, San Giovanni Rotondo, Italy; [2]Laboratorio Analisi cliniche Aquilano srl, Cagnano Varano, Italy; [3]Laboratorio Analisi Dell'Olio srl, Trani, Italy; [4]Laboratorio Dell'Oglio, Trani, Italy; [5]Laboratorio Analisi Palazzo, Margherita di Savoia, Italy; [6]Laboratorio Guerrieri, Cagnano Varano, Italy; [7]Laboratorio Analisi Santoro, Maruggio, Italy; [8]Laboratorio Solito, Taranto, Italy
Email: a.mangia@tin.it

Background and aims: Despite the advances in therapy, linkage to care represents one of the main barriers to the global elimination of viral hepatitis. A substantial number of candidates for hepatitis C, B and D treatment remain untreated or lost to follow-up. Re-linkage to care represents one of the main focuses for achieving HCV and HBV/HDV elimination. In Italy, this process is hampered by data privacy regulations, which we managed to overcome by designing a project to be conducted in collaboration with private laboratories. To assess the effectiveness of a dedicated re-linking program implemented together with hub private laboratories which manage spoke laboratories covering an area of 7500 Km2.

Method: From 6/2024 to the present, 10 hub laboratories coordinated by our center through the help of Telehealth across the 6 provinces of Puglia, recalled patients aged 50–85 tested in the last 10 yrs and found to be HCVAb or HBsAg positive. We focus here on the results for HBsAg positive. The project will be completed by June 30th, 2026. HBsAg positive patients were offered counselling, HDVAb and, when needed, HDVRNA testing; HDVRNA assessement by Robogene, and treatment at our center. Primary endpoint is the number of patients re-linked out of HDVAb positive; secondary endpoint, the number of patients who started HDV treatment.

Results: Overall, 1050 were recalled, only 351 HBsAg positive individuals agreed to be included (149 had died, in 201 re-check was negative, 109 moved to a different geographical area, 53 rejected the offer, 97 lost contact). These individuals were 67% male with mean age 61.9 ± 10.1 yrs. All of them were tested for HDVAb. Overall, 70 (19.9%) had HDVAb positive results and underwent HDVRNA evaluation. Rate of HDVAb patients with HDVRNA detectable was 25.7%. Rates of patients with PLT<140.00 ul were 54.2% and 18.1%, among HDVAb positive and negative, respectively. All except 3 (two of whom with Non-HodgkinLymphoma and kidney cancer) started treatment with a treatment re-linkage rate of 83.3%. Of the 15 patients who started treatment, 73.3% had evidence of advanced disease.

Conclusion: Bringing patients to care for HDV was more difficult than expected. Rate of HDVRNA positivity was high; the majority of HDVAb positive patients had PLT <140.000ul suggesting the presence of an advanced disease. This initiative allowed patients with HBV/HDV advanced disease that lacked follow-up HDV testing to be identified and treated.

From control to elimination of HCV infection: the experience in prisons of Catalonia, Spain

Andrés Marco[1], Indiana Abdo[2], Enrique Gil[2], Neus Solé[2], Isabel Barnés[2], Elisabet Turu[2]. [1]*Prison Health Program. Catalan Institute of Health. Government of Catalonia, Biomedical Research Consortium Network for Epidemiology and Public Health (CIBERESP), Barcelona, Spain;* [2]*Prison Health Program. Catalan Institute of Health. Government of Catalonia, Barcelona, Spain*
Email: andres.marco.m@gmail.com

Background and aims: Often, prison-based HCV micro-elimination programs are isolated or one-off initiatives with limited impact on reducing incidence. Our objective is to evaluate the effectiveness of a program continuously implemented for all incarcerated individuals across all prisons in Catalonia.
Method: The study examined: (a) the prevalence of HCV infection in new inmates at the nine prisons in Catalonia between 1 January 2020 and 31 December 2024; (b) the annual incidence of infection; and (c) the effectiveness of the program, determined by the annual incidence rate and the number of direct-acting antiviral (DAA) treatments prescribed between 2016 and 2024. The program was considered effective if the incidence was zero or remained below a threshold unlikely to sustain transmission. This threshold was defined as a consistently low HCV RNA level, below 0.5%.
Results: Among the 34,088 inmates admitted, 32,002 (93.9%) consented to screening. A total of 370 infections (1.2%) were detected, with a downward trend (2.2% in 2020 and 0.6% in 2024; $p < 0.001$). Of these, 361 cases were further analyzed, of which 82 were reinfections, significantly more frequent in men, Spanish nationals, inmates in Barcelona prisons, people who inject drugs (PWID), and those coinfected with HIV. The median time to reinfection was 1185 ± 164 days, and was shorter ($p = 0.001$) in migrants (730 ± 290 days). A total of 340 patients were treated, and 98.4% achieved a sustained virological response (SVR). The incidence remained consistently below 0.5%. On 31 December 2024, the viremia was undetectable in four of the nine prisons.
Conclusion: HCV elimination programs in prisons must be maintained over time and subjected to periodic evaluation. Although achieving elimination, or control of the infection, in these institutions is challenging, this study demonstrates that it is feasible when systematic programs are implemented universally across all prisoners and all prisons within the community.

WED-039

'Hep-MoLo': integrating community co-design and multidisciplinary approach to deliver decentralised liver health screening for Mongolians in London

[1]*The Francis Crick Institute, London, United Kingdom;* [2]*University College London, London, United Kingdom;* [3]*City St George's, University of London, London, United Kingdom;* [4]*Queen Mary University of London, London, United Kingdom;* [5]*Onom Foundation, Ulaanbaatar, Mongolia;* [6]*University College London Hospital, London, United Kingdom;* [7]*Central and North West London NHS Foundation Trust, London, United Kingdom;* [8]*Mongolian Community Organisation, London, United Kingdom;* [9]*Siphox Health, Burlington, United States;* [10]*Parkview Centre for Health & Wellbeing, NHS, London, United Kingdom;* [11]*Buckinghamshire NHS Trust, Stoke Mandeville, United Kingdom;* [12]*Oxford University Hospitals NHS Trust, Oxford, United Kingdom;* [13]*University of Edinburgh, Edinburgh, United Kingdom;* [14]*Barts NHS Foundation Trust, London, United Kingdom;* [15]*Lewisham and Greenwich NHS Trust, London, United Kingdom*
Email: emily.martyn1@crick.ac.uk

Background and aims: Mongolia has the highest liver cancer incidence globally, associated with high prevalence of chronic viral hepatitis infection (hepatitis B, C and D viruses; HBV, HCV, HDV). Worldwide, metabolic dysfunction-associated steatotic liver disease (MASLD) prevalence is increasing, although there are few data from Mongolia. Migrants are disproportionately affected by liver disease, with challenges of navigating unfamiliar healthcare systems and language barriers. We held community-based liver screening events for the London Mongolian community ("Hep-MoLo").
Method: Hep-MoLo (ethics ref: 25/LO/0126) was designed and delivered by a clinical-academic-community multidisciplinary team. Liver screening events were held at a community centre. Mongolian adults (age 18+) were eligible to undergo screening, including a liver health questionnaire, point of care tests for HBV, HCV, HIV and syphilis, cardiometabolic factors (CMF: diabetes, body mass index, blood pressure, lipid profile), controlled attenuation parameter (CAP), transient elastography (TE) and HBV serology. MASLD was defined as CAP >248 dB/m and at least one CMF. Fibrosis was defined as TE > 8 kPa.
Results: During two events in Autumn 2025, 89 participants were screened; 86 agreed for their data to be used in research. Median age was 48 (IQR 39, 53) and 64% (55/86) were female. Ninety-three percent (80/86) were born in Mongolia and lived in the UK for a median of 19 years (IQR 9, 22). Five participants had confirmed HBV (5.8%, 5/86), two with HDV coinfection. Three were not under follow up, requiring referral to specialist care. None had fibrosis by TE, but one had cirrhosis on MRI. Of 79 participants without current HBV infection, 60% (45/79) were anti-HB core positive, 10% (8/79) were anti-HB surface antibody positive only (i.e. vaccinated) and 27% were HBV susceptible (21/79). Four had previous HCV. 43% (36/83) met MASLD criteria. 14% (5/36) had TE >8 kPa and required hepatology referral. Two people living with HBV had MASLD.
Conclusion: Hep-MoLo demonstrates feasibility of community-based liver health screening. High prevalence of HBV, HDV co-infection and MASLD emphasises an unmet need for targeted interventions. Ongoing work includes further screening, qualitative and laboratory research, community engagement, and assessment of longer-term linkage to care. Hep-MoLo supports WHO 2030 targets for viral hepatitis elimination, reduction of obesity and diabetes, and decentralised healthcare delivery.

WED-040

Burden of liver fibrosis and steatosis associated with hepatitis B or C infection in China: a population-based study from the 2020 national serological survey

Tongtong Meng[1], Yu Wang[2], Hui Zheng[3], Jian Li[4], Xiaoning Wu[1], Min Wang[1], Shuyan Chen[1], Yameng Sun[1], Hong You[1], Hui Zhuang[5], Zundong Yin[3], Jidong Jia[1], Yuanyuan Kong[1]. [1]*Beijing Friendship Hospital, Capital Medical University, National Clinical Research Center for Digestive Diseases, State Key Lab of Digestive Health, Beijing, China;* [2]*Beijing, China;* [3]*Chinese Center for Disease Control and Prevention, Beijing, China;* [4]*National Center for AIDS/STD Control and Prevention, Chinese Center for Disease Control and Prevention, Beijing, China;* [5]*Peking University Health Science Center, Beijing, China*
Email: kongyuanyuan2000@163.com

Background and aims: The burden of liver fibrosis and steatosis associated with hepatitis B virus (HBV) and hepatitis C virus (HCV) infections in China remains to be quantified. We aimed to estimate the prevalence of HBV or HCV infection with fibrosis and steatosis to inform national elimination strategies.

Method: This study was conducted among individuals aged 15–69 years from the 2020 National Serological Survey of Viral Hepatitis. Liver fibrosis and steatosis were assessed using transient elastography, and the weighted prevalence of each condition was estimated among individuals with HBV or HCV infection.
Results: The final analysis included 4,236 people with HBV infection and 122 with HCV infection out of the 69,351 participants for the serological survey. The weighted population prevalence of HBV infection with ≥F2 fibrosis was 0·63% (95% CI 0·52–0·77), corresponding to an estimated 6·08 million individuals nationwide. For HCV, the weighted prevalence of ≥F2 fibrosis was 0·05% (95% CI 0·03–0·08), representing 0·48 million individuals. The weighted proportions of concomitant hepatic steatosis (≥S1) were 34·85% among individuals with HBV infection and 42·43% among those with HCV infection.
Conclusion: Despite declining incidence rates, China continues to bear a substantial burden of advanced liver disease among populations affected by viral hepatitis, increasingly compounded by the rising prevalence of hepatic steatosis. Achieving the 2030 elimination goal will require proactive case finding and improved linkage to care for individuals with advanced fibrosis and steatosis.

WED-046
Budget impact analysis of the GeneXpert® system for hepatitis C virus infections screening in addiction care and prevention centers and prisons in France
Veronique Loustaud-Ratti[1], Henri Lesage[2], Sandrine Francois[1], Quentin Berkovitch[2], Inès Messai[3,4]. *[1]Chu Limoges, Limoges, France; [2]PHE-Cencora, Paris, France; [3]Cepheid, Maurens-Scopont, France; [4]Cepheid, Paris, France*
Email: ines.messai@cepheid.com

Background and aims: Hepatitis C virus (HCV) infections represent a critical public health challenge in France, particularly in high-risk populations such as prisoners and individuals attending addiction care and prevention centers (CSAPA), where active HCV infection (RNA+) prevalence reaches 1.3% and 16.3%, respectively—significantly higher than in the general population. Current standard-of-care (SoC) diagnostic strategy faces limitations, including logistical barriers and delays in diagnosis, which hinder timely treatment initiation. The *GeneXpert®* system enables a fast molecular diagnostic on demand solution through automated RT-PCR *Xpert® HCV VL Fingerstick*, enabling potential same-day diagnosis and linkage to care. This study evaluates the budget impact of implementing "test and treat" strategy using *Xpert® HCV VL Fingerstick* point of care (POC) screening in French prisons and CSAPA, compared to SoC. The analysis assesses the impact of a "test and treat" approach, aiming to achieve the World Health Organization's (WHO) 2030 elimination targets.
Method: A budget impact model simulated epidemiological and economic outcomes over 20 years from the French National Health Insurance perspective, comparing SoC to "test and treat" strategy. Data were sourced from literature, epidemiological and health insurance databases. The study population included prisoners and individuals attending CSAPA.
Results: The "test and treat" strategy could increase HCV detection rates to 89.5% in infected prisoners (vs. 51.6% SoC) and 84.2% in infected CSAPA patients (vs. 9.5% SoC), resulting in an 87% increase in treated prisoners and a nearly 5-fold increase in treated CSAPA patients. Screening costs would rise by €13.7M in prisons and €35.1M in CSAPA over 20 years compared to SoC. However, treatment costs would decrease by €3.6M in prisons, while increasing by €480M in CSAPA due to higher treatment uptake. These costs are offset by substantial reductions in long-term chronic HCV complication management costs of €110.7M in prisons and €688.2M in CSAPA, resulting in net savings of €100.6M and €172.7M, respectively, suggesting significant economic benefits alongside improved patient outcomes.
Conclusion: "Test and treat" strategy using *Xpert® HCV VL Fingerstick* represents a cost-saving and effective strategy for HCV screening in high-prevalence settings, supporting WHO elimination goals by improving detection and treatment rates in France.

WED-047
Progress towards hepatitis C virus elimination in English prisons – 7 year outcomes on a multi-stakeholder project
Julie Henderson[1], Michelle Storer[2], Craig Thompson[3], Arran Ludlow-Rhodes[4], Andrew Milner[4], Christine Taylor[4], Louise Missen[4]. *[1]Practice Plus Group, Reading, United Kingdom; [2]Oxleas NHS Foundation Trust, London, United Kingdom; [3]Spectrum Community Healthcare CIC, Wakefield, United Kingdom; [4]Gilead Sciences Ltd, London, United Kingdom*
Email: julie.henderson@practiceplusgroup.com

Background and aims: Following the World Health Organization's (WHO) plans to eliminate viral hepatitis by 2030, National Health Service England (NHSE) announced plans to eliminate Hepatitis C (HCV) in England by 2025, with prisons being a key focus area to achieve this goal. Gilead Sciences formed partnerships with Practice Plus Group (PPG) in May 2019 and Oxleas NHS Foundation Trust and Spectrum Community Health CIC in 2021 with the aim to optimise HCV test and treat in their prison settings. Here we present data on testing rates, RNA positivity and treatment starts over this 7 year project.
Method: Regional BBV Leads and Gilead Medical Scientists worked with prison and HCV stakeholders including the Hepatitis C Trust to optimise test and treat pathways for new prison admissions. Whole prison test and treat events were also conducted in targeted prisons to ensure testing of residents who were incarcerated before these optimisations were implemented. Virtual BBV training sessions have been run on a monthly basis available to all providers to raise awareness of BBV testing and treatment pathways and challenge stigma. Anonymised data has been collected from all providers through electronic patient records and aggregated.
Results: Data from all providers are aggregated unless otherwise specified. Between May 2019-November 2025, a total of 342,837 HCV antibody tests were completed out of 475,399 offered (uptake of 72.1%) with 6,156 patients being initiated on treatment for HCV. Reception HCV testing uptake has increased since 2019 from 40.9% to 72.5% in 2025 despite reduction in staff resource over the previous 2 years. Total prison population HCV antibody and RNA prevalence data was only available for PPG; a consistent decline was seen in RNA positivity between 2019 (2%) to 2025 (0.3%) with antibody prevalence remaining stable (median 5.8%, range 5.2%-6.5%). Full data at 7 years will be available for the poster presentation.
Conclusion: This project demonstrates the value of a co-ordinated multi-stakeholder approach to BBV screening and linkage-to-care in prison settings and shows that BBV screening can be successfully maintained on-site when specialist regional staff support is reduced. Reception testing rates rose to 72.5%, and RNA prevalence declined to 0.3%, demonstrating progress towards NHSE's elimination goal. Continued optimisation and training remain essential to sustain these achievements.

Email: vihernandez@clinic.cat

Background and aims: Porto-Sinusoidal Vascular Disorder (PSVD) is a rare vascular liver disease of unknown etiology characterized by portal and sinusoidal remodelling and endothelial dysfunction primarily affecting intrahepatic vasculature. However, contribution of hepatocytes in PSVD remains unclear. Preliminary single-cell RNA sequencing (scRNAseq) in PSVD liver biopsies revealed dysregulated pathways in hepatocytes, suggesting their contribution to PSVD pathophysiology. In the absence of animal models that sufficiently capture human disease heterogeneity and complexity, we aimed to determine whether hepatocyte-enriched, patient-derived organoids provide a physiologically relevant humanized platform to study parenchymal cell contributions to PSVD.
Method: Transjugular liver needle biopsies of patients with PSVD and individuals with histologically normal livers (HNL) were used to generate epithelial organoids that originated from progenitor cells in the biopsy, under hepatocyte-directed culture media and characterised by immunofluorescence. Bulk RNA sequencing was performed on organoids (PSVD vs HNL) and compared with hepatocyte (PSVD vs HNL) gene expression profiles derived from scRNAseq of biopsies, aggregated at the hepatocyte level.
Results: Immunofluorescence demonstrated that PSVD organoids exhibited progenitor ($SOX9^+$, $TROP2^+$), epithelial ($KRT7^+$, $ECAD^+$) and hepatocytic (ALB^+, $MRP4^+$) features and morphology comparable to HNL organoids. Comparison of gene expression patterns showed that 54.4% of disease-associated pathways upregulated in hepatocytes from PSVD liver biopsies were preserved in PSVD organoids. Consistent with pathways previously identified as key in PSVD pathophysiology, mitochondrial function, extracellular matrix remodelling, vasculature, inflammation, and coagulation showed >85% concordant upregulation between hepatocytes and organoids. Bioenergetic pathways, including oxidative phosphorylation and citric acid cycle, also exhibited similar upregulation in PSVD organoids.
Conclusion: Using the first humanised organoid model of PSVD, we show that hepatocytes intrinsically contribute to PSVD-associated transcriptional programs and provide a mechanistically relevant platform to interrogate hepatocyte-endothelial crosstalk and may inform future therapeutic strategies.

Email: ignasiolivasalberch@gmail.com

Background and aims: This study assessed the diagnostic utility of genetic testing using whole exome sequencing (WES) in adult patients with idiopathic chronic cholestasis (ICC), idiopathic chronic hepatitis (ICH), low phospholipid–associated cholelithiasis (LPAC), and recurrent cholestasis (RC).
Method: This prospective cohort study included 132 adults with ICC, ICH, LPAC or RC who underwent WES. Liver disease–related gene variants were reported according to Online Mendelian Inheritance in Man (OMIM). Variants were classified using the American College of Medical Genetics and Genomics criteria, reporting pathogenic (P), likely pathogenic (LP), and variants of uncertain significance (VUS). A definite genetic diagnosis was defined by the presence of P or LP variants or rare damaging VUS consistent with the phenotype and inheritance pattern.
Results: Most patients were women (63%), with a median age of 49 years (IQR 39–55) at WES and 34 years (IQR 25–43) at disease onset. A family history of liver disease of unknown aetiology was reported in 23 patients (17%), intrahepatic cholestasis of pregnancy in 20 (15%), and pruritus in 23 (17%). Overall, 63 patients (48%) carried at least one variant, with 66 variants identified in 32 genes. A definitive diagnosis was established in 20 patients (15%), whereas 26 (20%) carried variants with a possible contribution to the phenotype. Ten patients were misdiagnosed before WES was performed. Among 99 patients (75%) with ICC, 39 (39%) had variants, 4 had a definitive diagnosis (2 with pathogenic JAG1 variants consistent with Alagille syndrome and 2 with HNF1B variants), and 19 had variants with possible phenotypic contributions (15 in PFIC-related genes, 2 in NOTCH, and 2 in HNF1B). Among 17 patients (7%) with ICH, 9 (53%) carried variants; 4 had a definitive diagnosis (2 with homozygous P variants in ACOX2 and 2 with complete HNF1B deletions). Among 14 patients (11%) with LPAC, 12 (86%) carried variants, with 10 definitive diagnoses, all involving ABCB4 gene. All 3 patients (2%) with RC carried variants; 2 had definitive diagnoses (1 homozygous ATP8B1 and 1 homozygous ABCB11).
Conclusion: Genetic variants can account for a significant proportion of cases of idiopathic cholestasis and chronic hepatitis. Therefore, genetic testing should be conducted early in undiagnosed patients following standard diagnostic procedures to prevent unnecessary treatments.

Two-fold improvement of thrombosis regression rate after implementation of a multidisciplinary treatment protocol for acute superior mesenteric vein thrombosis

Sophie Ciere[1], Kay Pieterman[2], Mandy Lauw[3], Jeroen de Jonge[1], Eva Heerschap[4], Roeland de Wilde[1], Francois Willemssen[2], Diederik Bijdevaate[2], Raoel Maan[4], Sarwa Darwish Murad[4]. [1]*Erasmus Medical Center Rotterdam, Transplant Institute, Department of Surgery, Division of HPB and Transplant Surgery, Rotterdam, Netherlands;* [2]*Erasmus Medical Center Rotterdam, Department of Radiology and Nuclear Medicine, Rotterdam, Netherlands;* [3]*Erasmus Medical Center Rotterdam, Department of Hematology, Rotterdam, Netherlands;* [4]*Erasmus Medical Center Rotterdam, Transplant Institute, Department of Gastroenterology and Hepatology, Rotterdam, Netherlands*
E-mail: s.ciere@erasmusmc.nl

Background and aims: The optimal treatment for acute superior mesenteric vein thrombosis (SMVT), a rare and severe condition with risk of acute mesenteric ischemia (AMI), remains controversial. This

study aims to evaluate our multidisciplinary treatment protocol, implemented in 2019.
Method: Patients admitted with acute SMVT, excluding cirrhotic, malignant or iatrogenic causes, were included (between 2010–2018 historic cohort (HC); 2019–2024 protocol cohort (PC)). All patients received therapeutic anticoagulation (AC). The PC received systematic daily assessment for AMI (predefined CT criteria) and bowel necrosis (CT criteria with peritonitis and/or sepsis). Endovascular recanalization (EVR; i.e. repeated thrombosuction, angioplasty and continuous local thrombolysis for 24–72 h) was performed upon suspicion of AMI, while suspicion of bowel necrosis prompted emergency surgery. Management in HC was non-protocolized. Bowel necrosis, mortality, bleeding, thrombosis regression (any regression) and complete recanalization rates were compared.
Results: In 30 PC patients with predominantly complete (83%) SMVT and concomitant (87%) portal vein thrombosis (PVT), immediate AC prevented AMI in 23%. The other 77% developed AMI and underwent EVR. In total, 37% required bowel resection. Compared to HC (n = 37) with similar clinical presentation, EVR was more utilized (77% vs 11%; p < .001), while AC (both 100%) and bowel necrosis (37% vs 22%; p = 0.17) were similar. Hospital stay (10 vs. 7d; p = 0.24), ICU stay (4,5 vs 6d; p = 0.66) and bleeding after EVR (52% vs 50%; p = 1.00) were similar, while surgical bleeding was lower in the PC (12% vs 57%; p = 0.02). Median follow-up was 582 days (range 4–5093). In-hospital mortality (13% vs 8%; p = 0.69) and 1-year survival (83% vs 92%; p = 0.24) were comparable. However, PC showed significantly higher 2-year regression rates of SMVT (72% vs 33% at 2y; p < .001) and PVT (68% vs 37%; p = 0.003) and, albeit non-significant, higher 2-year complete recanalization rates in SMVT (41% vs 26%; p = 0.19) and PVT (52% vs 24%; p = 0.06). Moreover, clinically significant portal hypertension developed less often after EVR than AC alone (40% vs 69%; p = 0.04).
Conclusion: Protocolized multidisciplinary management of SMVT resulted in more frequent use of EVR without increased adverse events. While mortality and bowel necrosis rates remained stable, a two-fold increased rate of regression and complete recanalization of SMVT and PVT was observed. Future studies with larger groups of patients are needed to confirm our results.

THU-251
Cuproptosis related atherosclerosis in Wilson's disease

Soner Altın[1], Sait Kayalı[2], Ahmet Oğuz Çelik[1], Gamze Kemeç[1], Zülal İstemihan[3], Bilger Çavuş[4], Aslı Çifcibaşı Örmeci[5], Filiz Akyuz[4], Fatih Beşışık[4], Sabahattin Kaymakoğlu[4], Mesut Bulakçı[6], Kadir Demir[4]. *[1]Istanbul Faculty of Medicine Department of İnternal Medicine, İstanbul, Türkiye; [2]Istanbul Faculty of Medicine Department of Radiology, İstanbul, Türkiye; [3]Niğde Ömer Halis Demir Training and Research Hospital, Niğde, Türkiye; [4]Istanbul Faculty of Medicine Department of İnternal Medicine, istanbul, Türkiye; [5]Göztepe Memorial Hospital, İstanbul, Türkiye; [6]Istanbul Faculty of Medicine Department of Radiology, istanbul, Türkiye*
E-mail: dr_bilgercavus@yahoo.com

Background and aims: Wilson's Disease (WD) is characterized by the accumulation of excess copper in various tissues, primarily the liver and brain, due to a defect in copper excretion via the bile ducts. Cuproptosis is a type of programmed cell death triggered by elevated copper levels. It has been demonstrated that elevated copper levels contribute to inflammatory vascular diseases such as atherosclerosis through various mechanisms, including oxidative stress and proteotoxic effects. In this study, we aimed to investigate the effect of copper levels on the development of atherosclerosis in patients diagnosed with WD.
Method: Two groups consisting of 92 patients with WD and 24 healthy controls were included in the study. Demographic, clinical, laboratory, and anthropometric measurements were recorded for all participants. The presence of atherosclerosis was evaluated by examining plaque presence, flow patterns, peak systolic velocity (PSV), and end-diastolic velocity (EDV) parameters in both carotid and femoral arteries.
Results: The two groups were similar in terms of demographic and anthropometric measurements. The results showed that the two groups were largely similar, but the EDV value in the left common femoral artery was found to be statistically significantly lower in the patient group compared to the control group (p = 0.041). It shows that the EDV value in the mixed (hepatic and neurological) involvement group is significantly lower than those in both the neurological and hepatic groups (p = 0.038). In addition, the left common femoral artery flow value was found to be significantly higher in the patient group compared to the control group (p = 0.029). A positive correlation was found between the intima-media thickness in both the carotid and femoral arteries and the disease period.
Conclusion: These findings strongly support that WD may be associated with a progressive vasculopathy. The earlier the disease onset and the longer its duration, the more blood flow velocities in large arteries decrease and the more arterial wall thickness increases. These results suggest that one of the underlying mechanisms of increased cardiovascular risk in WD may be progressive arterial involvement related to disease duration.

Liver stiffness in amyloid light-chain amyloidosis: interest in diagnosis and prognosis

Paul Carrier[1], Veronique Loustaud-Ratti[1], Jean-François Cadranel[2], Céline Rigaud[1], Bienvenue Randrianarivo[1], David Lavergne[1], Laurent Alric[3], Aurore Baron[4], Eric Nguyen-Khac[5], Arnaud Pauwels[6], Louis Bettan[7], Xavier Causse[8], Honoré Zougmoure[9], Abdelali El Kharrazi[2], Marilyne Gratien[1], Cypierre Anne[1], Murielle Roussel[1], Arnaud Jaccard[1]. *[1]Chu Limoges, Limoges, France; [2]ghspo, Creil, France; [3]Chu Purpan, Toulouse, France; [4]Hôpital Paul-Brousse, Villejuif, France; [5]Chu Amiens-Picardie, Amiens, France; [6]Centre Hospitalier de Gonesse, Gonesse, France; [7]Centre Hospitalier Intercommunal de Villeneuve-Saint-Georges Lucie & Raymond Aubrac, Villeneuve-Saint-Georges, France; [8]Centre Hospitalier Régional d'Orléans, Orléans, France; [9]ghpso, Creil, France*
E-mail: paul.carrier@chu-limoges.fr

Background and aims: The liver is frequently involved in amyloidosis. Diagnosis usually relies on hepatomegaly and elevated alkaline phosphatase levels. Its diagnostic and, in particular, its follow-up value remain to be clarified.
Method: We assessed liver stiffness (LS), measured by FibroScan®, at diagnosis in a retrospective multicenter cohort of patients with amyloid light-chain amyloidosis. Patients were classified as having liver involvement only (group 1), heart involvement only (group 2), both (group 3), or neither (group 4). In a prospective monocentric cohort, we evaluated changes in LS over time.
Results: In the retrospective cohort of 56 patients, median LS values were 75 kPa (17.5–75) in group 1 (n = 14), 11.6 kPa (6.5–21.3) in group 2 (n = 17), 28.8 kPa (15.7–70) in group 3 (n = 13), and 6.4 kPa (4.9–7.5) in group 4 (n = 12). The ROC curve comparing patients with liver involvement defined by consensus criteria and LS values identified an optimal cut-off of 13.6 kPa, with 92% sensitivity and 71% specificity. In the prospective cohort of 19 patients, median LS decreased from 51.4 to 4.5 kPa in group 1 (91% reduction), from 9 to 6.7 kPa in group 2 (26% reduction), from 28.8 to 6 kPa in group 3 (79% reduction), and from 6.8 to 5.5 kPa in group 4 (19% reduction).
Conclusion: LS measurement is useful for diagnosing hepatic involvement in amyloidosis. A threshold of 13.6 kPa, in the absence of other specific etiologies, could be incorporated into current diagnostic criteria. Moreover, a reduction in LS greater than 50% may serve as a marker of hepatic recovery.

THU-253

Study of the prevalence of hereditary hemochromatosis (HFE) and secondary causes of hiperferritinemia in patients participating in a bloodletting programme

Agustin Castiella[1], Iñigo Garaizabal[1], Ane Arteaga[1], Iratxe Urreta[1], Maria Jose Sanchez Iturri[1], Eva María Zapata[1]. [1]*Hospital Universitario Donostia, Donostia, Spain*
E-mail: agustincastiella@yahoo.es

Background and aims: Bloodletting is the cornerstone of treatment for patients with hereditary haemochromatosis (C282Y/C282Y). Its usefulness in patients with hyperferritinaemia (HF) and moderate iron overload remains controversial. In recent years, HF due to metabolic syndrome and obesity has increased significantly. Recently, a French multicentre study involving 1059 patients undergoing bloodletting treatment found that HH is overdiagnosed as an indication for bloodletting. The aims of our study were: to study the causes and indications for bloodletting in patients undergoing treatment and to determine the prevalence of HH and other causes of HF.
Method: The study period was January 2022 to May 2024. Review of the medical records of patients undergoing venesections indicated by the Gastroenterology Department. We studied the reason for the indication (HH or not), whether it was correct, other causes of HF (alcohol, metabolic syndrome, obesity), analysis with iron parameters, genetic study of HFE gene mutations (C282Y/C282Y and others), and hepatic iron concentration measured by MR.
Results: 179 patients were included. 48 women and 131 men. The median age was 55. In the homozygous C282Y group, it was 49.5 and in the rest 60 (p: 0.0019), requiring earlier treatment in the HH group. The indication for bloodletting was correct (HH with significant hepatic iron overload) in 48% of cases. HFE mutations: C282Y/C282Y 70 (39.55%), C282Y/H63D 50 (28.25%), H63D/H63D 21 (11.86%). Patients with metabolic syndrome and hyperferritinemia (33%) were placed on a bloodletting programme. Obesity (BMI>30) was present in 37.76% of patients. A significant alcohol consumption was present in 38.22% of patients. MR: only 25.50% of patients had elevated iron overload (>80 mmol/g), with 47.65% having moderate overload (>36<80). CHH was significantly higher in C282Y/C282Y patients (101.22 vs 51.98) (p: 0.0000). Of the non-homozygous patients, only 11% had high overload. Sixty per cent were C282Y/H63D. Of the patients who had been treated with >20 phlebotomies, 21 were homozygous and 8 were non-homozygous. Laboratory: Serum ferritin (p:0.0268), TSI (p:0.0000) and Iron (p:0.0000) values were significantly higher in patients with HH (C282Y/C282Y).
Conclusion: More than half of patients treated with bloodletting for suspected HH do not have this disease and most likely do not require such treatment. We must re-evaluate patients undergoing chronic bloodletting, as a high percentage do not benefit from it.

THU-254

Genotypic spectrum and clinical presentation of Wilson disease in a Brazilian cohort

Maria Chiara Chindamo[1], Ida Vanessa Schwartz[2], Gabriel Quintana[2], Paulo Sgobbi[3], Thais Guaraná[4], Vivian Rotman[1], Cibele Franz[5], Luciana Agoglia[4], Renata Perez[1]. [1]*Federal University of Rio de Janeiro, Rio de Janeiro, Brazil;* [2]*Federal University of Rio Grande do Sul, Porto Alegre, Brazil;* [3]*Federal University of São Paulo (UNIFESP), Sao Paulo, Brazil;* [4]*Federal Fluminense University, Rio de Janeiro, Brazil;* [5]*UNIRIO, Rio de Janeiro, Brazil*
E-mail: mchiara@terra.com.br

Background and aims: Wilson disease (WD) is an autosomal recessive disorder caused by pathogenic variants in the *ATP7B* gene. Although more than 2700 variants have been described worldwide, data on their distribution and genotype–phenotype association in Brazilian populations remain limited. Identifying regional variant patterns may improve diagnostic accuracy and cost-effectiveness. We evaluated the frequency of *ATP7B* variants in a Brazilian WD cohort and their association with clinical phenotypes.
Method: Next-generation sequencing covering all 21 exons and exon–intron junctions of the *ATP7B* gene was performed (Mendelics Labs) in WD patients from southeastern and southern Brazil. Variants were classified as pathogenic, likely pathogenic (LP), or variants of uncertain significance (VUS) according to ClinVar. Demographic data and clinical presentation were collected and correlated with genotypes.
Results: Forty-four patients were included (55% female; mean age 29 ± 12 years). Combined hepatic and neurological manifestations occurred in 45%, isolated hepatic in 41%, isolated neuropsychiatric in 7%, and 7% were asymptomatic. Thirty-three variants were identified: 61% pathogenic, 21% VUS, and 18% LP. Most patients were compound heterozygous (84%), followed by homozygous (12%) and simple heterozygous (4%). The most frequent variants were c.3402delC (18%), c.3818C>T (14%), and c.2123T>C (11%), predominantly associated with hepatic manifestations, with or without neurological involvement. Age at symptom onset did not differ by zygosity (19, 20, and 21 years for homozygous, compound heterozygous, and simple heterozygous, respectively; p = 0.94). Carriers of at least one c.3402delC allele had lower ceruloplasmin levels compared with other variants (median 3.0 vs 7.0 mg/dL; p = 0.025), without differences in age at symptom onset (p = 0.93**)**. Homozygous deletion of exon 2 was associated with severe neurological disease. VUS included c.2145C>T (6%), c.2755C>T (6%), c.1552T>C (3%), c.2866–6T>G (3%), c.2562G>C (3%), c.4388A>G (3%), and c.3188C>T (3%). LP variants were c.2072G>T (3%), c.3551T>C (3%), exon 3–4 deletion (6%), c.3071_3072delTG (3%), c.399G>A (3%), and c.3517G>A (3%).
Conclusion: The variants c.3402delC, c.2123T>C, and c.3818C>T were the most prevalent in this Brazilian cohort. Multiple VUS were identified in confirmed WD cases. Marked genotypic heterogeneity was observed, limiting robust genotype–phenotype associations.

THU-255

Dynamic changes in liver stiffness during anti-copper therapy in wilson disease: a longitudinal cohort study

Maria Chiara Chindamo[1], Luciana Agoglia[2], Thais Guaraná[2], Vivian Rotman[1], Maria Alice Madureira[1], Ana Carolina Cardoso[1], Renata Perez[1]. [1]*Federal University of Rio de Janeiro, Rio de Janeiro, Brazil;* [2]*Federal Fluminense University, Rio de Janeiro, Brazil*
E-mail: mchiara@terra.com.br

Background and aims: Liver stiffness (LS) measurements may be influenced by factors beyond fibrosis, including inflammation and intrahepatic deposits. In Wilson disease (WD), hepatic copper accumulation may affect LS, but longitudinal data during treatment are limited. We aimed to evaluate changes in LS assessed by transient hepatic elastography (THE) during anti-copper therapy in patients with different clinical presentations of WD.
Method: Patients with confirmed WD (Leipzig score ≥4) receiving chelation or zinc therapy and followed between 2014 and 2025 were included. Dynamic changes in LS were evaluated in patients who underwent at least two valid transient elastography examinations (FibroScan®, Echosens), with a minimum interval of one year. Liver-transplanted patients were excluded. Changes in liver stiffness were analyzed according to the clinical presentation of the disease.
Results: Thirty-one patients were included: 55% male, mean age of 29 ± 11 years at first THE, and a median disease duration of 12 years (IQR 4.8–17.0). Clinical presentation was isolated hepatic in 58%, combined hepatic–neurological in 35%, and isolated neurological in 7%. Most patients (90%) received chelation therapy, mainly penicillamine. The median of LS at baseline was 7.5 kPa (IQR 4.9–14.0), being 12.0 kPa (IQR 6.0–18.2) in patients with combined hepatic–neurological presentation, compared with isolated hepatic (6.6 kPa, IQR 4.7–8.7) and isolated neurological presentations (4.4 kPa) (p = 0.105). Patients with cirrhosis (n = 12) had significantly higher baseline LS

than non-cirrhotic patients (14.1 vs 5.3 kPa; p = 0.001). Eighteen patients had longitudinal LS assessment over a median follow-up of 2.8 years (IQR 1.9–5.1). Liver stiffness decreased significantly from 8.3 kPa (IQR 6.1–16.6) to 5.3 kPa (IQR 4.3–11.8; p <0.001), with reductions observed both in cirrhotic (14.0 to 12.3 kPa; p = 0.001) and non-cirrhotic patients (5.5 to 4.5 kPa; p = 0.026). Overall, liver stiffness reduced in 89% of patients. One patient showed marked LS reduction with resolution of esophageal varices.
Conclusion: Liver stiffness decreased in most patients with WD during anti-copper therapy, including those with cirrhosis. These findings suggest that elevated LS in WD may reflect reversible copper-related factors rather than fibrosis alone, supporting THE as a non-invasive tool for monitoring treatment response.

E-mail: l.cristoferi@campus.unimib.it

Background and aims: Cholestatic liver diseases are heterogeneous and may remain unexplained despite extensive work-up. Genetic variants in bile acid transport and hepatobiliary homeostasis may contribute. We assessed the diagnostic yield of a cholestasis-targeted next-generation sequencing (NGS) panel in a multicentre adult cohort.
Method: Adult patients from 8 Italian centres with cholestatic phenotypes and no alternative/prior genetic diagnosis were included: chronic unexplained cholestasis (CUC), low-phospholipid–associated cholelithiasis (LPAC), intermittent cholestasis (IC), drug-induced cholestasis (DIC), intrahepatic cholestasis of pregnancy (ICP). Clinical, biochemical, imaging and histology data were collected. A 77-gene panel of PFIC (progressive familial intrahepatic cholestasis), non-PFIC cholestasis genes, ciliopathies and inborn errors of metabolism was analysed. Variants were classified by ACMG as pathogenic/likely pathogenic (P/LP) or variants of uncertain significance (VUS) - sub-tiered by the ACGS framework. Genetic diagnosis required P/LP variants consistent with phenotype and inheritance; a possible contribution required monoallelic P/LP variant in recessive genes or warm/hot VUS in disease-related genes.
Results: Among 263 patients, phenotypes were CUC in 196 (74.5%), LPAC in 26 (9.9%), IC 20 (7.6%), DIC 12 (4.5%), ICP 9 (3.4%). Overall, 417 variants across 74 (96.1%) genes were identified in 253 (96.2%) patients: 57 (13.7%) were in PFIC genes. Of these, 64 (15.34%) were P/LP and 352 (84.41%) were VUS. Genetic diagnosis was confirmed in 11 (4.2%) patients, while a possible genetic contribution was identified in 76 (28.9%): 50 (67.6%) with monoallelic P/LP variants in recessive genes; 24 (32.4%) with ACGS warm/hot VUS in disease-related genes. Among contributing variants, 29 (39.2%) involved PFIC genes. PFIC-related variants were associated with female sex (p < 0.05), higher serum bile acids (p < 0.01) and LPAC/DIC/ICP phenotypes (p < 0.05), with more MRCP abnormalities and hepatobiliary complications (p < 0.01). Pruritus tended to be more common (p = 0.055) whereas cirrhosis was less frequent (p < 0.05).
Conclusion: In adults with unexplained cholestasis, a targeted NGS panel provided a definitive genetic diagnosis in 4.2% and contributory variants in a further 28.9%. These findings may support counselling and follow-up refining prognosis and management. Systematic re-evaluation and data-sharing may upgrade contributory findings to definitive diagnoses over time.

Background and aims: Familial intrahepatic cholestasis protein 1 (FIC1) deficiency is a rare pediatric cholestatic liver disease, caused by mutations in the ATP8B1 gene. Previously, we showed that natural history was not related to the number of truncating mutations (Hepatology, 2021). Before Ileal Bile Acid Transporter (IBAT) inhibitor availability, many FIC1 deficiency patients underwent surgical biliary diversion (SBD), but its effect on native liver survival (NLS) was variable. We evaluated whether serum bile acid (sBA) levels in early life provide prognostic information on the course of disease in FIC1 deficiency patients, who later did or did not undergo SBD.
Method: We retrospectively and prospectively analyzed patients with genetically confirmed FIC1 deficiency in the global NAPPED registry (NCT03930810). We assessed 18-year NLS and SBD rate. Median sBA levels within the first year of life, or until SBD if <1 year, were calculated. The association between sBA levels and NLS in patients was tested using Cox regression analysis. ROC analysis identified the optimal cut-off. Median and interquartile range described continuous variables.
Results: One hundred eighty-three FIC1 deficiency patients were included (59% male). Age at data extraction was 16.0 (10.7–23.7) years. Of the included patients, 33% had undergone liver transplantation at age of 4.0 (2.7–7.2) years. NLS at 18 years was 50%. By age 18 years, 58% of the patients had undergone SBD, at median age of 1.5 (0.9–2.9) years. Time-dependent Cox regression showed that SBD was associated with slightly lower NLS (overall HR 2.46, p = 0.013). In patients without SBD (n = 38), early sBA were not associated with NLS (p = 0.89). In patients with SBD (n = 26), however, early sBA <197 µmol/L was significantly associated with higher NLS (HR 0.14, p < 0.05).
Conclusion: In the largest global database of FIC1 deficiency patients, SBD is not uniformly associated with prolongation of the NLS. However, in a subgroup of SBD patients, low early life sBA levels were associated with prolonged NLS in comparison to patients with high early sBA levels.

E-mail: maria.del94@gmail.com

Background and aims: Liver disease associated to alpha-1 antitrypsin deficiency (AATD) has classically been considered a rare liver disease and related with the phenotype. On the other hand, metabolic dysfunction-associated steatotic liver disease (MASLD) is nowadays the first cause of liver disease. However, there is little information about the impact of MASLD on liver disease associated to AATD. The aim is to evaluate the presence of MASLD and its characteristics in patients with AATD.
Method: Retrospective and single-center study that included patients with AATD, between 2019 and 2023, for whom both phenotype and transient elastography (TE) data were available. MASLD was defined by the presence of liver steatosis (CAP ≥ 275) and ≥ 1 metabolic comorbidity.
Results: A total of 104 patients were included, among whom 68 (65.4%) were MZ, 19 (18.3%) SZ and 17 (16.3%) ZZ. Liver steatosis was present in 30 patients (28.8%), all of them meeting MASLD criteria. These patients had more frequently metabolic comorbidities: diabetes 16.7% vs 1.4% p 0.002; arterial hypertension 30% vs 18.9% p 0.217; dyslipidaemia 60% vs 28.4% p 0.003; hypertriglyceridemia 36.7% vs 12.2% p 0.004; metabolic syndrome 23.3% vs 8.1% p 0.033; and a higher body mass index 29.1 vs 25 kg/m^2 p 0.000. Moreover, they had a significant higher ferritin level and a higher prevalence of hypertransaminasemia, at the limit of significance. Furthermore, these patients showed significant higher values of APRI and FIB-4. Also, they more frequently presented ET values associated with risk of events in patients with AATD (ET ≥7,1 kPa: 30% vs 12.2% p 0.029). Finally, they showed a significantly higher CAP. Regarding lung involvement, MASLD patients did not have worse respiratory function, showing AATD patients a worse diffusion with a lower KCO. There were no differences between groups in other extrahepatic complications (chronic kidney disease (CKD), emphysema, cholelithiasis or panniculitis). We identify a higher prevalence of emphysema associated to different phenotypes (ZZ 47.1%, MZ 6.8% and SZ 8.3% p 0.001), as well as CKD (ZZ 29.4%, MZ 4.4%, SZ 0% p 0.001).
Conclusion: In AATD patients, the prevalence of MASLD is high and it is associated to a higher risk profile for events and progression.

However, the presence of emphysema and/or CKD and a greater alteration in KCO were associated with the DAAT phenotype.

Ileal bile acid transporter (IBAT) inhibitor therapy in adults with hereditary bile salt export pump (BSEP) deficiency: a case series

Carola Dröge[1], Eva-Doreen Pfister[2], Pavel Strnad[3], Giuseppe Rusignuolo[4], Ulrich Baumann[2], Sebastian Schulz-Jürgensen[5], Martina Sterneck[6], Tobias Götze[1], Martin Zenker[7], Denny Schanze[7], Katrin Hippe[8], Robert Thimme[4], Verena Keitel-Anselmino[1]. *[1]Department of Gastroenterology, Hepatology, and Infectious Diseases, Medical Faculty, Otto von Guericke University Magdeburg, Magdeburg, Germany; [2]Pediatric Gastroenterology and Hepatology, Department for Pediatric Kidney, Liver and Metabolic Diseases, Hannover Medical School, Hannover, Germany; [3]Department of Gastroenterology, Hepatology, Aachen University Hospital, Aachen, Germany; [4]Clinic for Internal Medicine II, Freiburg University Medical Center, Faculty of Medicine, University of Freiburg, Freiburg im Breisgau, Germany; [5]Pediatric Gastroenterology and Hepatology, Department for Pediatric Kidney, Liver and Metabolic Diseases, University Hospital Hamburg Eppendorf, Hamburg, Germany; [6]Department of Internal Medicine, University Medical Centre Hamburg-Eppendorf, Hamburg, Germany; [7]Department of Human Genetics, University Hospital Magdeburg, Magdeburg, Germany; [8]Institute of Pathology, University Hospital Magdeburg, Medical Faculty, Otto von Guericke University Magdeburg, Magdeburg, Germany*
E-mail: carola.droege@med.ovgu.de

Background and aims: Variants in the bile salt export pump BSEP predispose to a variety of cholestatic liver diseases. While patients carrying biallelic protein truncating variants present in infancy with rapidly progressive familial intrahepatic cholestasis (PFIC2), patients with missense mutations and residual BSEP function tend to present with slower disease progression. Therapeutic approaches for BSEP deficiency aim to lower serum bile acids (SBA) to prolong native liver survival. Ileal bile acid transporter inhibitors (IBATi) are reduce SBA and pruritus in PFIC2 patients. So far, little is known about the use of IBATi in adults. This case series summarises the IBATi treatment of 8 adults with BSEP deficiency.
Method: Patients presented at outpatient clinics of German University Hospitals. Most of the patients were enrolled in the HiChol registry. Disease onset, symptoms, interventions, medication, lab values, personal and family medical history as well as quality of life data including pruritus assessment were collected prospectively. Whole exome sequencing (WES) was used to determine underlying genetic variants.
Results: 5 patients reported disease onset within first months of life while 3 patients had reached adolescence or adulthood at symptom onset. In 2 patients, liver disease had already progressed to histologically confirmed cirrhosis while all others showed signs of fibrosis at IBATi initiation as determined by elastography and/or histology. WES revealed biallelic (likely) pathogenic BSEP mutations in 4 patients with disease onset in infancy. For the others, monoallelic BSEP mutations were detected. Of these, 1 patient carried a nonsense mutation, whereas all others have BSEP missense mutations. Without treatment, all patients suffered from severe itch affecting quality of life. IBATi therapy improved itch ≥2 points on a VAS in all patients with clinically significant itch (≥5/10) at IBATi initiation. Furthermore, SBA reached values <102µmol/l in all patients. IBATi therapy was stopped after 7 months in 1 cirrhosis patient due to increase in transaminases, bilirubin, SBA and liver stiffness, interpreted as disease progression and not as IBATi-related adverse event.
Conclusion: Adults with BSEP deficiency showed similar reduction in itch and SBA in response to IBATi therapy as reported in paediatric phase III trials. Weight adjusted IBATi dosing as used in paediatric trials was safe and well tolerated in our cohort.

Structured transition care program for chronic liver disease: a 6-Year clinical audit demonstrating superior outcomes

Victoria Ekstrom[1], Pei-Yuh Chia[1], Kong Boo Phua[2], Fang Kuan Chiou[2], Jia Min Lim[2], Hiang Keat Tan[1], Lynette Goh[2]. *[1]Singapore General Hospital, Singapore, Singapore; [2]KK Women's & Children's Hospital, Singapore, Singapore*
E-mail: vekstrom@gmail.com

Background and aims: Transition from paediatric to adult hepatology care represents a high-risk period, with published loss-to-follow-up rates of 8–15% and increased risks of non-adherence and disease progression. While structured transition programs are recommended in international guidelines, robust outcome data remain limited, particularly for non-transplant chronic liver disease populations. We evaluated long-term clinical and service outcomes of a comprehensive multidisciplinary transition program.
Method: We implemented a structured program at a tertiary hepatology centre comprising: pre-transition education clinics, joint paediatric-adult consultations, disease-specific online resources, dedicated adult transition clinics with extended 30-minute appointments, specialised transition nursing support, and direct clinician communication access. We conducted a retrospective audit of patients who transitioned between 2018–2024, analysing patient survival, disease progression, care continuity, and appointment adherence.
Results: 37 patients completed transition (median age 19 years, range 16–38; median follow-up 30 months, range 14–93). Primary diagnoses: MASLD (38%), biliary atresia (24%), autoimmune hepatitis/overlap syndrome (11%), chronic hepatitis B (11%), others (16%). Care continuity: Exceptional retention was achieved with 35 patients (94.6%) maintaining active follow-up. Only 1 patient (2.7%) was lost to follow-up and 1 (2.7%) transferred to private care, substantially outperforming published benchmarks of 8–15% loss-to-follow-up. Clinical outcomes: Patient survival was 100% at 5 years. Disease remained stable in 88.6% of patients. Three patients (8.1%) progressed to require liver transplantation during follow-up. Engagement metrics: Median clinic appointment attendance was 92%, with 73% of patients attending ≥80% of scheduled appointments, demonstrating sustained healthcare engagement.
Conclusion: This patient-centred, multidisciplinary transition program achieved exceptional care continuity (94.6% retention rate), significantly exceeding published benchmarks and demonstrating that structured programs can substantially improve outcomes in chronic liver disease transition populations. The model combining dedicated resources, and multidisciplinary support provides a replicable framework that should be considered for transition services in chronic liver disease.

Baseline fibrosis stage predicts risk of progression in patients with alpha-1 antitrypsin deficiency and a protease inhibitor (Pi)*ZZ/SZ genotype: longitudinal data from the Birmingham AATD registry

Paul Ellis[1,2], May Hagiwara[3], Pavel Strnad[4], Virginia C. Clark[5], Jeanine M. D'Armiento[6], Monica P. Goldklang[6], Jeffrey H. Teckman[7], Doneal Thomas[8], Flavia Soares Peres[9], Eric Gemmen[10], Gerald Lebovic[8], Chitra Karki[3], Tami Nussbaum[3], Suna Park[3], Kaili Ren[3], Alice Turner[1,2]. *[1]School of Health Sciences, University of Birmingham, Birmingham, United Kingdom; [2]University Hospitals Birmingham NHS Foundation Trust, Birmingham, United Kingdom; [3]Takeda Development Center Americas, Inc., Cambridge, MA, United States; [4]University Hospital RWTH Aachen, Aachen, Germany; [5]University of Florida, Gainesville, FL, United States; [6]Columbia University Medical Center, New York, NY, United States; [7]St. Louis University School of Medicine, St. Louis, MO, United States; [8]IQVIA Real*

World Solutions, Mississauga, ON, Canada; [9]IQVIA Real World Solutions, Lisbon, Portugal; [10]IQVIA Real World Solutions, Falls Church, VA, United States
E-mail: p.ellis@bham.ac.uk

Background and aims: Alpha-1 antitrypsin deficiency (AATD) is associated with heterogeneous liver disease, yet data on predictors of fibrosis progression are limited. We characterized baseline fibrosis patterns, natural history and determinants of fibrosis progression in adults with AATD and a protease inhibitor (Pi)*ZZ/SZ genotype from a large tertiary registry.
Method: Adults (≥ 18 years) with AATD and a Pi*ZZ/SZ genotype were eligible (2010–2023); patients (pts) with prior liver transplantation were excluded. Baseline fibrosis stage was determined using a hierarchical approach (FibroScan® [n = 193] > APRI [n = 276]). Fibrosis staging by FibroScan was defined as: F0/1, > 2.0–≤ 7.1 kPa; F2, > 7.1–≤ 10.0 kPa; F3, > 10.0–≤ 15.0 kPa; F4 > 15.0 kPa; staging by APRI was defined as: F0/F1, ≤ 0.43; F2, > 0.43–≤ 0.63; F3, > 0.63–≤ 1.5; F4, > 1.5. Fibrosis progression and regression (≥ 1-stage increase or decrease in fibrosis stage, respectively) were assessed on serial assessment. Kaplan–Meier analysis assessed time to progression and mortality. A Cox proportional hazards model was estimated to identify predictors of fibrosis progression. Lung function decline was also assessed.
Results: The Pi*ZZ cohort included 399 pts (median [SD] follow-up: 3.7 ± 1.9 years): F0/1, n = 290; F2, n = 77; F3, n = 30; F4, n = 2. Overall, 19.0% of F0/F1 pts, 39.0% of F2 and 6.7% of F3 had fibrosis progression; rates were twofold greater in pts staged as F2 at baseline versus F0/F1 (log-rank $p < 0.001$). Pts staged as F3 at baseline had low rates of fibrosis progression, although the small sample size may have reduced detectable progression in these pts. Higher fibrosis stage was associated with male sex, older age, higher body mass index, elevated liver enzymes and lower platelet count, but not alcohol or smoking exposure. There was no association between baseline fibrosis stage and all-cause mortality, fibrosis regression (F2, 48.7%; F3, 50.0%; F4, 100%) or lung function decline. The Pi*SZ cohort (n = 70) showed no clear signal of progression or regression, although numbers were small.
Conclusion: In pts with AATD and a Pi*ZZ genotype, baseline F2 was associated with higher rates of fibrosis progression versus F0/F1. These findings position F2 fibrosis as a clinically meaningful threshold for intensified hepatic surveillance and risk stratification and may inform the design of future interventional therapies targeting fibrosis progression in AATD-associated liver disease.

Age-stratified genetic testing for liver disorders improves diagnostic yield and clinical impact in pediatric and adult patients

Angelo Corso Faini[1,2], Michele Pinon[3], Giulia Mrgherita Brach del Prever[1,2], Carmelo Maria Romeo[1,2], Maria Luca[1,2], Fiorenza Mioli[1,2], Claudia Saglia[1,2], Caterina Scolari[1,2], Tullia Carradori[1,2], Francesca Arruga[1,2], Diana Carli[1,2], Pier Luigi Calvo[3], Tiziana Vaisitti[1,2], Silvia Deaglio[1,2]. *[1]Immunogenetics and Transplant Biology Service, Città della Salute e della Scienza Hospital, Turin, Italy; [2]Department of Medical Sciences, University of Turin, Turin, Italy; [3]Pediatric Gastroenterology Division, Regina Margherita Children's Hospital, Turin, Italy*
E-mail: angelocorso.faini@unito.it

Background and aims: Genetic testing is becoming crucial for better understanding the etiology of different liver conditions, improving their diagnostic workflows and clinical management. This study aims at designing an algorithm to efficiently implement genetic testing – and particularly clinical exome sequencing (CES) – in the diagnostic workup of both adult and pediatric patients with liver diseases.
Method: We retrospectively analyzed patients with liver disorders of potential genetic origin referred to the Città della Salute e della Scienza Hospital of Turin between July 2003 and February 2024. According to the clinical manifestation, patients were classified into different diagnostic categories, specifically cholestatic liver disorders, unexplained liver dysfunctions, liver accumulation diseases, ciliopathies, enzymatic deficiencies, syndromic disorders and isolated non-cystic liver malformations, and underwent CES. Variants of unknown significance deemed as potentially causative of the disease were re-evaluated upon completion of family segregation studies.
Results: 203 patients were included in the study (71% pediatrics, 29% adults). Median age was 8 years [1–21]; 65.5% were male and 84.7% White; 56 patients (27.6%, mostly children) underwent liver transplantation. The most common diagnostic categories were cholestatic liver disorders (n = 61, 30%) and unexplained liver dysfunction (n = 41, 20.2%). Genetic testing yielded a definitive diagnosis in 35.5% overall: 41.4% in children and 20.7% in adults. Metabolic conditions showed the highest yield (83.3%) while PFIC/BRIC and Alagille syndrome were the most frequent diagnoses. Among conclusive cases, 106 variants were reported, 52 (49.1%) classified as pathogenic, 49 (46.2%) as likely pathogenic and 5 (4.7%) as known pathogenic polymorphisms. Most variants fell within genes associated with autosomal recessive diseases, while only a few involved autosomal dominant (n = 5) or X-linked (n = 3) conditions. A ~10% increase in the global diagnostic rate and across disease categories was reached by applying age-tailored (i.e., pediatric- and adult-specific) optimized diagnostic workflows.
Conclusion: CES is a valuable tool for diagnosing liver diseases, showing a good diagnostic yield. However, its performance depends on the patient's clinical features and particularly age at presentation. Therefore, age-tailored workflows may improve efficiency and performance of genetic testing.

THU-264-YI

Liver disease manifestations in signal transducer and activator of transcription gain-of-function mutation

Sawsan Fathma[1], Nehna Majeed[2], Wesam Aleyadeh[1], Sana Pirzada[1], Alexandra Freeman[3], Steven Holland[3], Jenna Bergerson[3], Christopher Koh[1], David E Kleiner[4], Theo Heller[1]. *[1]Translational hepatology section, liver disease branch, national institute of diabetes and digestive and kidney diseases, national institutes of health, Bethesda, United States; [2]Department of gastroenterology and hepatology, university of maryland medical center, Baltimore, United States; [3]Laboratory of clinical immunology and microbiology, national institute of allergy and infectious diseases, national institutes of health, Bethesda, United States; [4]Laboratory of pathology, national cancer institute, national institutes of health, Bethesda, United States*
E-mail: sawsanf@gmail.com

Background and aims: Signal transducer and activator of transcription 1 (STAT1) gain-of-function (GOF) mutations cause impaired dephosphorylation and prolonged nuclear accumulation of phosphorylated STAT1, leading to immune dysregulation characterized by chronic mucocutaneous candidiasis, autoimmunity and recurrent infections. Despite well-documented immunological complications, hepatic manifestations of STAT1 GOF remain poorly defined. We aimed to describe liver disease manifestations in patients with STAT1 GOF mutations.
Method: We performed a retrospective study of patients with genetically confirmed STAT1 GOF evaluated at the Primary Immunodeficiency Clinic at the National Institutes of Health between 1996 and 2022. Clinical, laboratory, imaging, and histopathologic data were analyzed.
Results: Of forty-two patients with STAT1 GOF, 17 (40%) met criteria for liver disease. Baseline biochemical parameters, including liver enzymes, synthetic function, and platelet count, did not differ between groups and remained mostly within normal limits during follow-up. However, platelet count declined significantly in the liver disease group (median 254 to 168 × 10^9/L; p = 0.0053). Cross sectional imaging demonstrated hepatomegaly in 15 of 17 liver disease patients. Liver biopsy was performed in nine liver disease patients,

revealing porto-sinusoidal vascular disease (PSVD) in five and features suggestive of PSVD in two additional patients. PSVD findings closely correlated with declining or persistently low platelet counts. All-cause mortality was higher in the liver disease group (23% vs 12%), with deaths occurring at younger ages mostly from sepsis.
Conclusion: Liver disease is a clinically significant manifestation of STAT1 GOF, characterized by features of non-cirrhotic portal hypertension. Although autoimmune hepatitis has previously been described, histopathology in this cohort frequently demonstrated PSVD, establishing a link between STAT1 GOF and vascular liver pathology. Recognition of this association provides unique insights into PSVD pathophysiology, a condition whose underlying mechanisms remain incompletely understood and warrant further studying.

THU-265-YI
Quantitative histological evaluation reveals duct paucity in children with severe alpha-1 antitrypsin deficiency (Pi*ZZ genotype)

Background and aims: Liver disease in severe alpha-1 antitrypsin (AAT) deficiency (Pi*ZZ genotype) displays a biphasic pattern with the first peak in early childhood and the second, adult peak after the age of 40 years. Our aim was to histologically characterize the pediatric and adult liver disease.
Method: We recruited 67 adults and 48 Pi*ZZ children aged four weeks to 17 years from six countries who underwent a liver biopsy/transplantation. A blind histological scoring was performed by two histopathologists. COMET staining quantified histological features in a representative adult and pediatric sample.
Results: Pediatric Pi*ZZ samples originated more often from liver transplantation (64.6 vs. 21.2%, p <.0001) and children displayed significantly higher liver enzymes than adults. Compared to adults, children presented a significantly higher fibrosis stage according to METAVIR (4.0 vs. 2.5, p <.0001). Higher liver steatosis was more prevalent in Pi*ZZ adults, while bile plugs and duct paucity were significantly more common in Pi*ZZ children (bile plugs: 43.8 vs. 10.4%, p <.0001; duct paucity 58.3 vs. 1.5%, p <.0001). No difference in AAT accumulation scores according to Clark was found. When subdividing the pediatric cohort based on age (<1 year, 1–5 years and 6–17 years), cirrhosis was more common in both older age groups than in younger children (64.7 vs. 75.0 vs. 30.8%, p = .045). There were no differences in liver steatosis, inflammation, or cholestasis parameters, but youngest children displayed less AAT accumulation and less frequently had larger aggregates.
Conclusion: Our study reveals unique histological patterns in Pi*ZZ children and adults thereby providing basis for patient counseling and further mechanistic studies.

Background and aims: Fibrosis progression in patients (pts) with alpha-1 antitrypsin deficiency (AATD)-associated liver disease (LD) with the protease inhibitor (Pi)*ZZ genotype is poorly understood. Vibration-controlled transient elastography (VCTE) and aspartate aminotransferase-to-platelet ratio index (APRI) are increasingly used to monitor fibrosis progression. We evaluated fibrosis progression over 8 years in pts with Pi*ZZ AATD using Alpha-1 Liver Network data, RWTH Aachen University.
Method: Adults with Pi*ZZ AATD enrolled in the Alpha-1 Liver Network (2015–2024) were eligible. Fibrosis stage was assessed by reliable VCTE (≥ 10 measurements, ≥ 60% success rate, IQR/median value ≤ 30%) or APRI, matched at baseline and follow-up (≤ Year 8), using a hierarchical approach (VCTE > APRI using pre-defined cutoffs). Fibrosis progression was defined as an increase in ≥ 1 fibrosis stage from baseline or incidence of LD-related clinical event. Fibrosis stage increase was also defined by a ≥ 30% increase in reliable VCTE from baseline, and stage increase in both reliable VCTE and APRI.
Results: Overall, 655 pts were included with baseline fibrosis stage (F0/F1: n = 479, 73%; F2: n = 74, 11%; F3: n = 54, 8%; F4: n = 36, 5%; missing/unknown: n = 12, 2%) based on reliable VCTE (n = 580, 89%) or APRI (n = 63, 10%). Of those, 281 pts with matched staging were analysed for fibrosis progression (median [IQR] follow-up: 56 [24, 83] months). In total, 24/211 (11%) F0/F1, 8/34 (24%) F2, 11/29 (38%) F3 and 5/7 (71%) F4 pts progressed from baseline to Year 8 (≥1 fibrosis

stage increase [≤F2: 30/245, 12%; F3: 7/29, 24%]; incidence of an LD-related clinical event [≤ F2: 2/245, 1%; F3: 4/29, 14%; F4: 5/7, 71%]). Fibrosis progression was more frequently observed in pts with baseline F3/F4 (n = 16/36, 44%) than ≤ F2 (n = 32/245, 13%). Median (95% CI) time to fibrosis progression was 87 (39, not estimable [NE]) and 37 (30, NE) months for pts with baseline F3 and F4 fibrosis, respectively, and was not reached in baseline ≤ F2. From baseline to Year 8, 39/207 (19%) and 7/207 (3.4%) F0-F2 fibrosis pts and 7/24 (29%) and 4/24 (17%) F3 pts experienced fibrosis stage advancement when defined by a ≥ 30% increase in reliable VCTE or advancement from baseline in both reliable VCTE and APRI, respectively.
Conclusion: Among pts with Pi*ZZ AATD, 11%–71% experienced fibrosis progression during follow-up. Pts with advanced fibrosis may experience higher rates of LD progression.

Background and aims: Liver biopsy is widely used in Wilson disease (WD), but the lesions are common to other pathologies (except for tissue copper), and their influence on patient evolution and phenotype is not well studied. Hence we decided to study these data in a large group of cases.
Method: Retrospective study including baseline biopsies, baseline biochemistry and phenotypes, transaminase improvement at 1 and 3 years (normal or decrease > 70%), clinical outcomes (cirrhosis de novo, decompensation, liver transplantation or death from WD), and the mutations frequently found in our population: M645R, L708P, H1069Q and Loss-Of-Function (LOF). We evaluated these data for 3 biopsy lesions, divided each into two subgroups: steatosis (S: yes or not), advanced fibrosis (AF: F3-4 vs. F0-2) and high inflammatory activity (HIA: A2-3 vs. A0-1). The reported differences were $p < 0.05$ or higher (Chi^2, parametric or non-parametric, as appropriate).
Results: We evaluated 282 cases, 56% male, median age at diagnosis of 16 years, and 60% with hepatic presentation. The presence of AF was associated with higher serum and urinary copper, and GGT levels, and lower baseline cholesterol and triglycerides. Neurological manifestations (NM) (KF ring, symptoms or positive MRI) and LOF mutations were more frequent in AF. HIA was associated with higher baseline serum and urinary copper, transaminases, and GGT. Hepatic presentation was more frequent, and asymptomatic cases were rare. NMs appeared similarly in A2-3 vs A0-1. Steatosis was associated with higher baseline ALT, GGT, and triglycerides, with no differences in serum or urinary copper levels. Hepatic presentation was more frequent and NM were rare. We found no differences in transaminase improvement at 1 and 3 years related to any of the three lesions studied. AF and HIA were associated with a higher frequency of poor clinical outcome and S was associated with a lower risk for it. There were no differences in age at diagnosis or baseline ceruloplasmin within each lesion. Cases with M645R presented with less AF and HIA and a higher frequency of S.
Conclusion: Of the lesions studied, AF and HIA were associated with more advanced phenotypes, worse clinical outcomes and greater impairment of copper metabolism, without influencing transaminase improvement at 1 and 3 years. S was associated with better clinical outcomes, with dyslipidemia and milder phenotypes, but not with copper metabolism. M645R was associated with milder lesions and LOF with higher presence of AF.

Background and aims: Porto-sinusoidal vascular disorder (PSVD) is a clinico-pathological entity affecting intrahepatic liver vessels in the absence of cirrhosis. Its definition and exclusion criteria, proposed in 2019 by VALDIG, were based on expert opinion. While portal vein thrombosis was permitted, portal cavernoma was considered an exclusion criterion. The aim of this study was to reassess this exclusion criterion and determine whether portal cavernoma may occur during the natural history of PSVD.
Method: We retrospectively analysed imaging findings of patients with PSVD, diagnosed according to VALDIG criteria, from three European reference centres for vascular liver diseases. We identified patients without portal cavernoma at the time of PSVD diagnosis (defined as the date of liver biopsy), who subsequently developed a portal cavernoma during follow-up, diagnosed using cross-sectional imaging (CT or MRI).
Results: Out of 625 patients with PSVD, 10 patients (1.6%) developed a portal cavernoma, after a median follow-up of 114 months (IQR, 66–162) after PSVD diagnosis. All 10 patients had a history of portal vein thrombosis (PVT) either before (n = 7) or concurrently with cavernoma (n = 3) diagnosis. Cavernoma location was intrahepatic in 7 patients and extrahepatic (pericholedochal and pericholecystic) in 7 patients (4 patients had both intrahepatic and extrahepatic cavernoma). There was no portal trunk cavernoma. Out of the 10 patients who developed cavernoma, 6 were men; median age was 38 (IQR, 28–47). Conditions associated with PSVD included human immunodeficiency virus (HIV) infection (n = 2), TERT mutation (n = 1), common variable immune deficiency (n = 1), splenic marginal zone lymphoma (n = 1), history of azathioprine treatment for polyradiculoneuritis (n = 1), and Crohn's disease (n = 1), while no associated condition was found in 3 patients. These patients had advanced PSVD: 6 of them experienced variceal bleeding, ascites and/or hepatic encephalopathy before or within one year after cavernoma diagnosis. The 4 remaining patients all had specific signs of portal hypertension at the time of cavernoma diagnosis.
Conclusion: Our findings suggest that, although uncommon, portal cavernoma can occur during the natural course of PSVD, most often in association with portal vein thrombosis and advanced portal hypertension. It should therefore be reconsidered as an exclusion criterion and warrant reconsideration in future diagnostic classifications.

THU-269

Ultrasound markers of high-output heart failure in hereditary Haemorrhagic Telangiectasia with hepatic vascular malformations: a danish cohort study

Pernille Haahr[1], Mikael Kjær Poulsen[2], Jens Kjeldsen[1], Massar Omar[2], Simon Tholander[3], Annette Dam Fialla[1], Anette Kjeldsen[3].
[1]Department of Medical Gastrointestinal Diseases, Odense University Hospital, Odense, Denmark; [2]Department of Cardiology, Odense University Hospital, Odense, Denmark; [3]Department of Oto-rhino-laryngology, Head and Neck surgery, Odense University Hospital, Odense, Denmark
E-mail: pernille.darre.haahr3@rsyd.dk

Background and aims: Hereditary haemorrhagic telangiectasia (HHT) is a rare autosomal dominant disorder frequently associated with hepatic arteriovenous malformations (HAVMs). Up to 78% of patients with HHT develop HAVMs, which may lead to haemodynamic alterations, increased cardiac preload, and progression to high-output heart failure (HOHF). This study aimed to determine the prevalence of HOHF and assess the relationship between HAVM severity, stroke volume, cardiac output, and index in patients with HHT. A secondary aim was to explore the haemodynamic mechanisms underlying HOHF and evaluate the usefulness of transthoracic echocardiography (TTE) in this patient group.
Method: A cohort study was conducted including all HHT patients registered in the national Danish HHT database residing in the regions of Zealand and Southern Denmark. Eligible participants underwent clinical evaluation, hepatic ultrasound, and transthoracic echocardiography. HAVMs were graded according to the Buscarini classification.
Results: Of 203 eligible patients, 152 (75%) consented to participate. The mean age was 51 years (range 18–84), and 58% were female. HAVMs were identified in 102 (67.1%) of participants, of whom 23 (15.1%) were classified as Grade 4. HOHF was present in 10 (6.6%) of patients, with nine (90%) of these cases occurring in individuals with grade 4 HAVMs. Cardiac index demonstrated a significant positive correlation with HAVM severity, with a mean increase of 0.81 L/min/m^2 between HAVM grades 0–1 and grade 4 (95% CI [0.48–1.13]).
Conclusion: The prevalence of HOHF was consistent with previous findings. Stroke volume, cardiac output and cardiac index increased in parallel with HAVM severity, supporting the role of transthoracic echocardiography as a valuable screening tool for identifying HHT patients at risk of haemodynamic complications.

E-mail: gideon.hirschfield@uhn.ca

Background and aims: Liver stiffness measurement (LSM) is a non-invasive indicator associated with clinical outcomes in patients with liver disease, including primary biliary cholangitis (PBC). The ongoing, open-label Phase 3 ASSURE study (NCT03301506) is evaluating long-term efficacy and safety of seladelpar (SEL). We recently reported stability of LSM in patients (pts) treated with SEL with up to 3 years of treatment in an interim ASSURE analysis. Here, we report the association of biochemical response at Month (M)12 with LSM change in ASSURE.
Method: Patients from RESPONSE (NCT04620733) and legacy SEL studies enrolled in ASSURE and received open-label SEL 10 mg once daily. LSM by FibroScan was an exploratory endpoint. Values with confirmed interquartile range (IQR)/LSM ratio > 30% were excluded. We conducted an interim analysis of all patients in ASSURE with ≥ 1 post-baseline (BL) LSM as of Jan 31, 2025. BL was defined as SEL initiation in RESPONSE or ASSURE. Composite biochemical response (CBR) at M12 was defined as alkaline phosphatase (ALP) < 1.67 times

the upper limit of normal (ULN), ≥ 15% ALP reduction from BL and total bilirubin ≤ ULN. LSM changes by CBR status at M12 were assessed through M36. LSM change > 30% was considered clinically meaningful. Comparison of BL characteristics and multivariate analysis were performed to identify factors associated with stable/improved vs worsening LSM (> 30%) at M36.
Results: A total of 311 pts were evaluable; 114 had available M36 LSM values. Among all pts, 68% (213/311) achieved CBR at M12. In pts with CBR at M12, BL age was 59 years, ALP 244 U/L, and LSM 8.9 kPa. In pts without CBR at M12, BL mean age was 57 years, ALP 384 U/L, and LSM 12.1 kPa. In pts with CBR at M12, LSM remained stable (median change, −7%) at M36, vs an LSM increase in pts without CBR at M12 (median change, +27% at M36). Among pts with vs without CBR at M12, 19% vs 9% improved by > 30% and 15% vs 48% worsened LSM by > 30%. Pts who were stable or improved were older and had lower ALP (< 1.5 × ULN, 19% vs 0%) at BL with higher rates of achieving CBR at M12 (87% vs 56%) compared to those who worsened ($p < 0.05$). Multivariate analysis showed CBR at M12 was associated with stable/improved LSM at M36 (odds ratio 5.57; $p < 0.05$).
Conclusion: In ASSURE, biochemical response with SEL at M12 was associated with liver stiffness stability at up to 3 years. Further assessment of the impact of biochemical improvement on liver stiffness with SEL is warranted.

THU-271
Impact of UGT1A1 variants on longitudinal Bilirubin trajectories in Korean infants with prolonged unconjugated hyperbilirubinemia

Kyung Jae Lee[1], Jeana Hong[2,3]. [1]*Department of Pediatrics, Korea University Guro Hospital, Seoul, Korea, Rep. of South;* [2]*Kangwon National University College of Medicine, Chuncheon, Korea, Rep. of South;* [3]*Department of Pediatrics, Kangwon National University Children's Hospital, Chuncheon, Korea, Rep. of South*
E-mail: kjlee@kumc.or.kr

Background and aims: Genetic varints of UDP-glucuronosyltransferase1A1 gene (*UGT1A1*) influence susceptibility to neonatal unconjugated hyperbilirubinemia, with ethnic differences noted. We investigated the spectrum of *UGT1A1* variants in Korean infants with prolonged jaundice and evaluated their longitudinal effect on the clinical course.
Method: This multicenter retrospective study included 65 Korean infants referred for prolonged or severe unconjugated hyperbilirubinemia. Clinical and laboratory data were collected, and *UGT1A1* genotyping was performed. Variant frequencies were compared with the Korean Reference Genome Database (KRDGB). Longitudinal total bilirubin (TB) trajectories across predefined postnatal age intervals (2–4, 5–7, 8–10, 11–13 weeks) were assessed using linear mixed-effects models. Multivariable linear regression evaluated independent predictors of TB at presentation and during follow-up. An additive genetic risk score (GRS) was constructed from the variants positively associated with prolonged hyperbilirubinemia.
Results: The c.211G>A variant was the most prevalent polymorphism, with a risk allele frequency of 54.6%, significantly higher compared to the KRDGB (OR = 5.75, $p < 0.001$). Significant associations were also observed for c.1091C>T, c.1456T>G, and c.-64G>C, while c.-3156G>A showed a reduced risk. Among the 5 variants, c.211G>A was the only variant associated with higher initial TB levels, and GRS positively correlated with initial TB level ($\rho = 0.32$, $p = 0.008$). The c.211G>A risk allele number independently predicted higher TB at presentation ($\beta = +1.91$ mg/dL per allele, $p = 0.043$) and at 2–4 weeks ($\beta = +2.80$ mg/dL per allele, $p = 0.008$); however, this effect attenuated and lost statistical significance after 5 weeks of age. Neither individual variants nor a cumulative *UGT1A1* GRS altered the rate of bilirubin decline through 13 weeks of age. Family history of jaundice was also independently associated with hyperbilirubinemia at presentation ($\beta = +3.44$, $p = 0.025$) and remained significant at 5–7 weeks of age ($\beta = +4.06$, $p = 0.029$).
Conclusion: The c.211G>A variant is the dominant genetic determinant of higher bilirubin burden, early in the clinical course in Korean infants, but its influence is transient. These findings support genotype-informed risk stratification and counseling in prolonged neonatal jaundice.

THU-272
The pharmacokinetic profile of a new trientine tetrahydrochloride formulation supports simpler once-daily dosing for the treatment of wilson disease: results of the triumph-3 study

Karl Heinz Weiss[1], Thomas Ashdown[2], Ulrike Lorch[2], Carla Bennett[3], Nick Manamley[3], Farah Lawrence-Wilde[3], C. Omar Kamlin[3].
[1]*Krankenhaus Salem der Evang. Stadtmission Heidelberg gGmbH, Heidelberg, Germany;* [2]*Richmond Pharmacology, London, United Kingdom;* [3]*Orphalan SA, London, United Kingdom*
E-mail: karlheinz.weiss@krankenhaus-salem.de

Background and aims: The therapeutic goal of Wilson Disease (WD) is to control copper levels and to modify disease progression. All approved anti-copper drugs require life-long medication with at least twice-daily dosing. Known food-drug interactions make timing of intake critical, thus creating difficulties and challenges for people living with WD to maintain long-term adherence. Efficacy of chelation is determined by total exposure of active drug determined by pharmacokinetic measure of area under the curve (AUC). This study describes the pharmacokinetic (PK) profile a new trientine tetrahydrochloride (TETA 4HCl) formulation developed to be administered once a day (QD).
Method: This phase 1, single centre, randomised, open-label, cross-over study evaluated and compared the PK, safety and tolerability of a new 300 mg trientine base TETA 4HCl formulation with EU approved 150 mg trientine base (TETA 4HCl; Cuprior product; NCT06128954). A total daily dose (TDD) of 900 mg trientine base was evaluated by comparing QD dosing of the new formulation (x3 tablets = 900 mg) with 6 × 150 mg trientine base in 2 [BID] equally divided doses 8 hours apart. Initial dosing occurred following an overnight fast and 1 hour prior to breakfast. Blood samples were taken prior to dosing and at prespecified intervals for 48 hours followed by a 5–7-day washout period between cross-over.
Results: A total of 26 participants received both treatment sequences and completed the study. PK profiles of the two formulations were as expected, single peak and gradual decline in plasma levels with the QD formulation, and a bimodal pattern, with BID TETA 4HCl respectively. A dose-dependent higher peak concentration (C_{max}) suggesting linear PK was observed with new QD TETA 4HCl, with comparable systemic TETA AUC_{0-24} values observed for QD and BID TETA 4HCl respectively. The geometric mean ratios (GMR) of the new QD formulation relative to the same TDD of BID TETA 4HCl were the following: C_{max} (2.192), AUC_{0-24} (1.155) AUC_{0-48} (1.14) and AUC_{inf} (1.12). Five participants experienced a total of 8 adverse events (AE); 3 and 5 following new QD and BID TETA 4HCl formulations respectively. All AEs were mild apart from 1 moderate (viral infection after BID TETA 4HCl) event.
Conclusion: The new 300 mg trientine base formulation of TETA 4HCl administered QD with a TDD of 900 mg was well tolerated and demonstrated comparative PK profile to 900 mg of approved TETA 4HCl administered BID.

THU-273
Has the clinical profile of hypoxic hepatitis changed over the past decades?

Edeline Kaze[1], Vincent Huberlant[2], Jean Henrion[2]. [1]*Hôpital Érasme-Cliniques Universitaires de Bruxelles, Clinique de l'Europe, Bruxelles, Belgium;* [2]*CHU Helora - Hôpital de la Louvière - Site Jolimont, La Louvière, Belgium*
E-mail: kazeedeline@gmail.com

Background and aims: Hypoxic Hepatitis (HH) is defined by a massive and brutal elevation of serum aminotransferases activities (S-AT > 20XULN) occurring in the context of hemodynamic failure, after exclusion of other causes of acute hepatocellular necrosis. Thirty-five years ago, we collected the first large series of HH (more than 100 cases) and subsequently, we reported the first hemodynamic study on this topic (1). Recently, we had the impression that the clinical profile of HH has changed. The aim of this study was to assess whether the frequency, causes and prognosis of HH have changed over the last 35 years.
Method: We compared a series of 138 cases of HH prospectively collected during a 10-year period (1981 to 1991 - Series 1) to a series of 139 cases of HH retrospectively collected during a 4-year period (2020 to 2023 - Series 2). Both series were collected in the intensive care units (ICUs) of the same hospital under the supervision of the same investigator (JH). For Series 1, a new analysis of the individual data – still available – was performed. For Series 2, cases of HH were identified through the hospital laboratory database by screening for all ICU patients with S-AT ≥ 20XULN followed by review of their electronic medical records.
Results: There were no significant differences in age and gender between the two series with a 65% male prevalence in both series and a mean age of 68 years in Series 1 compared to 67 years in Series 2. The prevalence of HH in ICUs increased from 0.8% (138/15,616 admissions) in Series 1 to 2.5% (139/5118 admissions) in Series 2 ($p < 0.001$). The main causes of hemodynamic failure were cardiac in 67% versus 45% ($p < 0.001$), respiratory in 17% versus 8% ($p < 0.02$), toxic-infectious in 12% versus 27% ($p < 0.01$) or hypovolemic-hemorrhagic in 1% versus 17% ($p < 0.001$) between Series 1 and Series 2, respectively. The in-hospital mortality was higher in the more recent cohort : 56% in Series 1 versus 68% in Series 2 ($p = 0.05$).
Conclusion: The clinical profile of HH has changed markedly over the last decades. The frequency of HH in ICUs has increased, the underlying causes of hemodynamic failure have evolved and the mortality has not decreased despite advances in intensive care medicine.

Exploring pregnancy among Wilson disease patients in Europe: results from an exploratory survey to patients from the ERN RARE-LIVER consortium

Paulina Kremser[1], Aida Regi[2,3], Wiebke Papenthin[1,3], Caren Ramien[3], Willy Visser[3,4], Thomas Sandahl[3,5], Zoe Mariño[3,6], Wilhelmus J Kwanten[3,7]. *[1]German Association for Wilson Disease Patients (Morbus Wilson e.V.), Berlin, Germany; [2]Asociación Española de Familiares y Enfermos de Wilson (AEFE), Barcelona, Spain; [3]ERN-RARE LIVER, Hamburg, Germany; [4]Erasmus MC, Rotterdam, Netherlands; [5]Aarhus University Hospital, Aarhus, Denmark; [6]Liver Unit, Hospital Clínic Barcelona, IDIBAPS, CIBERehd, Universitat de Barcelona, Barcelona, Spain; [7]Department of Gastroenterology and Hepatology, Antwerp University Hospital (UZA), Laboratory of Experimental Medicine and Pediatrics (LEMP), Faculty of Medicine and Health Sciences, University of Antwerp, Antwerp, Belgium*
E-mail: zmarino@clinic.cat

Background and aims: Wilson Disease (WD) is frequently diagnosed when young. Consequently, WD patients will face challenges regarding family planning and pregnancy. This survey aimed to explore management, concerns and perceived impact of pregnancy amongst WD women.
Method: The survey was designed by patients' representatives and physicians within the ERN Wilson and Pregnancy Working Groups and launched through the ERN platform (Nov.24 – Feb.25). The survey contained 35 questions on demographics, counselling, management, outcomes and concerns related to family planning, pregnancy and breastfeeding.
Results: We received responses from 44 adult WD women (84% within 18–50 years) in 13 different countries, mainly followed by hepatologists and/or neurologists (77%). Among them, 79 pregnancies were recorded, while 11 were never pregnant. In 44% of the women, family planning was affected by WD. Up to 35/44 (80%) referred active concerns, frequently (43%) related to the babies' health. Specific worries about contraceptive methods were collected and included potential impact on WD (92%), treatment adverse events (32%) or contraceptive effectiveness because of WD (12%). Information given by their primary treating physician was felt as insufficient for both contraceptive methods (63%) and pregnancy (38%). Active advice against pregnancy was reported in 10 cases. Most of the pregnancies (93%) occurred after WD diagnosis. Miscarriages occurred in 22 pregnancies (28%; 86% of them after diagnosis), while 57 offspring were delivered at term (96% healthy). Only 25% of the pregnancies were labelled as high-risk and followed at WD reference centres. Follow-up increased in 65% of pregnancies. D-penicillamine and zinc were used in 55% and 26% of the pregnancies. Most of the pregnancies (89%) were uncomplicated for the mother, with 8 mild WD-related complications (liver biochemistry). After birth, 66% gave breastfeeding, even though 32% of them were advised against.
Conclusion: This survey describes the real-life experiences among patients with WD in Europe. Most of the pregnancies were successful. However, when asked in a systemic approach, many active concerns existed. Patients faced lack of or incorrect information likely reflecting limited experience amongst health care providers. This survey helps to raise awareness and activates the need for improvement to inform and manage WD patients with parental desire.

Understanding Wilson disease beyond traditional phenotypes: cross-sectional analysis of study entry data from an international registry (iWilson)

Marina Berenguer[1], Zoe Mariño[2], Emmanuel Tsochatzis[3], Piotr Socha[4], Christian Hartmann[5], Thomas Berg[6], Frank Tacke[7], Aurélia Poujois[8], Eduardo Couchonnal[9], Heiner Wedemeyer[10], Saad Alghamdi[11], David Cassiman[12], Anna Czlonkowska[13], Javier Ampuero[14], Ildefonso Quinoñes Morales[15], Joanna Moore[16], Caroline Roatta[17], C. Omar Kamlin[18], Farah Lawrence-Wilde[19], Claus Niederau[20], Anil Dhawan[21], Dave Shaw[22], Pramod K. Mistry[23]. *[1]Hospital Universitario Y Politécnico La Fe, Valencia, Spain; [2]University Hospital Clinic of Barcelona, Barcelona, Spain; [3]Royal Free Hospital, London, United Kingdom; [4]The Children's Memorial Health Institute, Warsaw, Poland; [5]Universitätsklinikum Düsseldorf, Düsseldorf, Germany; [6]Universitätsklinikum Leipzig, Leipzig, Germany; [7]Charité - Universitätsmedizin Berlin, Berlin, Germany; [8]Hospital Foundation Adolphe de Rothschild, Neurology, Paris, France; [9]Hospices Civils De Lyon, Lyon, France; [10]Hannover Medical School, Hannover, Germany; [11]King Faisal Specialist Hospital & Research Centre, Riyadh, Saudi Arabia; [12]University Hospital Leuven, Leuven, Belgium; [13]Instytut Psychiatrii I Neurologii, Warszawa, Poland; [14]Hospital Universitario Virgen del Rocío, Sevilla, Spain; [15]Hospital Universitario de Gran Canaria Doctor Negrín, Las Palmas de Gran Canaria, Spain; [16]Saint James' University Hospital, Leeds, United Kingdom; [17]Association Bernard Pepin, Paris, France; [18]Orphalan Ltd, Birkirkara, Malta; [19]Orphalan SA, London, United Kingdom; [20]St. Josef-Hospital Oberhausen, Oberhausen, Germany; [21]King's College Hospital, London, United Kingdom; [22]Orphalan SA, Boston, United States; [23]Yale University, New Haven, United States*
E-mail: marina.berenguer@uv.es

Background and aims: Rare disease registries are an important source of real-world evidence that small, randomised trials cannot capture. The International Wilson Disease (iWD) registry was established in 2021 (NCT05239858) with the objective to describe, through prospective data collection, the natural history of treated Wilson disease (WD). We aim to provide a descriptive cross-sectional analysis from the study entry visit of enrolees in the iWD.
Method: Baseline visit data from 16 sites in 7 countries, including demographics, WD phenotype, WD specific clinical parameters, current health status and medications.

Results: Between June 2022 and July 2024, 387 subjects (194; 50.1% female) were enrolled. (Number; number of sites in the region) from Belgium (15;1), France (60;2), Germany (86;4), Poland (67;2), Spain (87;4), Saudi Arabia (24;1) and UK (48;2). Median (range) age at diagnosis was 18 years (0,67). At enrolment, median time from diagnosis and onset of first WD symptoms was 15.5 (1,58) and 19 (3,60) years respectively with 42.6% diagnosed <18 years of age. Clinical symptoms were reported in 360 subjects (hepatic [58%], neurologic [21%], hepato-neuropsychiatric [4%], psychiatric [2%]. 15% were asymptomatic. The proportion of this cohort diagnosed later in life (36–65 years) was 10.3%. The greatest proportion identifying as asymptomatic were from the UK (20/42; 48%). The majority (77.2%) self-reported their current health to range from good to excellent. A liver ultrasound (n = 140; 36.2%) confirmed cirrhosis in 31 subjects (8%). Liver biopsy (n = 18), 5 with evidence of cirrhosis. Utilisation of Liver MRI was low with exception of Saudi Arabia. Distribution of WD therapy from 369 records: d-penicillamine (DPA; 41.6%), zinc salts (28.8%), trientine tetrahydrochloride (16.2%), trientine dihydrochloride (8.5%), unspecified trientine (8.1%). Marked geographic variation in treatment patterns was observed. Zinc salts predominated in Poland (70%) with minimal trientine use (<1%), DPA was most frequently prescribed in Belgium (69%) with trientine predominating (52%) in France.
Conclusion: Baseline data from iWD gathered across geographic boundaries, captures real-time commonalities and differences of cross-sectional disease status and treatment experience from more than 380 people living with WD. Future longitudinal analyses may enable comparison of regional diagnostic and therapeutic approaches and outcome assessment across healthcare systems over time, supporting the evolution toward biology-informed care.

THU-276-YI
Safety of infliximab in sarcoidosis and effect on hepatic involvement – a retrospective cohort study
Elizabeth Low[1], Katie Ward[2,3], Huw Beynon[4], Shahir Hamdulay[4], Pamela Mangat[4], Neil Halliday[1,5]. *[1]Department of Hepatology, Royal Free Hospital, London, United Kingdom; [2]Department of Respiratory Medicine, Royal Free Hospital, London, United Kingdom; [3]Imperial College London, London, United Kingdom; [4]Department of Rheumatology, Royal Free Hospital, London, United Kingdom; [5]University College London, London, United Kingdom*
E-mail: elizabeth_low312@hotmail.com

Background and aims: Hepatic involvement in systemic sarcoidosis is increasingly recognised but remains under-reported due to heterogeneous disease manifestations. Infliximab, an anti–tumour necrosis factor-alpha agent, is used for refractory sarcoidosis; however, its liver safety and efficacy in hepatic sarcoid are poorly characterised. We evaluated the impact of infliximab on liver function tests (LFTs) in sarcoidosis patients with or without hepatic involvement and assessed hepatic disease resolution rates.
Method: We conducted a single-centre retrospective cohort study of adults prescribed infliximab for sarcoidosis between January 2003 and September 2025 at a UK tertiary sarcoidosis referral centre. Baseline characteristics, organ involvement, infliximab indication and dosing, and serial LFTs were extracted from medical records. Infliximab-related LFT derangement was defined as a new liver enzyme abnormality outside reference intervals from previously normal results without an alternate cause. Univariate analyses assessed the impact of hepatic sarcoid and infliximab therapy on liver enzymes.
Results: 118 patients (50.9% female; mean age 55.0 ± 11.2 years) were followed for a mean of 49.8 ± 45.5 months. Sixteen (13.6%) had hepatic sarcoidosis, with hepatic disease the primary indicator for infliximab in one (0.9%). Baseline transaminases were higher in the hepatic sarcoid cohort than those without liver involvement (ALT 48 vs. 22 IU/L, AST 35 vs. 19 IU/L, $p < 0.001$), but remained within reference limits. Median baseline alkaline phosphatase was 70 IU/ml (IQR 53–89), with a median reduction of 69.5 IU/L (IQR −99.0 to −31.0) in those with elevated pre-infliximab levels. Infliximab-related LFT derangement occurred in 21 (17.8%), resolving in 19 (90.5%) within a median 3.0 months (IQR 1.0–6.0) without treatment withdrawal. LFT changes from infliximab were not more frequent in those with hepatic sarcoid; only two (12.5%) experienced transient derangement, both resolving with continued therapy. No patient discontinued infliximab due to hepatotoxicity. Hepatic sarcoid resolution – defined by biochemical, radiologic and/or clinical improvement – occurred in 10 (62.5%) patients, with 3 awaiting reassessment at study end.
Conclusion: In the largest reported cohort of hepatic sarcoidosis receiving infliximab, LFT abnormalities were infrequent and self-resolving. These findings support the safety of infliximab in sarcoid patients with or without liver involvement and suggest favourable outcomes in hepatic sarcoidosis.

THU-282
Spectrum of hepatic nodules and hepatocellular carcinoma in Fontan-associated liver disease: a real-world cohort
Camilla Mancini[1,2], Rosalinda Palmieri[3], Giulia Di Già[3], Demma Shirin[2], Claudia Telesca[2], Margherita Spigaroli[4], Giuseppe Maria Ettorre[5], Adriano Pellicelli[2], Valerio Giannelli[2]. *[1]University of Modena and Reggio Emilia, Internal Medicine Departement, Modena, Italy; [2]San Camillo Forlanini Hospital, Inter-hospital Transplant Unit, Hepatology Unit, Roma, Italy; [3]Ospedale Pediatrico Bambino Gesù, Department of Medical and Surgical Sciences – Pediatric Cardiology, Roma, Italy; [4]Sapienza University of Rome, Department of Translational and Precision Medicine, Roma, Italy; [5]San Camillo Forlanini Hospitasl, Inter-hospital Transplant Unit, General Surgery and Transplantation Unit, Roma, Italy*
E-mail: cmancinimed@gmail.com

Background and aims: Fontan-associated liver disease (FALD) results from chronic hepatic congestion and hypoxia, leading to nodular transformation and an increased risk of hepatocellular carcinoma (HCC) through pathways that may differ from conventional inflammatory liver diseases. We aimed to describe the real-world spectrum of hepatic nodules in FALD and to explore clinical and laboratory correlates of regenerative/focal nodular hyperplasia (FNH)-like lesions and HCC, contextualising prevalence estimates according to follow-up duration.
Method: We performed a retrospective cross-sectional analysis of Fontan patients evaluated at our centre. Hepatic imaging reports were reviewed and patients were classified as having no nodules, regenerative/focal nodular hyperplasia (FNH)-like nodules, mass-like lesions, or hepatocellular carcinoma (HCC). Continuous variables were compared using Mann–Whitney tests and categorical variables using Fisher's exact test; Spearman correlations were used for exploratory analyses. Histology was recorded when available.
Results: Among 243 patients, hepatic nodules were identified in 136 (56.0%): 72 regenerative/FNH-like nodules, 58 mass-like lesions and 4 HCC. The point prevalence of HCC was 1.65% (4/243) in the overall cohort and 2.94% among patients with documented nodules, despite a predominantly short-to-mid term follow-up. Time since Fontan completion was available in 129/243 patients (median 4 years, IQR 3–6), with limited representation of long-term survivors (>10 years). Compared with patients without nodules (n = 107), regenerative/FNH-like lesions were associated with perihepatic effusion (11.1% vs 1.9%; OR 6.56; $p = 0.016$) and lower systolic blood pressure (median 111 vs 119 mmHg; $p = 0.025$). In exploratory comparisons, patients with HCC showed markedly higher alpha-fetoprotein levels (median 280.5 vs 2.3 ng/mL; $p = 0.0007$) and higher aspartate aminotransferase levels (median 44 vs 26 U/L; $p = 0.006$), while gamma-glutamyl transferase was not significantly associated.
Conclusion: In this real-world FALD cohort, hepatic nodules were frequent and HCC was already detectable despite predominantly short-to-mid term follow-up. Regenerative/FNH-like lesions

correlated with markers of systemic/hepatic congestion, supporting a distinct biological context in FALD. AFP and AST, together with older age and higher NT-proBNP, identified an exploratory signal associated with HCC. Larger datasets with longer follow-up are needed to refine time-dependent HCC risk estimates in this population.

THU-283

Exploring pregnancy among Wilson disease patients in Europe: results from a health-care providers' exploratory survey from the ERN RARE-LIVER consortium

Wilhelmus J Kwanten[1,2], Aida Regi[2,3], Paulina Kremser[4], Wiebke Papenthin[2,4], Caren Ramien[2], Willy Visser[2,5], Thomas Sandahl[2,6], Zoe Mariño[2,7]. *[1]Department of Gastroenterology and Hepatology, Antwerp University Hospital (UZA), Laboratory of Experimental Medicine and Pediatrics (LEMP), Faculty of Medicine and Health Sciences, University of Antwerp, Antwerp, Belgium; [2]ERN-RARE LIVER, Hamburg, Germany; [3]Asociación Española de Familiares y Enfermos de Wilson (AEFE), Barcelona, Spain; [4]German Association for Wilson Disease Patients (Morbus Wilson e.V.), Berlin, Germany; [5]Erasmus MC, Rotterdam, Netherlands; [6]Aarhus University Hospital, Aarhus, Denmark; [7]Liver Unit, Hospital Clínic Barcelona, IDIBAPS, CIBERehd, Universitat de Barcelona, Barcelona, Spain*
E-mail: zmarino@clinic.cat

Background and aims: Management of pregnancy in patients with Wilson Disease (WD) is challenging. Current guidelines recommend drug modifications and close follow-up to ensure favourable outcomes. However, due to its rarity and the lack of high-quality evidence-based data, monitoring is heterogeneous. We aimed at exploring how pregnancy in WD was managed among HCPs in Europe to have a broad understanding of real-life practice.

Method: The survey was designed by physicians and patients' representatives within the ERN Wilson and Pregnancy Working Groups and launched through the ERN platform (Nov.24–Feb.25). The ERN office was responsible for raw data compilation. The survey was composed of 35 questions; only one answer per centre was allowed to avoid duplications.

Results: We received results from 33 centres in Europe; most of them (66%) were ERN (affiliated) members and 39% were considered large (>30 WD patients). 76% of the surveys were led by hepatologists; 60% male; 54% with >10 years of experience in WD. Interestingly, 51% reported no previous experience with WD pregnant patients. Contraception and childbearing were claimed to be actively explored with patients in 76%, and pregnancy was planned in advance by 69%. When a patient became pregnant, 54% followed a multidisciplinary approach, and 91% increased monitoring (to ≥1 visit per trimester) by means of ALT (all centres) and urinary copper excretion (76%). Considering treatment, 79% reduced the dose of chelators, while zinc was maintained in most cases (79%), and very few (3) advocates for a switch to zinc in patients treated with chelators. The main reason to reduce WD therapy during pregnancy was to avoid potential harm to the foetus (66%). Breastfeeding was either encouraged or pro-cons discussed with the patient in most of the centres, but 8 (24%) recommended additional copper in the newborn by means of complementary formula milk or supplements. Guidelines and/or PubMed were consulted in >85% of centres whenever a patient with WD became pregnant. No differences were observed between large and small institutions.

Conclusion: This survey reflects real-life practice in Europe for WD and pregnancy. Most of the answers followed current guidelines' recommendations, although the level of evidence for these recommendations is low. In addition to raising awareness on the topic, this European survey may be the starting point for future research in this neglected but vitally important scenario.

E-mail: m.nomden@umcg.nl

Background and aims: Patients with Bile Salt Export Pump (BSEP) deficiency have variable native liver survival (NLS) and serum bile acid (sBA) response to interruption of the enterohepatic circulation (iEHC) via surgical biliary diversion (SBD) or ileal bile acid transporter inhibition (IBATi). The missense variants E297G and D482G (ED) retain some BSEP transport functionality: patients carrying these variants have higher sBA responsiveness to iEHC and longer NLS. We aim to identify whether missense variants other than E297G and D482G (OMS) are associated with sBA response to iEHC and NLS, compatible with residual BSEP transport functionality.
Method: In the global NAPPED registry (NCT03930810), we categorized ABCB11 variants as ED, OMS or variants leading to a truncated protein (T). Based on the combination of two allelic variants, 6 genotype groups were then compared: ED/ED, ED/OMS, ED/T, OMS/OMS, OMS/T, and T/T. We analyzed sBA response rate after iEHC (sBA concentration <102 uM or decrease ≥75% within two post iEHC visits) and 5-year NLS without iEHC. Five-year NLS was assessed by Cox regression, and patients were grouped based on sBA response to iEHC.
Results: We included 75 BSEP-deficient patients with iEHC (59 SBD, 16 IBATi) and available sBA levels, and 204 without iEHC. The sBA response to iEHC was ≤20% in ED/T and T/T patients, but ≥50% in ED/ED, ED/OMS, OMS/OMS and OMS/T patients. Among patients without iEHC, the group of ED/ED, ED/OMS, OMS/OMS & OMS/T patients had a significantly higher 5-year NLS rate than ED/T and T/T (HR: 0.48 [0.32–0.72]; $p < 0.001$).
Conclusion: In BSEP deficiency, missense variants other than E297G and D482G are associated with sBA responsiveness to iEHC and with 5-year NLS without iEHC, compatible with relatively high residual BSEP functionality. We expect that the further identification of these variants will allow to optimize treatment strategies in patients with BSEP deficiency.

THU-285
Alpha-1 foundation research registry: highlighting pulmonary manifestations among liver-affected alpha-1 antitrypsin deficiency patients in the United States

Alison Keaveny[1], Nadine Nuchovich[1], Jennifer Illarramendi[1], Randel Plant[1], Jeanine M. D'Armiento[2], Monica P. Goldklang[2]. *[1]Alpha-1 Foundation, Coral Gables, FL, United States; [2]Columbia University Irving Medical Center, New York, NY, United States*
E-mail: akeaveny@alpha1.org

Background and aims: Alpha-1 Antitrypsin Deficiency (AATD) is a rare genetic disorder that is characterized by misfolding and retention of AAT protein in hepatocytes, predisposing patients to liver disease. Many individuals with AATD-related liver disease also experience pulmonary manifestations due to low circulating AAT protein. We therefore analyzed liver-affected individuals and assessed pulmonary comorbidities among this population.
Method: Utilizing REDCap, the Alpha-1 Research Registry (A1F Registry) has enrolled 3395 AATD patients who completed a liver specific questionnaire between June 2019 to December 2025. We identified 1656 liver-affected patients, defined as those who reported a positive history of abnormal liver function tests, liver symptoms, cirrhosis, MASH /MASLD, ascites, cholestasis, hepatopulmonary syndrome, portopulmonary hypertension, or bacterial peritonitis.
Results: Liver-affected A1F Registry participants identify largely as female (68.5%), white (97.3%) with a mean age of 50.53 ± 16.5 years. Nearly half of liver-affected individuals reported pulmonary symptoms including coughing most or several days a week (48.9%) and/ or experience shortness of breath most or several days a week (45.1%), while wheezing attacks occurring most or several days a week were seen in only 16.8% of participants. Diagnoses of obstructive lung disease were reported in 60% of liver- affected AATD participants, with COPD reported in 34.5%, emphysema in 25.8%, bronchiectasis 17.8% and adult asthma 37.3%. Among liver-affected participants with pulmonary comorbidities, PiZZ genotype was reported most frequently (43.3%), followed by PiMZ (28.1%) and PiSZ (9.4%). Common current pulmonary pharmacologic use in liver-affected AATD participants overall include corticosteroids (oral 10.2%, inhaled 33.8%), anticholinergics (15.0%), beta agonists (41.5%), and oxygen therapy (16%). Current or prior alpha-1 antitrypsin protease inhibitor therapy usage was reported in 32.2% of liver-affected AATD participants.
Conclusion: A considerable proportion of liver-affected AATD participants reported pulmonary involvement and therapy usage. Given this overlap, it is imperative that AATD liver affected patients be routinely screened for lung disease, and for pulmonologists and hepatologists to work collaboratively for comprehensive patient care. The A1F Registry continues to be a valuable resource that can use patient reported data to identify liver-affected AATD patients and support a comprehensive analysis of AATD comorbidities.

THU-286
Immunological landscape of autoimmune hepatitis: clinical insights from a retrospective cohort of 48 patients

Dahri Ouafae[1], Mohamed Borahma[1], Fatima Zahra Chabib[1], Nawal Lagdali[1], Sabbah Selma[1], Fatima Zahra Ajana[1], Maryeme Kadiri[1]. *[1]Mohammed V University, Ibn Sina Hospital, Gastroenterology C department, Rabat, Morocco*
E-mail: dahriouafae1@gmail.com

Background and aims: Autoimmune hepatitis (AIH) is a chronic immune-mediated liver disease characterized by hepatocellular injury, circulating autoantibodies and hypergammaglobulinemia. While immunological markers are central to diagnosis, their relationship with disease severity, biochemical activity and liver fibrosis remains incompletely understood. This study aimed to characterize the immunological profile of AIH patients and evaluate its association with clinical presentation, laboratory parameters and fibrosis severity.
Method: We conducted an 8-year retrospective single-center cohort study including 48 AIH patients. Immunological assessment included anti nuclear antibodies (ANA), anti-smooth muscle antibodies (ASMA/AML), anti-SLA, anti-LKM1, anti-LC1 antibodies and serum IgG levels. Liver biopsy findings were reviewed when available, with advanced fibrosis defined as F3–F4. Hepatic decompensation was defined by ascites, variceal bleeding or hepatic encephalopathy. Associations were analyzed using Fisher's exact test; $p < 0.05$ was considered statistically significant.
Results: The cohort comprised 48 patients (83.3% female), mean age 39.5 ± 16.8 years. Serum IgG was elevated in 65.9% of patients. Immunologically, ANA were detected in 63.4%, ASMA/AML in 36.6%, anti-SLA in 7.7%, anti-LKM1 and anti-LC1 in 3.8% of patients, confirming the predominance of type 1 AIH. Histological evaluation showed that a substantial proportion of patients already had significant liver damage at diagnosis. Advanced fibrosis was present in 63.4%, including cirrhosis in 9.8%. ASMA/AML positivity was significantly associated with advanced fibrosis, observed in 92.3% of ASMA/AML-positive patients versus 54.5% in ASMA/AML-negative patients (OR 10.0, $p = 0.027$). ANA, IgG elevation and other autoantibodies were not significantly associated with fibrosis severity. Hepatic decompensation occurred in a considerable proportion of patients. ASMA/AML-positive patients showed a higher rate of decompensation (66.7% vs 34.6%; OR 3.78, $p = 0.059$), representing a strong trend toward significance.
Conclusion: This cohort confirms the predominance of ANA and ASMA/AML in AIH and the frequent presence of elevated IgG and

advanced fibrosis at diagnosis. Importantly, ASMA/AML positivity was significantly associated with advanced fibrosis and tended to predict hepatic decompensation, highlighting its potential as a prognostic marker. These findings underscore the value of immunological profiling in AIH and warrant validation in larger prospective studies.

Machine learning–based prediction of immunosuppressive treatment response in autoimmune hepatitis

Azzaoui Oumaima[1], Mohamed Borahma[1], Fatima Zahra Chabib[1], Nawal Lagdali[1], Sabbah Selma[1], Fatima Zahra Ajana[1], Maryeme Kadiri[1]. [1]*Mohamed V university, Ibn Sina Hospital, Rabat, Morocco*
E-mail: oumaimaazzaoui12@gmail.com

Background and aims: Autoimmune hepatitis (AIH) is a rare, immune-mediated liver disease with heterogeneous clinical presentation and variable response to immunosuppressive therapy. Early identification of patients at risk of suboptimal response is crucial to optimize management. Recent advances in artificial intelligence, particularly machine learning (ML), offer promising tools to integrate multidimensional clinical, biological and histological data to predict treatment outcomes. This study aimed to evaluate the performance of a ML-based model in predicting complete biochemical response to immunosuppressive therapy in AIH patients.
Method: A retrospective monocentric study included 37 patients diagnosed with AIH according to international criteria. Variables collected encompassed demographics, clinical presentation, relapses, treatment-related adverse events, laboratory data (serum transaminases, bilirubin, IgG), histopathology (fibrosis stage), and therapeutic details (duration of therapy, corticosteroid use, second-line treatment). The primary endpoint was complete biochemical response. Data preprocessing included encoding categorical variables, normalization, and exclusion of cases with missing target values. A Random Forest algorithm was trained using stratified cross-validation. Model performance was assessed via accuracy, sensitivity (recall), and area under the receiver operating characteristic curve (AUC-ROC). Feature importance analysis identified key predictors of treatment response.
Results: The Random Forest model achieved an accuracy of 86% and sensitivity of 84% in predicting complete response. The AUC-ROC was 0.90, reflecting excellent discrimination between responders and non-responders. Key predictive factors included marked IgG hypergammaglobulinemia, advanced fibrosis (F3–F4), severe hepatocellular injury (ALT >5 × ULN), presence of autoimmune thyroiditis, and early corticosteroid initiation. Variables such as isolated AST elevation, post-withdrawal relapse and type 2 diabetes mellitus were not significant predictors.
Conclusion: Machine learning models show strong potential to predict response to immunosuppressive treatment in AIH, enabling early identification of patients at risk of non-response and supporting precision medicine approaches. Despite limitations related to small sample size and monocentric design, these results warrant multicenter validation in larger cohorts. The integration of AI tools into autoimmune hepatology could improve therapeutic efficacy and patient management.

THU-288

Seladelpar vs Elafibranor as second-line treatments for primary biliary cholangitis: asystematic review and meta-analysis

Naren Nallapeta[1], Shayan Mahapatra[2], Bharadwaj Jilakaraju[3], Aiken Muratova[4], Adarsh Gande[5], Rakhshanda Khan[6], Dhanraj Ramteke[7], Sahana Parthasarathy[1], Yashaswi Koguru[1], Gary Drew[1], Brenden Pearce[1]. [1]*Grand Strand Medical Center, Myrtle Beach, United States;* [2]*Aiken Regional Medical Centers, Aiken, United States;* [3]*Archbold Medical Center, Thomasville, United States;* [4]*Adventhealth Orlando, Orlando, United States;* [5]*Jipmer Hospital, Puducherry, India;* [6]*Ayaan Institute of Medical Sciences, Moinabad, India;* [7]*Anhui medical university, Hefei, China*
E-mail: naren.nallapeta@Gmail.com

Background and aims: Primary biliary cholangitis (PBC) requires second-line therapy in up to 40% of patients with inadequate UDCA response. Seladelpar and elafibranor, newly approved PPAR-targeted agents, significantly reduce ALP and improve symptoms. Their comparative effectiveness is unknown. This meta-analysis evaluates biochemical response, ALP normalization, pruritus, and safety to determine the superior second-line option.
Method: A systematic search of five databases was performed using predefined terms through December 2025 to identify eligible RCTs. Statistical analyses were conducted using STATA 18.0, and risk of bias was assessed using the ROB 2.0 tool.
Results: A total of 5 RCTs involving 426 patients were included (Seladelpar n = 265; Elafibranor n = 161), of whom 94.5% were female and 5.5% male, with a mean age of 56.4 ± 9.1 years and baseline ALP 2.3 ± 0.7 × ULN. Seladelpar achieved a higher composite biochemical response than elafibranor (70.1% vs 56.3%; OR 1.78, 95% CI 1.22–2.61) and greater ALP normalization (29.9% vs 16.5%; OR 2.19, 95% CI 1.31–3.66), while mean ALP reduction was similar (−41.3% ± 12.6 vs −44.3% ± 14.1). Pruritus improvement favored seladelpar (−3.14 ± 1.8 vs −1.93 ± 1.4; MD −1.21, 95% CI −1.98 to −0.44), and bilirubin and ALT remained stable in both groups. Drug-level pooled adverse events showed lower overall AE incidence with seladelpar (86.7% vs 96.3%; RR 0.90, 95% CI 0.83–0.97). Specific AEs also favored seladelpar, including pruritus (RR 0.23, 95% CI 0.10–0.55), diarrhea (RR 0.56, 95% CI 0.24–1.33), nausea (RR 0.56, 95% CI 0.24–1.33), abdominal pain (RR 0.63, 95% CI 0.28–1.44), and fatigue (RR 0.68, 95% CI 0.28–1.65). Serious AEs were similar (RR 0.69, 95% CI 0.30–1.60), discontinuations remained low (RR 1.05, 95% CI 0.62–1.78), and no drug-related hepatotoxicity was identified.
Conclusion: Seladelpar demonstrated superior biochemical and symptomatic efficacy compared with elafibranor, with comparable safety, and all included trials showed a low risk of bias.

THU-289

Utility of using modified Leipzig score for diagnosis of Wilson's disease in a resource-limited setting

Yumnah Riaz[1], Ammara Naveed[1], Bilal Ahmad Shoukat[1], Ahmad Malik[1], Fatima Chaudry[1], Usman Aujla[1]. [1]*Pakistan Kidney and Liver Institute and Research Center, Lahore, Pakistan*
E-mail: yumnahriaz7@outlook.com

Background and aims: Wilson's disease is an autosomal recessive disorder diagnosed with a Leipzig score of 4 or more. This scoring system uses complex criteria which are not entirely available in many resource-limited countries. A modified Leipzig has been proposed by Nagral et al. with more weightage to serum ceruloplasmin less than 5, family history and presence of neurobehavioral symptoms irrespective of severity. We aimed to evaluate the utility of the modified Leipzig scoring system in our cohort to improve the diagnostic accuracy of the disease.
Method: This is a retrospective study of 120 patients who presented to our centre from 2017 to 2025 with high clinical suspicion of Wilson's disease and were treated based on suggestive clinical and laboratory parameters. We assessed the modified Leipzig score's ability to establish the diagnosis of Wilson disease in patients who remained indetermined on Leipzig score due to unavailability of advanced tests like genetic testing, relative exchangeable copper and hepatic copper quantification.
Results: Of 120 patients, 87 (72.5%) were male. The median age of patients was 15.5 (IQR 10.96–21.80). Pediatric population (aged less than 15) was 52 (43.3%). In patients who were assessed, hepatic manifestations were n = 92 (76.6%), neurological n = 29 (46%), psychiatric n = 12 (31.6%). Of the overall cohort n = 77 (%) were cirrhotic at the time of presentation and n = 42 (54.5%) had model for end-stage liver disease score of >15 and were transplant candidates. Only 14 out of 42 eligible patients underwent liver transplantation. 100 out of 120 patients had a Leipzig score of 4 or more confirming definitive diagnosis. A modified Leipzig score was applied, and

among 20 indeterminate cases, 5 were classified as definitive Wilson's disease. Thus the modified Leipzig score identified 25% additional cases as definitive Wilson's disease.
Conclusion: Given the challenges of diagnosing Wilson's disease, a modified Leipzig score offers an improved diagnostic criteria in a resource-limited setting; however, there still is a need for a simplified diagnostic algorithm.

THU-290
Changes in gastroenterology and hepatology practice through primary biliary cholangitis education
S Christy Rohani-Montez[1], Marinella Calle[1], Margaux Le Berre[1], Adriaan J. van der Meer[2], Emma Culver[3], David E. Jones[4]. *[1]Medscape Education Global, London, United Kingdom; [2]Erasmus MC, Rotterdam, Netherlands; [3]John Radcliffe Hospital, Oxford, United Kingdom; [4]University of Newcastle, Newcastle upon Tyne, United Kingdom*
E-mail: srohani@medscape.net

Background and aims: With the recent EU withdrawal of obeticholic acid and approval of peroxisome proliferator-activated receptor (PPAR) agonists for primary biliary cholangitis (PBC) in Europe, second-line therapy has had an overhaul. We sought to improve physicians' confidence and behaviours in implementing these new therapies in real-world practice through accredited education.
Method: Gastroenterologists & hepatologists (gastro/heps) participated in a 38-minute, debate-style video-based online CME activity about whether patients with PBC need to be evaluated for second line therapy now (available at: www.medscape.org/viewarticle/1002006). Education effects were assessed in part A using a 3-question, repeated pairs, directly pre- & post-assessment study; and part B using a performance survey 30–60 days after participation. The activity launched in 12–2024, and data collected through 10-2025.
Results: Of 1413 gastro/heps who had engaged with the program, 58 completed all questions in part A and 33 in part B. 52% were community practitioners, 39% in academic settings, and 8% other. In part A, overall 54% had correct responses at pre-assessment vs 70% at post-assessment; p <.001, Cohen's d = 0.77, N = 58. At this time, although 84% pre- and 90% post-assessment understood that response to UDCA should be regularly monitored, 16% at pre- and 45% at post-assessment were not clear on which specific patient characteristics (age and liver stiffness) inform the need for second-line therapy; and 62% at pre- and 76% at post-assessment were unfamiliar with the expectations of PPAR agonists. 49 participants (84%) indicated they had patients with PBC they felt should be reassessed for second line therapy; and directly after participating, 36% had measurable improved confidence regarding which patients should be evaluated. Survey results 30–60 days after participation for 18 gastros and 15 heps revealed that 94% modified their practice, implemented a new practice, or had their practice reinforced as a result of the education. Specifically, 14 (78%) gastros and 9 (60%) heps had reassessed their PBC patients for second line treatment, and 67% of gastros and 60% of heps had discussed PPAR agonists with patients experiencing an inadequate response to UDCA. Key barriers to implementing changes included capacity challenges and access to PPAR agonists.
Conclusion: This study demonstrates that online video-based education can impact gastroenterology and hepatology practice regarding second line PPAR agonist therapy for PBC.

THU-291
Non-ceruloplasmin bound copper measured by speciation assay: prospective evaluation over 12 months in real world setting of unstable Wilson disease patients
Michael Schilsky[1], Amanda Cheung[2], Valentina Medici[3], Regino Gonzalez-Peralta[4], James Hamilton[5], Cynthia Levy[6], Kalyan Bhamidimarri[7], Steven Lobritto[8], Amy Brown[9], C. Omar Kamlin[10], Jamie Heise[11], Nick Manamley[10], Fred Askari[12]. *[1]Divisions of Digestive Disease and Transplant and Immunology, Yale University Medical Center, New Haven, CT, United States; [2]Northwestern University, Evanston, United States; [3]University of California Davis, Gastroenterology and Hepatology, Sacramento, United States; [4]AdventHealth for Children, AdventHealth Transplant Institute, Orlando, United States; [5]The Johns Hopkins University School of Medicine, Division of Gastroenterology and Hepatology, Baltimore, United States; [6]Division of Digestive Health and Liver Diseases, University of Miami Miller School of Medicine, Schiff Center for Liver Diseases, University of Miami Miller School of Medicine, Miami, United States; [7]Cleveland Clinic, Cleveland, United States; [8]NY Presbyterian, Columbia University Irving Medical Center, New York, United States; [9]Vanderbilt University, Nashville, United States; [10]Orphalan, London, United Kingdom; [11]Orphalan, Boston, United States; [12]Gastroenterology and Hepatology, University of Michigan Health, Michigan, United States*
E-mail: michael.schilsky@yale.edu

Background and aims: Accurate assessment of copper status is critical for guiding therapy in Wilson disease (WD), yet no universally accepted biomarker exists. Non-Ceruloplasmin bound Copper (NCC) is the labile, bioavailable form of copper found in serum and implicated in organ injury seen in WD. Estimation of NCC is unreliable due to limitations with ceruloplasmin measurement. A novel method using anion exchange chromatography followed by inductively coupled plasma mass spectroscopy (ICPMS) quantifies NCC by copper protein speciation (NCC-Sp). Laboratory validated NCC-Sp was used as a primary endpoint in a Phase 3 (NCT03539952**)** study in stable WD. NCC-Sp data in biochemically unstable WD is limited. Our aim was to describe NCC-Sp in biochemically unstable WD.
Method: The REASON study (NCT05783687) was a prospective, non-interventional study conducted across 9 U.S. sites designed to evaluate the clinical utility of NCC-Sp in monitoring adult WD patients (Leipzig score ≥4) if either newly diagnosed within 28 days of baseline visit or biochemically unstable, defined by urinary copper excretion (UCE) outside the recommended therapeutic range or AST/ALT >1.5× upper limit of normal. During standard of care (SoC) visits an additional blood sample was collected for NCC-Sp over a12-month period. Clinical management was not protocolized, followed SoC and NCC-Sp was evaluated at end of study.
Results: In all, fifty-two patients were enrolled of which 43 (83%) met criteria for biochemical instability. Enrolees were 22/43 (51%) female with mean (SD) age of 37.1 (14.4) years. Baseline treatments included trientine (N = 29), zinc salts (N = 8) and d-penicillamine (N = 6). Baseline median (IQR) NCC-Sp concentrations were higher in newly diagnosed vs biochemically unstable patients: 183.0 (124.0, 241.0) vs 96.0 (70.8, 116.0) mcg/L respectively. Mean (SD) baseline and end of study ALT were 79.3 (59.2) vs 63.4 (39.9), for AST 54.5 (37.3) vs 39.3 (17.0), respectively. Mean (SD) change from baseline in ALT and AST were −22.0 (57.9) and −21.9 (53.3) IU/L respectively. End of study median NCC-Sp values declined across both groups 66.45 (57.95, 98.15) and 64.6 (50.7, 94.3) mg/L for newly diagnosed and unstable patients, respectively.
Conclusion: Observed NCC-Sp reductions support the potential clinical utility of NCC-Sp as a treatment responsive, clinically meaningful biomarker for monitoring response to, adherence and guiding treatment decisions in biochemically unstable WD.

THU-298
Non-ceruloplasmin bound copper measured by speciation assay: response to therapy over 12 months in real world setting of newly diagnosed Wilson disease patients
Michael Schilsky[1], Amanda Cheung[2], Valentina Medici[3], Regino Gonzalez-Peralta[4], James Hamilton[5], Cynthia Levy[6], Kalyan Bhamidimarri[7], Steven Lobritto[8], Amy Brown[9], C. Omar Kamlin[10], Jamie Heise[11], Nick Manamley[10], Fred Askari[12]. *[1]Divisions of Digestive Disease and Transplant and Immunology, Yale University Medical Center, New Haven, CT, United States; [2]Northwestern University, Evanston, IL, United States; [3]University of California Davis, Gastroenterology and Hepatology, Sacramento, United States;*

E-mail: michael.schilsky@yale.edu

Background and aims: Wilson disease (WD) is a rare genetic disorder of impaired copper transport. Non-Ceruloplasmin bound Copper (NCC), the labile form of copper found in serum contributes to organ injury. Serum NCC and tissue copper levels are in dynamic equilibrium with elevated NCC observed in symptomatic individuals at diagnosis. Estimation of NCC is unreliable due to limitations with ceruloplasmin measurement. A novel method was developed and validated to quantify NCC using anion exchange chromatography followed by copper protein speciation (NCC-Sp) with inductively coupled plasma mass spectroscopy (ICPMS). NCC-Sp was used as a primary endpoint in a Phase 3 (NCT03539952) study in stable WD patients. Our aim was to evaluate and monitor NCC-Sp in newly diagnosed WD.
Method: The REASON study (NCT05783687) was a prospective, non-interventional study conducted across 9 U.S. sites between June 2023 and October 2025 designed to evaluate the clinical utility of NCC-Sp in monitoring adult WD patients (Leipzig score ≥4) newly diagnosed (within 28 days) or if biochemically unstable. The primary objective was to describe NCC-Sp values during standard of care (SoC) visits when an additional blood sample was collected for NCC-Sp and analysed (Quotient laboratories, Alnwick, UK) over a12-month period. Clinical management was not protocolized and NCC-Sp was evaluated at the end of study.
Results: The study enrolled a total of 52 patients of whom 9 (17%) were newly diagnosed. Seven of these 9 were male (78%) with mean (SD) age of 29.7 (9.0) years. Most common first line therapy was zinc salts (N = 6) followed by d-penicillamine (N = 2) and trientine (N = 1). Baseline median (IQR) NCC-Sp was 183.0 (124.0, 241.0) mcg/L; change from baseline was −59.85 (−101.50, −21.50) and −64.35 (−184.55, −19.60) mcg/L at 6 months and end of study visit respectively. At baseline and end of study mean (SD) ALT was 35.0 (23.7), 34.1 (13.6) and for AST 37.0 (25.6), 28.6 (9.6) with change from baseline of −1.4 (15.7) and −3.0 (10.5) IU/L respectively.
Conclusion: NCC-Sp is elevated in newly diagnosed WD and falls in response to treatment in the first 6 months. Liver enzymes are modestly elevated at diagnosis and remain static over 12 months. NCC-Sp has the potential, if confirmed in future studies, to be an accurate and precise biomarker to monitor de-coppering and facilitate response-based titration of medication.

THU-299

Genome-wide association study to identify novel genetic variants associated with primary Budd-Chiari syndrome

Shalimar[1], Sonu Kumar[1], Sagnik Biswas[1], Samagra Agarwal[1], Ayush Agarwal[1], Anzar Ashraf[1], Dibyabhaba Pradhan[1], Baibaswat Nayak[1]. [1]All India Institute of Medical Science, New Delhi, India
E-mail: drshalimar@yahoo.com

Background and aims: Primary Budd-Chiari Syndrome (BCS) is rare hepatic vascular disorder characterized by obstruction of hepatic venous outflow, involving the hepatic veins (HV) and/or inferior vena cava (IVC). There is marked geographic variation in vascular anatomy and prothrombotic profile, suggesting an underlying genetic predisposition. We aimed to identify genetic variants associated with primary BCS using a genome-wide association study (GWAS) and to characterize implicated biological pathways.
Method: In a case–control study (June 2020–May 2022), 310 adults with primary BCS and 312 age- and sex-matched healthy controls were recruited; after quality control, 262 cases and 265 controls were included. We performed GWAS using an Illumina bead array-based high-density whole-genome single nucleotide polymorphism (SNP) genotyping. Rigorous quality control excluded SNPs with high missingness, low minor allele frequency, or Hardy–Weinberg disequilibrium, and samples with excess missing genotypes. Identified SNPs were annotated with their respective genes, and functionally analyzed for molecular pathways, gene ontology and organ-specific expression.
Results: A total of 778 783 high-quality SNPs were analysed; 1549 were associated with BCS at $p < 0{\cdot}05$, and 340 lead SNPs had $p < 0.001$. Fifteen top SNPs ($p < 5 \times 10^{-5}$) were mainly intronic, intergenic, or regulatory, mapping to genes including rs13164180, rs6883351, rs1558294, rs2656107, rs1413229, rs2903138, rs4919217, rs11948339, rs6936121, rs62218439, rs12966305, rs1609245, rs965428, rs697957, and rs34176204. Gene ontology analysis implicated these variants in extracellular matrix constitution, cell-cell junctions, focal adhesion and vasoconstriction pathways. No overlap was seen between lead SNPs and canonical hypercoagulable genes (e.g., protein C/S, antithrombin III, Factor V, JAK2, Calreticulin).
Conclusion: This GWAS with primary BCS identified novel germline loci predominantly in non-coding and regulatory regions, implicating extracellular matrix remodelling, vascular tone, and cell-adhesion pathways rather than classical thrombophilia genes. These findings highlight a distinct pathogenesis of BCS and support further functional and multi-ethnic studies to validate candidate genes and refine genetic risk stratification.

THU-300

Fazirsiran treatment reduces serum biomarkers that predict major adverse liver outcomes in patients with alpha-1 antitrypsin deficiency-associated liver disease

Jen-Chieh Chuang[1], Ying-Wooi Wan[1], Maria D. Paraskevopoulou[1], Ruixue Hou[1], Pedrum Mohammadi-Shemirani[1], Abeer Zeitone[1], Banishree Saha[1], Vinayagam Arunachalam[1], Susana Gonzalez[1], Nirav K. Desai[1], James Hamilton[2], Thomas Schluep[2], Malin Fromme[3], Virginia C. Clark[4], Pavel Strnad[3]. [1]Takeda Development Center Americas, Inc., Cambridge, MA, United States; [2]Arrowhead Pharmaceuticals, Inc., Pasadena, CA, United States; [3]University Hospital RWTH Aachen, Aachen, Germany; [4]University of Florida, Gainesville, FL, United States
E-mail: jen-Chieh.chuang@takeda.com

Background and aims: Alpha-1 antitrypsin deficiency-associated liver disease (AATD-LD) results from the hepatic accumulation of misfolded alpha-1 antitrypsin (Z-AAT) leading to liver fibrosis in patients (pts) with the protease inhibitor (Pi)*ZZ genotype. Fazirsiran, an investigational siRNA targeting Z-AAT, is in phase 3 development for the treatment of AATD-LD. Prior analysis of plasma proteomics data from the UK Biobank Pharma Proteomics Project (UKB-PPP) identified biomarkers predicting major adverse liver outcomes (MALOs; Balasubramani S *et al. medRxiv* 2025). Using data from phase 2 clinical trials, we assessed if fazirsiran treatment changes levels of predictive biomarkers for MALOs in pts with AATD-LD.
Method: Baseline (BL) and post-treatment (Month 6, Year 1 and Year 2) serum samples from pts with AATD-LD and a Pi*ZZ genotype treated with fazirsiran (n = 32) or placebo (n = 9) in AROAAT-2001/-2002 (NCT03945292/NCT03946449) were included in the proteomics analysis using the Olink Explore HT platform (~5400 unique proteins). Predictive biomarkers for MALOs from the UKB-PPP data were ranked and selected based on the combined ranking of the average log2-fold change and false discovery rate (FDR). Change from BL in levels of all, and the top 10, 30 and 50, predictive biomarkers were evaluated in pts treated with fazirsiran or placebo using a linear

mixed effect model for repeated measures (FDR ≤ 0.05 and ≥ 5% expression change from BL).
Results: Overall, 1410 predictive proteins for MALOs were identified from the UKB-PPP data (FDR < 0.05). Fazirsiran treatment (placebo-corrected) led to significant reductions in 176, 382 and 411 proteins at Month 6, Year 1 and Year 2, respectively. From BL up to Year 2 after fazirsiran treatment, there were significant reductions in 80% of the top 10 predictive proteins, 77% of the top 30 and 76% of the top 50 proteins. The top predictive biomarkers reduced by fazirsiran treatment included ADAMTSL2, GDF15, IGFBP7, ITGBL1, KRT18 and THBS2, associated with hepatocyte apoptosis, inflammation, fibrogenesis and fibrosis.
Conclusion: Fazirsiran treatment in pts with AATD-LD reduced levels of circulating biomarkers that predicted MALOs from the UKB-PPP data, supporting evaluation of the therapeutic potential of fazirsiran in a phase 3 clinical trial. Cell-type enrichment and pathway analyses are ongoing to better understand the biological and clinical relevance of these proteins following fazirsiran treatment.
Study/writing funding: Takeda Development Center Americas, Inc.

THU-301
Novel serum proteomic signatures associated with disease burden in alpha-1 antitrypsin deficiency-associated liver disease
Ying-Wooi Wan[1], Jen-Chieh Chuang[1], Abeer Zeitone[1], Ruixue Hou[1], Banishree Saha[1], Maria D. Paraskevopoulou[1], Vinayagam Arunachalam[1], Susana Gonzalez[1], Nirav K. Desai[1], James Hamilton[2], Thomas Schluep[2], Virginia C. Clark[3], Pavel Strnad[4]. *[1]Takeda Development Center Americas, Inc., Cambridge, MA, United States; [2]Arrowhead Pharmaceuticals, Inc., Pasadena, CA, United States; [3]University of Florida, Gainesville, FL, United States; [4]University Hospital RWTH Aachen, Aachen, Germany*
E-mail: ying-wooi.wan@takeda.com

Background and aims: In patients with alpha-1 antitrypsin deficiency-associated liver disease (AATD-LD) and a protease inhibitor (Pi)*ZZ genotype, hepatic misfolded alpha-1 antitrypsin (Z-AAT) aggregates can cause cell stress, inflammation, apoptosis and ultimately liver fibrosis/cirrhosis. Blood proteomic signatures associated with the Pi*ZZ genotype were previously identified (Chuang *et al. J Hepatol* 2024;80:S696–7; Balasubramani S *et al. medRxiv* 2025), but association with disease burden remains unclear. This study delineated serum proteomic profiles associated with AATD-LD clinical burden parameters.
Method: Baseline serum samples from 41 adults with fibrosis and a Pi*ZZ genotype from phase 2 trials (AROAAT-2001/-2002 [NCT03945292/NCT03946449]) of fazirsiran (an investigational siRNA therapy) were used for biomarker discovery via Olink Explore HT (~5400 unique proteins). Correlations between serum proteomics and parameters of AATD-LD clinical burden (Z-AAT burden [assessed by periodic acid-Schiff staining with diastase, total intrahepatic Z-AAT, serum Z-AAT], fibrogenesis [Pro-C3], fibrosis severity [METAVIR and liver stiffness measured by FibroScan®] and liver enzyme levels [ALT, AST, GGT]) were examined using Spearman's correlations. Pathway analysis (Reactome and Kyoto Encyclopedia of Genes and Genomes) was conducted for proteins with adjusted p-values (Benjamini-Hochberg method) ≤ 0.1.
Results: Serum proteomics correlations (adjusted p-value ≤ 0.1) were identified for 89 proteins (63 positive/26 negative) associated with all Z-AAT burden parameters, 171 (157 positive/14 negative) associated with fibrogenesis, 113 (96 positive/17 negative) associated with both fibrosis severity parameters, and 421 (336 positive/85 negative) associated with liver enzymes. Fifteen proteins (including ACY1, ADAMTSL2, HAO1, ITGBL1, FSTL1, FGFR2, FABP1) associated with ≥ 1 AATD-LD burden parameter overlapped with proteomic signatures identified in other fibrotic liver diseases (e.g. MASH). Pathway analysis suggests that these proteins are involved in hepatocyte function disruption and fibrosis (e.g. insulin-like growth factor signalling, extracellular membrane interactions).
Conclusion: This study identified novel serum proteins correlated with AATD-LD disease burden, advancing understanding of AATD-LD pathophysiology. Possible use of these markers for diagnosis, prognosis and/or monitoring treatment response in AATD-LD will be investigated in future studies.
Study/writing funding: Takeda Development Center Americas, Inc.

THU-302
Prevalence and risk factors of hemochromatosis arthropathy in HFE p.Cys282Tyr homozygotes: a cross-sectional study using adapted EULAR criteria
Maria Rosina Troppmair[1], Daniel Theurl[1], Lorenz Pammer[1], Bernhard Glodny[2], Gerald Degenhart[2], Laura Stein[1], David Haschka[3], Benedikt Schaefer[1], Heinz Zoller[1], Herbert Tilg[1]. *[1]university clinic innsbruck internal medicine 1, Innsbruck, Austria; [2]university clinic innsbruck department for radiology, Innsbruck, Austria; [3]university clinic innsbruck internal medicine 2, Innsbruck, Austria*
E-mail: m.troppmair@i-med.ac.at

Background and aims: Hemochromatosis arthropathy (HA) represents an unmet medical need, because phlebotomy rarely improves associated symptoms and affected patients often require premature joint replacement. Prevalence and understanding of risk factors for the development of HA is incomplete. The European Alliance of Associations for Rheumatology (EULAR) has recently proposed classification criteria for HA. The aim of the present study was to assess the prevalence and risk factors associated with HA among patients homozygous for the common disease-associated HFE genotype.
Method: Individuals with known homozygosity for p.Cys282Tyr in HFE were invited to participate in this cross-sectional study on HA. Participants underwent comprehensive clinical, radiological and biochemical assessment for the presence of HA, which was diagnosed when study participants had a score of greater or equal to 5 points on the adapted EULAR score.
Results: The prevalence of HA among 105 individuals (40% females) homozygous for p.Cys282Tyr was 25% (26/105). Mean age of the study population was 59 years (95% confidence interval 39; 80 years). Patients with HA were significantly more likely to be male (80%; 21/26), older (57 vs 67 years; p = 0.012) and had significantly higher transferrin saturation (58.5% vs 83%; p < 0.001) than patients without HA. Binary logistic regression analysis showed that age, sex, serum iron, transferrin saturation, but not ferritin of transferrin were independently associated with HA.
Conclusion: In this study one quarter of individuals with p.Cys282Tyr homozygosity meets the adapted EULAR diagnostic criteria for HA, where older age, male sex and higher transferrin saturation are risk factors for the disease. Patient recruitment by invitation could have resulted in selection bias and thereby resulted in a higher HA prevalence than in unselected p.Cys282Tyr homozygous populations.

THU-304
Multidisciplinary care in adult patients with Fontan-associated liver disease
Gabriella Tomaiuolo[1], Margherita Saracco[1], Silvia Strona[1], Chiara Manuli[1], Roberta Lasco[1], Michela Helga Falzone[1], Rachele Gastaldi[1], Elena Gribaudo[2], Giuseppe Annoni[2], Francesca Ferroni[2], Carlo Pace Napoleone[3], Massimo Boffini[4], Mauro Rinaldi[4], Renato Romagnoli[5], Silvia Martini[1]. *[1]SSD Insufficienza Epatica e Trapianto Epatico, AOU Città della Salute e della Scienza di Torino, University of Turin, Torino, Italy; [2]Division of Pediatric Cardiology, AOU Città della Salute e della Scienza di Torino, Torino, Italy; [3]Department of Pediatric Cardiac Surgery, AOU Città della Salute e della Scienza di Torino, Torino, Italy; [4]Cardiac Surgery Division, Surgical Sciences Department, AOU Città della Salute e della Scienza di Torino, Torino, Italy; [5]General Surgery 2U and Liver Transplant Center, AOU Città della Salute e della Scienza di Torino, Torino, Italy*
E-mail: gabriella.tomaiuolo@gmail.com

Background and aims: Survival into adulthood after palliative Fontan surgery for univentricular heart disease is increasing. Chronic hemodynamic changes can lead to multiorgan complications, including Fontan-associated liver disease (FALD) with risk of hepatocellular carcinoma (HCC) and hepatic decompensation. We report our experience in adult FALD patients (pts).
Method: All pts referred from Cardiology to our Liver Clinic since 2024 were included. Comorbidities screening followed EASL-ERN recommendations (*Téllez L. J Hepatol 2018)*. Disease severity was classified by VAST score (1 point each for esophageal varices, ascites, splenomegaly, platelets < 150.000). Follow-up closed at 31/12/25.
Results: From 01/2024 to 12/2025, 24 FALD pts were evaluated. 20 pts (83.3%) underwent extracardiac and 4 (16.7%) intracardiac Fontan surgery in childhood (median age 6 years - y - [IQR 3.8–7]). At our first evaluation, median age was 29 y [26.5–37]; median time from Fontan surgery 23 y [18.8–25]; 70.8% male. NYHA class I in 15 pts (62.5%), II in 8 (33.3%), III in 1 (4.2%). 8 pts (33.3%) were on anticoagulants, 10 (41.7%) on pulmonary vasodilators and 10 (41.7%) on diuretics. Extrahepatic complications included 8 (33.3%) tachyarrhythmia, 3 (12.5%) sinus node dysfunction, 1 (4.2%) plastic bronchitis and 2 (8.3%) protein-losing enteropathy. 5 pts (20.8%) had implanted pacemakers, 4 pts (16.7%) experienced ischemic strokes, 3 peri-Fontan surgery or Fontan conduit replacement. VAST score was 0 in 6 pts (25%), 1 in 12 pts (50%), 2 in 5 pts (20.8%) and 4 in 1 pt (4.7%) with median time from Fontan surgery of 23.5 y [21.5–29.5], 23.5 y [22.8–25.3], 19 y [17–19] and 19 y, respectively. Notably, 5 pts (20.8%) had esophageal varices, 2 (13.6%) ascites, 8 (33.3%) splenomegaly and 11 (45.8%) thrombocytopenia. 21 pts (87.5%) underwent liver stiffness measurement (LSM), median of 20.9 kPa [16.0–26.4], without significant differences among VAST groups (p = 0.53, ANOVA test). 2 pts were referred due to HCC (Up-to-Seven in; AFP 1042 and 2.4 ng/mL at referral): both underwent combined heart-liver transplant (CHLT) after HCC downstaging and bridge therapy respectively. 1 pt had CHLT due to liver failure (NaMELD 24). The 3 transplanted pts are alive after 15 months, 13 days and 13 months respectively.
Conclusion: FALD is a major long-term complication in adult Fontan pts. Multidisciplinary follow-up is essential for early complication detection and timely CHLT referral. The role of LSM remains debated.

THU-305-YI

Dysregulation of hepcidin in hemochromatosis: results from a multinational cross-sectional study on serum iron parameters and MRI

Maria Rosina Troppmair[1], Lorenz Pammer[1], Jeremy Shearman[2], Dimitris Grammatopoulos[3], Sonia Distante[4], Andrea Ricci[5], Graca Porto[6], Benedikt Schaefer[1], John Ryan[7], Edouard Bardou-Jacquet[8], Fabiana Busti[9], Domenico Girelli[9], Elena Corradini[5], Heinz Zoller[1]. *[1]Medical University of Innsbruck, Department of Internal Medicine I – Gastroenterology, Hepatology and Endocrinology, Innsbruck, Austria; [2]Department of Gastroenterology, South Warwickshire University NHS Foundation Trust, Warwick, United Kingdom; [3]Warwick Medical School, University of Warwick, Coventry, United Kingdom; [4]Oslo University Hospital, Oslo, Norway; [5]Department of Medical and Surgical Sciences for Children and Adults, University of Modena and Reggio Emilia, Modena, Italy; [6]Serviço de Imuno-hemoterapia, Centro Hospitalar Universitário de Santo António, Unidade Local de Saúde de Santo António, Porto, Portugal; [7]Hepatology Unit, Beaumont Hospital/RCSI University of Medicine and Health Sciences, Dublin, Ireland; [8]Department of Liver Diseases CHU de Rennes, Rennes 1 University, Pontchaillou Hospital, Rennes, France; [9]Department of Medicine, Section of Internal Medicine, University of Verona and Azienda Ospedaliera Universitaria Integrata of Verona, ERN-EuroBloodNet, Verona, Italy*
E-mail: m.troppmair@i-med.ac.at

Background and aims: Hemochromatosis results from genetic dysregulation of the hepcidin–ferroportin axis, which precedes the development of overt iron overload. Homozygosity for p.Cys282Tyr in *HFE* is present in >80% of patients with hemochromatosis and UK Biobank data suggest a cumulative incidence of hemochromatosis of 56.4% in males and 40.5% in females by age 80. Elevated ferritin is a non-specific finding and is frequently observed in the context of inflammation or metabolic syndrome, limiting its diagnostic utility. The objective of this study was to assess markers of an inappropriately blunted hepcidin response in relation to serum iron parameters as well as liver and spleen iron concentrations to validate the concept that hemochromatosis is a state of hepcidin deficiency.
Method: Hepcidin, serum iron parameters and liver and spleen iron assessed by magnetic resonance imaging (MRI) were collected in a multinational cohort including 8406 individuals with *HFE* p.Cys282Tyr homozygosity and control participants with a normal *HFE* genotype and high ferritin in the majority in both groups.
Results: When patients were grouped by *HFE* genotype as p.Cys282Tyr homozygotes and controls, regression analysis of serum ferritin with hepcidin demonstrated a significantly shallower slope of the regression line in p.Cys282Tyr homozygous, consistent with an inappropriately low hepcidin response in this group. Ferritin and transferrin saturation (TSAT) showed log-linear correlations, with 20% higher TSAT values in p.Cys282Tyr homozygotes than in controls. Liver iron concentration (LIC), assessed by R2*-weighted MRI, was associated with ferritin in both groups; however, p.Cys282Tyr homozygotes exhibited higher LIC despite comparable ferritin values. Spleen iron was also related to systemic iron measures, but p.Cys282Tyr homozygotes consistently showed lower spleen iron, indicating relative iron sparing of the spleen.
Conclusion: This study confirms that the principal biochemical manifestation of hemochromatosis is elevated TSAT and a blunted hepcidin response to iron loading. Additional surrogates of this dysregulation include altered relationships between ferritin, liver iron and spleen iron. Based on these findings, phenotypic criteria supporting the diagnosis of hemochromatosis could include high TSAT, elevated liver iron and inappropriately low spleen iron and/or hepcidin.

THU-306-YI

Prevalence and risk factors of sarcopenia throughout the disease spectrum of symptomatic polycystic liver disease: a retrospective multicentre cohort study

Nele Van Horebeek[1], Ozgur Koc[1], Walter Coudyzer[1], Antoon Billiet[2], Isabelle Colle[3], Filip Janssens[4], Stephane Demaeght[5], Hans Orlent[6], Sofie Decock[7], Jean Delwaide[8], Charlotte De Vloo[9], Sven Francque[10], Christophe Moreno[11], Dirk Sprengers[12], Diethard Monbaliu[1], Jacques Pirenne[1], Frederik Nevens[1], Jef Verbeek[1]. *[1]UZ Leuven, Leuven, Belgium; [2]AZ Oostende, Oostende, Belgium; [3]Azorg, Aalst, Belgium; [4]Jessa Hospital, Hasselt, Belgium; [5]Grand Hopital de Charleroi, Charleroi, Belgium; [6]AZ Sint-Jan, Brugge, Belgium; [7]AZ Sint-Lucas, Brugge, Belgium; [8]CHU, Liège, Belgium; [9]AZ Delta, Roeselare, Belgium; [10]Antwerp University Hospital, Edegem, Belgium; [11]ULB Erasme, Bruxelles, Belgium; [12]ZAS, Antwerpen, Belgium*
E-mail: nelevanhorebeek@hotmail.com

Background and aims: The severity of symptoms and complications such as malnutrition are key indications for volume-reducing therapy in patients with polycystic liver disease (PLD). Malnutrition is traditionally assessed by the mid–upper arm circumference (MUAC), although skeletal muscle index at the third lumbar vertebra (SMI-L3) is increasingly recognized as a more accurate marker of sarcopenia. This study aimed to determine the prevalence and clinical predictors of sarcopenia in patients with PLD, and assess whether sarcopenia predicts the need for volume-reducing therapy.
Method: This multicentre retrospective cohort study included 296 adult patients with symptomatic PLD. Sarcopenia was defined using SMI-L3 on CT: <39 cm^2/m^2 for females and <50 cm^2/m^2 for males. Reference values for MUAC were <23.1 cm for females and <23.8 cm for males. Additional variables included BMI, height-adjusted total liver volume (htLV), symptom severity (POLCA score), creatinine

levels and Charlson Comorbidity Index (CCI). Associations between sarcopenia and therapeutic needs were assessed using univariate tests and multivariable logistic regression adjusting for confounders (age, sex, BMI, ADPKD, malnutrition, POLCA score, htLV, creatinine levels and CCI).
Results: SMI-L3 was available for 137/296 (46.3%) patients of whom 80 (58.3%) had sarcopenia. Patients with and without sarcopenia showed no significant differences in MUAC value (39.4% vs 32.6%), POLCA score (22 ± 18 vs 20 ± 17), htLV (2667 ± 1675 mL vs 2539 ± 2048 mL) or CCI (2 ± 3 vs 3 ± 4); p-values all > 0.05. There was a significant difference in BMI (22 ± 4 vs 24 ± 5 kg/m^2, p = 0.009) and creatinine levels (1.01 ± 0.63 vs 1.14 ± 3.05 mg/dL, p = 0.040) among patients with and without sarcopenia respectively. In multivariable analysis only BMI (OR 0.81, p = 0.008) was an independent predictor for sarcopenia. The need for volume-reducing therapy was high (86.8%): somatostatin analogue (46.7%), resection/sclerotherapy (11.0%) and LTx (42.6%) (multiple treatments possible). After multivariable adjustment, sarcopenia independently predicted the need for volume-reducing therapy (OR 8.49, p = 0.018), alongside htLV (OR 1.001, p = 0.038) and CCI (OR 2.56, p = 0.033).
Conclusion: Sarcopenia is highly prevalent in patients with symptomatic PLD and predicts the need for volume-reducing therapy, whereas MUAC does not. Therefore, we recommend prioritizing sarcopenia measured by L3-SMI over MUAC in the management of PLD patients, especially in determining transplant eligibility.

THU-307

Genotype phenotype correlations and clinical presentation patterns in Wilson disease in a Sardinian cohort

Alberto Civolani[1], Emanuela Vargiu[2], Rocco Civolani[2], Orazio Sorbello[2], Erica Loddo[2], Michela Fansecco[2], Massimo Fantini[2]. *[1]AOU CAGLIARI, UOC Gastroenterology, Cagliari, Italy; [2]Azienda Ospedaliero Universitaria Cagliari "Duilio Casula", Cagliari, Italy*
E-mail: alberto.civolani@virgilio.it

Background and aims: Wilson disease results from ATP7B mutations and presents with variable clinical expression. Sardinia shows a unique genetic profile dominated by the c.-436_-422del15 promoter deletion. This study aimed to evaluate genotype-phenotype associations, age at onset and clinical presentation patterns in a large Sardinian cohort.
Method: We retrospectively analyzed 118 patients with Wilson disease (Leipzig score >=4) followed between 1978 and 2024. Clinical, biochemical, neurological, radiological and genetic data were collected. Liver fibrosis was assessed using Metavir. Patients were classified by genotype, phenotype (hepatic or neurological) and outcome (alive, transplanted, deceased). Statistical analyses included chi-square, t-test and ANOVA (p < 0.05).
Results: The Sardinian promoter deletion accounted for 89.5% of genotypes and was strongly associated with a hepatic phenotype (84%) and lower aspartate aminotransferase and alanine aminotransferase values compared with non-Sardinian genotypes. Variants p.V1146M and p.R778W showed higher neurological involvement (52% and 67%). The mean age at diagnosis was 24.5 years, with 76% diagnosed <=35 years. Early diagnosis correlated with milder fibrosis (p = 0.02). Patients alive at last follow-up were diagnosed significantly earlier than transplanted or deceased patients (p = 0.003). Histology showed milder fibrosis in the promoter deletion, while non-Sardinian genotypes exhibited more advanced staging.
Conclusion: The Sardinian promoter deletion is associated with hepatic involvement, lower necro-inflammatory activity and a more favorable clinical course. Non-Sardinian genotypes display a higher neurological burden and more severe fibrosis. Early diagnosis remains a key determinant of outcome, supporting targeted screening in genetically enriched regions.

THU-308

Characteristics of the adolescent population with Alagille syndrome and their liver survival

Nitika Gupta[1], Dominika Wojdyla[2], Bettina E. Background and aims: Alagille Syndrome (ALGS) is a genetic disorder that mostly manifests in infancy. The ALGS trajectory is evolving with the emergence of new therapies, yet little is known

about ALGS adolescence patients. This study provides descriptive data on ALGS in adolescents.
Method: We analysed data from the Global ALagille Alliance study, which contains 1535 patients from 79 centers/34 countries. ALGS patients surviving 12 years with their native liver were included. Variables analysed included age, platelets and bilirubin at presentation, site, clinical interventions, and sentinel events (transplant and death). Cox Regression with Kaplan-Meier and log-rank test evaluated hazard ratios and survival.
Results: 58% (95% CI: 54–61%) of children survived until 12 years with their native liver. This study analysed 248 patients (55% males). 40% were from North America, 37% from Europe and 23% from elsewhere. At 12 years median bilirubin was 1.56 mg/dL (IQR: 0.51–3.14) and median platelets were 239×10^9/L (IQR:182–303). 21 patients had interventions before inclusion: 4 had Kasai portoenterostomy, 13 had biliary diversion and 4 had endoscopic intervention for varices. 29 events occurred during follow-up. Event-free survival at 21 years was 72% (95% CI: 62–85). The most striking difference in survival at 18 years was between patients with prior clinical intervention (56%) compared to those without (87%) ($p < 0.0001$). Patients with platelets $< 150 \times 10^9$/L or bilirubin > 2 mg/dL at 12 years had worse survival than patients with higher platelets ($p < 0.0013$) or lower bilirubin ($p < 0.0001$). These results are compatible with the risks of events. Patients with prior clinical intervention, higher bilirubin, and lower platelets at 12 years had a higher risk of event (HR = 4.91 for children with prior intervention, 95% CI2.162–11.13, $p < 0.0001$, HR = 1.61 per 1 mg/dL of bilirubin increase, 95%CI 1.328–1.948, $p < 0.0001$, HR = 0.93 per 10×10^9/L platelets increase, 95%CI 0.87–0.99, $p < 0.04$). The differences in survival between the groups at the clinically meaningful cut-off points (platelets $< 150 \times 10^9$/L and bilirubin > 2 mg/dL) were significant. No significant differences between geographical location or mutation type were observed.
Conclusion: After 12 years, patients remain at high risk for an event. Platelets and bilirubin appear to be useful indicators of disease progression. Survival is better in those with a milder phenotype and without surgical interventions in childhood.

Background and aims: Biliary Atresia (BA) is the leading cause of pediatric liver transplantation. Peribiliary signals governing jaundice clearance after a Kasai hepatoportoenterostomy remain unclear.
Method: A multidimensional workflow of BA patients at "Kasai" and cholestatic controls (total n = 46) investigated liver samples via 3D-light-sheet microscopy, multiplexed immunofluorescence (mpIF), single-nuclei RNA sequencing (snRNA-Seq), and spatial transcriptomics (10X VisiumHD & Stereo-Seq). To identify biliary niche signals dictating clinical outcomes, the stratification divided BA patients at the timepoint of Kasai into those who later proceeded to spontaneously clear jaundice within 100 days post-Kasai and those who required liver transplantation. Intrahepatic cholangiocyte organoids (ICOs), human induced pluripotent stem cell-derived hepatocytes (iHeps), and multicellular fetal liver-like organoids (FLOs) validated the impact of lymphatic signaling on various developmental epithelial compartments.
Results: snRNA-seq data established profound molecular dysregulation of lymphatic endothelial cells (LECs) in BA patients with poor outcomes. Light-sheet imaging and mpIF revealed expansion and 3D remodeling of the liver's lymphatic system, characterized by disorganized, simplified lumina within BA tissue. Lymphatic endothelial cell (LEC) hyperplasia at the Kasai timepoint predicted inability to clear jaundice and progression to liver transplant. Within LECs, snRNA-Seq, spatial transcriptomics and mpIF identified a surge in the chemokine CCL21 in patients with poor outcomes. To interrogate the impact of secreted mediators, we first added BA tissue secretome collected from incubated liver explants to FLO cultures. Within this multicellular organoid, cholangiocytes dedifferentiated and delumenized into tissue-like CK19+ conglomerates in a ductular-like reaction. Focusing on CCL21, we treated ICOs and iHeps with increasing doses of CCL21, consistently upregulating *SOX9* and *LGR5,* respectively, in biliary progenitor and stemness programs. Importantly, the co-culture of BA patient-derived hepatic LECs with ICOs recapitulated this result, confirming lymphatic-to-epithelial fate regression in BA.
Conclusion: An expanding, CCL21-enriched hepatic lymphatic vasculature predicts outcomes after Kasai. LECs reprogram cholangiocytes into reactive progenitors via CCL21, explaining the severe ductular reaction and impaired bile clearance in BA. Restoring dysfunctional LEC signaling may be a future avenue in BA treatment.

Precision gene-edited and functionally enhanced human hepatic organoids establish a novel therapeutic strategy for Wilson disease

Jiaqi Li[1], Pengfei Yu[1], Jiateng Zhang[1], Huaibin Zou[1], Yu Chen[1], Zhongping Duan[1]. *[1]Beijing You'an Hospital, Capital Medical University, Beijing Key Laboratory of Liver Regeneration and Artificial Liver Transformation Research, Beijing, China, Beijing, China*
Email: jairalee@163.com

Background and aims: Wilson disease (WD), caused by *ATP7B* mutations, lacks curative treatments. Cell therapy is limited by poor engraftment of 2D hepatocytes. 3D liver organoids, mimicking native tissue, offer a superior platform. We aimed to develop gene-corrected, patient-derived hepatic organoids and evaluate their therapeutic potential.
Method: Isogenic iPSC lines (CRISPR-corrected *ATP7B* R778L and uncorrected) from a WD patient were differentiated into hepatocyte-like cells (HLCs). Both lines were differentiated into hepatocyte-like cells (HLCs). The HLCs were then mixed with a growth factor-reduced (GFR), phenol red-free Matrigel matrix on ice and plated as three-dimensional domes to mimic a basal membrane microenvironment. Organoids were expanded and maintained in HepatiCult™ Organoid Growth Medium (OGM), a system designed to preserve a hepatic progenitor state. In vitro, we systematically compared the 3D organoids to their originating 2D monolayer HLCs, assessing key hepatic functions including albumin secretion, urea synthesis, and CYP3A4 enzymatic activity, as well as the formation of complex bile canalicular networks via immunofluorescence imaging. For in vivo evaluation, organoids were transplanted via intraperitoneal injection into ATP7B-knockout M-NSG mice (a WD model). Serum/urinary copper and liver function were monitored. Liver tissues were

analyzed by histopathology (H&E, Masson's, Oil Red O), transmission electron microscopy, and multi-omics.
Results: Using the optimized GFR Matrigel/OGM system, we generated proliferative 3D hepatic organoids. These organoids exhibited significantly enhanced functional maturity over 2D HLCs, with superior albumin secretion, urea production, and CYP3A4 activity. High-resolution imaging revealed the formation of highly organized, apicobasally polarized bile canalicular networks within organoids. In WD model mice, the gene-corrected organoid treatment group showed restored serum copper/ceruloplasmin levels, increased urinary copper excretion, and marked amelioration of liver histopathology (reduced damage, inflammation, fibrosis, and steatosis). Supporting analyses indicated the restoration of ultrastructural polarity and molecular shifts towards copper homeostasis and metabolic remodeling.
Conclusion: This study establishes that gene-corrected hepatic organoids exhibit superior functional and structural maturity over conventional hepatocytes and can reverse systemic copper dysregulation and liver injury in a WD model.

Email: nicole.antolini@clin.au.dk

Background and aims: Wilson disease (WD) is caused by loss of function of the copper transporter ATP7B, leading to copper accumulation primarily in the liver and brain. While hepatic copper overload reflects impaired biliary excretion, it remains debated whether cerebral copper accumulation is secondary to hepatic spillover or due to impaired ATP7B-dependent copper clearance within the central nervous system. Using intracerebroventricular (ICV) ^{64}Cu, we aimed to assess cerebral copper clearance dynamics independently of systemic copper metabolism in a WD rat model.
Method: Atp7b LPP rats of both sexes were used as a model of WD. ^{64}Cu was administered ICV to access the cerebrospinal fluid (CSF) and bypass systemic copper transport. Copper distribution and retention were assessed using PET-MRI immediately after injection and at 4 and 24 hours. Homozygous (−/−) WD rats were compared with heterozygous (+/−) and wild-type (+/+) controls. Group comparisons of copper retention at 24 hours were performed using the Kruskal-Wallis test. The study was approved by the local animal ethics committee.
Results: WD rats (Atp7b −/−) showed increased cerebral copper retention, compared with heterozygous (Atp7b +/−) and wild-type (Atp7b +/+) controls. At 24 hours, the median (IQR) percentage of injected ^{64}Cu retained within the CSF and brain parenchyma was 65% (63.1–66.8%) in Atp7b −/− rats (n = 4) in contrast to 44.9% (33.2–56.7%) in Atp7b +/− (n = 4) and 53.9% (53.0–54.9%) in Atp7b +/+ LPP rats (n = 3). Genotype-dependent differences were statistically significant, p = 0.030.
Conclusion: By isolating cerebral copper kinetics from systemic copper metabolism, this study provides first in vivo evidence that loss of ATP7B function directly impairs copper clearance from the brain. These findings support a primary role of ATP7B in CNS copper homeostasis. ^{64}Cu PET-MRI represents a promising translational tool for investigating neurological Wilson disease and evaluating therapies targeting brain copper clearance.

WED-283
Loss of STN1 expression due to bi-allelic intronic mutations induces a pro-inflammatory liver sinusoidal endothelial cell phenotype and drives porto-sinusoidal vascular disease development
Lise Bertin[1], Nadia Ciriaci[1], Hammoutene Adel[1], Samira Laouirem[1], Alexandre Sayadi[1], Antoine Wawrzyniak[1], Emmanuel Gonzalès[2], Anne Spraul[2], Elodie Lainey[3], Helene Morel[4], Kannengiesser Caroline[4], Patrick Revy[5], Valerie Paradis[1], Pierre-Emmanuel Rautou[6]. *[1]Centre de recherche sur l'inflammation, INSERM U1149, Paris, France; [2]Hopital Bicêtre, Le Kremlin-Bicêtre, France; [3]Hopital Robert Debré, Paris, France; [4]Hopital Bichat, Paris, France; [5]Institut Imagine, Paris, France; [6]Hopital Beaujon, Clichy, France*
Email: lise.bertin@inserm.fr

Background and aims: Porto-sinusoidal vascular disease (PSVD) is a rare liver disorder that predominantly affects young or middle-aged adults. Pathophysiology of PSVD remains elusive. In this study, we took advantage of a monogenic form of PSVD to get insight into mechanisms leading to PSVD.
Method: Whole genome sequencing was performed in a 19-year-old patient with PSVD and his relatives. Proband's and his relatives' lymphocytes were immortalised. Following liver transplantation, proband's liver sinusoidal endothelial cells (LSECs) and whole liver tissue were isolated from the explanted liver. Western blot and RNA sequencing were performed on whole liver and LSECs from the proband as well as from patients with mild or with advanced liver fibrosis.
Results: Whole genome sequencing revealed compound heterozygous deep intronic mutations in the *STN1* gene, encoding a component of the CST-telomere complex. The proband had PSVD complicated with recurrent portal hypertensive bleeding, ascites and finally partial portal vein thrombosis. Extrahepatic features associated with *STN1* mutations in this patient included premature greying of hair and intestinal vascular ectasias. Immortalised lymphocytes from the proband showed a virtual absence of STN1 protein expression. Each parent of the proband (each carrying one of both *SNT1* mutation) had reduced STN1 expression compared with immortalised lymphocytes from healthy donors. STN1 protein expression was also markedly reduced in whole-liver tissue and undetectable in LSECs of the proband, as compared with preserved expression in corresponding samples from patients undergoing surgery for benign hepatocellular adenoma *(no or mild liver fibrosis, n = 3)*. We then compared transcriptomics results of the proband with those of 17 patients with no or mild liver fibrosis and those of 16 patients with advanced liver fibrosis. While no major difference was observed on whole-liver transcriptomic profile, proband's LSECs exhibited a marked deregulation of inflammatory pathways, including complement activation, IL-6 signalling, interferon and TNF-alpha response and vascular pathways, such as coagulation and Notch activation.
Conclusion: We identified novel bi-allelic deep intronic *STN1* mutations that result in a virtual loss of STN1 expression and are associated with PSVD. Transcriptomics results suggest that LSECs are particularly affected in this setting. The identified LSEC proinflammatory phenotype observed may suggest an immune component to PSVD.

WED-284

High copper levels induce oxidative stress and inflammatory processes in a cell culture model of Wilson's disease

Martha-Julia Sasula[1], Anna Held[1], Stefan Schefczyk[1], Marcin Krawczyk[1], Andree Zibert[2], Hartmut Schmidt[1], Ruth Broering[1].
[1]*Dept. of Gastroenterology, Hepatology and Transplantation Medicine, Medical Faculty, University Duisburg-Essen, Essen, Germany;* [2]*Department of Internal Medicine B, University Hospital Muenster, Muenster, Germany*
Email: ruth.broering@uni-due.de

Background and aims: Wilson's disease (WD) is a genetic disorder resulting from mutations in the *ATP7B* gene that lead to copper overload in hepatocytes. This study aims to address WD-associated cellular mechanisms in HepG2 ATP7B knockout (ATP7B-KO) cells, increasing its significance for the development and testing of direct-acting therapeutic targets.
Method: To gain a deeper understanding of the cellular mechanisms underlying WD, a reanalysis of the GSE1073236 dataset was conducted. Gene expression of selected genes in immunity and oxidative was validated by quantitative PCR in HepG2 and HepG2 ATP7B-KO cells, as well as in primary hepatocytes from WD patients and controls. NFκB and AP1 luciferase reporter, oxidative stress and functional assays were performed in HepG2 and HepG2 ATP7B-KO cells.
Results: Increased expression levels of genes associated with autophagy, oxidative stress and inflammation were observed in copper-treated HepG2 ATP7B-KO cells and in primary hepatocytes from patients with WD. Furthermore, copper increased the secretion of IL1B, TNF, GM-CSF, and IL8 in HepG2 ATP7B-KO cells. Accordingly, copper exposure enhanced NFKB promoter activity 6 h after treatment. However, the transcriptional activity of AP1 and NFKB was reduced in these cells 24 h after treatment with 0.6 mM $CuCl_2$. In addition, both HepG2 and HepG2 ATP7B-KO cells showed increased oxidative stress and H_2O_2 levels after copper treatment, indicating that reactive oxygen species could play a role in WD.
Conclusion: In the cell culture model of Wilson's disease, excessive copper accumulation unleashed a cascade of cellular stress responses, including autophagy, oxidative stress, and inflammation driven in part by the dysregulation of key signalling hubs such as NFKB and AP1. These critical mechanisms behind copper-related cell death underscore the importance of this model for developing molecular targets for future therapeutic strategies aimed at halting WD progression at its core.

WED-285

Decoding the molecular and histological architecture of liver yolk sac tumor and its patient-derived cell line reveals c-MYC–FOXM1 oncogenic dependencies

Darko Castven[1], Diana Becker[2], Nathalie Martin[1], Megan Sondermann[1], Jovana Castven[1], Carolin Zimpel[1], Stefanie Heilmann-Heimbach[3], Wilfried Roth[2], Nils Hartmann[2], Beate Straub[2], Hauke Lang[2], Peter R. Galle[2], Jens U. Marquardt[1].
[1]*University Hospital Schleswig-Holstein, Lübeck, Germany;* [2]*University Medical Center Mainz, Mainz, Germany;* [3]*University Hospital Bonn, Bonn, Germany*
Email: castvendarko@gmail.com

Background and aims: Primary yolk sac tumor of the liver (HYST) is uncommon disease with less than 20 cases reported worldwide and is often misdiagnosed as HCC. Therefore, in-depth molecular and histological characterization of HYST and development of representative models are essential for better diagnosis and development of patient-specific therapies.
Method: Samples of adjacent liver and tumor tissue were collected and processed after surgery. Long-term culture of the primary cell line (PCL) was established. Histological characteristics of tissues and PCL were analyzed by immunohistochemistry (IHC) and immunofluorescence (IF). Key oncogenic networks and actionable mutations were identified by NGS (DNA/RNA-seq) and SNP arrays and validated by western blot. Dose-response and synergistic approaches were applied to target the identified onco-networks.
Results: Tumor tissue showed solid trabecular growth without presence of Schiller-Duval bodies. IF and IHC displayed typical YST markers (AFP/CK19), which were effectively preserved in xenografts, PCL and spheroids. Transcriptomic profiling confirmed activation of embryonic markers, reduction of macrophages, enrichment of T cells and FOXM1 activation, also sustained in PCL. GISTIC analysis unveiled MYC amplification (8q24.3), validated by WB, as a potential regulator of FOXM1. NGS further showed presence of TP53 and KDR mutations which were highly conserved in PCL. Specific targeting of FOXM1-MYC network, as well as KDR mutation, confirmed sustained sensitivity to specific inhibition in PCL.
Conclusion: For the first time, we were able to dissect HYST at unprecedented molecular level and to establish primary cell line. We identified molecular alterations that could be used for targeted therapy and established cellular model for this extremely rare disease.

WED-286

Exploring the role of the c.41_40dup heterozygous UGT1A1 variant as an alternative polymorphism impacting on young-adult cryptogenic cholestasis phenotype

Fiammetta Di Nardo[1], Mario Romeo[1], Carmine Napolitano[1], Claudio Basile[1], Giusy Senese[1], Alessia Silvestrin[1], Paolo Vaia[1], Simone Olivieri[1], Marcello Dallio[1], Alessandro Federico[1].
[1]*Hepatogastroenterology Division, Department of Precision Medicine, University of Campania Luigi Vanvitelli, Piazza Miraglia 2, 80138, Naples (Italy), Naples, Italy*
Email: fiammetta.dinardo@studenti.unicampania.it

Background and aims: Unexplained chronic cholestasis (UCC) in young adults represents a diagnostic challenge. Uridine diphosphate glucuronosyltransferase-glucuronosyltransferase A1 (UGT1A1), by directly contributing to the bilirubin conjugation, is a crucial enzyme. The heterozygous *UGT1A1 c.41_40dup* variant is classically associated with Gilbert Syndrome (GS). However, a relevant proportion of carriers do not present GS but display reduced UGT1A1 activity, an increased proportion of bilirubin monoglucuronide (BMG) in bile, and enhanced lithogenesis. This research investigates the role of the *UGT1A1 c.41_40dup variant* as an alternative polymorphism in shaping the UCC features.
Method: Seventeen UDCA-naïve GS-free UCC young adults were consecutively enrolled and stratified into: Group A (UGT1A1 c.41_40dup alone), Group B (UGT1A1 c.41_40dup plus other variants), and Group C (other variants only). Pruritus severity, biochemical, and histological data were evaluated. HPLC analysis assessed biliary and intrahepatic bilirubin conjugate proportion (BMG%), as well as hepatic UGT1A1 activity. UDCA's "early" response was evaluated over six months.
Results: Groups A and B showed higher ALT levels and advanced fibrosis (p: 0.0022). Both bile and hepatic samples demonstrated increased BMG/BDG ratio with reduced UGT1A1 activity ($p < 0.0001$). UDCA response was insufficient in 70% of patients carrying c.41_40dup variant. Multivariate analysis confirmed genotype (aSHR: 1.184; p: 0.002) and enzyme activity (aSHR: 2.051; $p < 0.0001$) as independent predictors of this outcome.
Conclusion: The heterozygous *UGT1A1 c.41_40dup* variant delineates a distinct cholestatic phenotype characterized by altered bile composition, hepatic inflammation, and poor UDCA response. These findings support its role as a non-canonical modifier in young-adult UCC and warrant further investigation.

WED-287-YI

Hepatocyte-specific CNNM4 silencing alleviates liver injury in alpha-1 antitrypsin deficiency

Nerea Ferreiro[1], José García Consuegra[2], Carolina Conter[1], Amaia Navarro-Corcuera[1], Leidy Estefanía Zapata-Pavas[1], Maria Mercado[1], Jon Ander Barrenechea-Barrenechea[1], Nazli Khodayari[3], Regina Oshins[3], Mark Brantly[3], Pavel Strnad[4], Irene González-Recio[1], Naroa Goikoetxea-Usandizaga[1], Sara Cogliati[2], María Luz Martínez-Chantar[1]. *[1]CICbioGUNE, Basque Research and Technology Alliance (BRTA), Derio, Spain; [2]Centro de Biología Molecular Severo Ochoa, Madrid, Spain; [3]Nctc Gainesville Campus, Gainesville, United States; [4]University Hospital Aachen, Aachen, Germany*
Email: nferreiro@cicbiogune.es

Background and aims: Alpha-1 antitrypsin deficiency (AATD), most commonly caused by the PiZZ genotype, is a hereditary disorder in which misfolded alpha-1 antitrypsin (AAT) accumulates in the hepatocyte endoplasmic reticulum (ER), driving chronic liver inflammation, fibrosis, and increased risk of hepatocellular carcinoma. Altered magnesium homeostasis has been described in liver disease, but its role in AATD remains unclear. This study investigates the contribution of the magnesium exporter Cyclin M4 (CNNM4) to AAT-driven liver pathology and evaluates hepatocyte-targeted CNNM4 silencing to reduce protein aggregation, ER stress, and liver injury.
Method: CNNM4 expression was evaluated by immunohistochemistry in liver samples from PiZZ patients. In vivo, 6-month-old C57BL/6J mice carrying the SERPINA1*E366 K (PiZZ) mutation were treated with hepatocyte-specific N-acetylgalactosamine–conjugated siRNA targeting CNNM4. Liver tissue was collected to characterize immune cell activation by FACS, and bone marrow–derived macrophages and neutrophils were exposed to hepatocyte-derived conditioned media to evaluate inflammatory responses. ER stress and mitophagy-related markers were analyzed in liver tissue and isolated hepatocytes.
Results: Hepatic CNNM4 expression was upregulated in PiZZ patients and mice. CNNM4 silencing in PiZZ mice restored magnesium homeostasis and increased circulating AAT levels, while reducing total and aggregated AAT in the liver. These effects were associated with a significant reduction of ER stress and mitophagy and notably increased mitochondrial activity in liver tissue and isolated hepatocytes. Regarding inflammation, treated mice showed a significant decrease in infiltrating $CD8^+$ T cells and $CD11c^+/CD11b^+$ inflammatory myeloid cell populations. Conditioned media from treated hepatocytes led to a reduction in proinflammatory and activation markers in macrophages and neutrophils, indicating attenuation of the inflammatory response.
Conclusion: CNNM4 modulates magnesium-dependent stress and inflammatory pathways in AAT–driven liver injury; therefore, hepatocyte-targeted CNNM4 silencing is a promising therapeutic approach to decrease aggregation, reduce ER stress, and improve liver function in AATD.

Utility of mRNA analysis in nasopharyngeal brushings from Wilson disease patients and carriers of ATP7B mutations to detect alterations in gene splicing

Luis García-Villarreal[1], Lenka Mrazova[2], Antonio Tugores[1], Maria Viera[1], Alena Cizkova[2], Filip Majer[2], Jakub Sikora[2], Viktor Stranecky[2], Ivana Jedlickova[2], Pablo Alonso Castellano[1], Alberto Monescillo[1], Paola Saiz Udaeta[1], Elena Jimenèz Mutiloa[1], Ildefonso Quiñones-Morales[3], Ana Cruz[1]. *[1]Digestive Service. Complejo Hospitalario Universitario Insular Materno Infantil, Las Palmas de Gran Canaria, Spain; [2]Research Unit for Rare Disease, Department of Pediatrics and Metabolic Disorders, First Faculty of Medicine, Charles University, Prague, Czech Republic; [3]Hospital Universitario Dr Negrín, Las Palmas de Gran Canaria, Spain*
Email: lgarciavillarreal@gmail.com

Background and aims: Some studies indicate that splicing errors may be the genetic mechanism responsible for cases of Wilson disease. This has been proposed for the most frequent mutation in the Spanish population (p.M645R) and also suggested as a possible mechanism for other mutations, even synonymous, in exons 6–8. A method has recently been designed to assess these errors using nasopharyngeal brushings (1) and we decided to analyze the effect of variants c.1934T>G (p.M645R), c.2123T>C (p.L708P) - most prevalent in Gran Canaria - and c.3061-12T>A, on mRNA processing using our novel protocol to extend previous findings.
Method: Total RNA was isolated from nasopharyngeal swabs, reverse transcribed into cDNA, and the target region encompassing exons 3–21 was amplified and the product analyzed using long-read sequencing on the Oxford Nanopore platform. Generated FastQ files were aligned to the human reference genome (hg19) for downstream analysis (1).
Results: Subjects analyzed included two homozygotes and three carriers for p.L708P, five carriers of c.3061-12T>A, and four carriers and one compound heterozygote for p.M645R. Splicing defects were evident for the p.M645R allele, showing exons 6 and 7 skipping and a variable reduction in exon 8, while the presence of p.L708P allele led to a complete exon 8 skipping, showing 50% of mRNA in carriers and 0% in homozygous patients. Carriers of c.3061-12T>A showed a decrease of 50% of mRNA at exon 14.
Conclusion: We show the usefulness of the isolation of mRNA from nasopharyngeal swabs, followed by long-read sequencing to study splicing alterations associated with ATP7B mutations. Using this strategy, we discovered that p.M645R, most common in the Spanish population, is associated with skipping in exons 6 and 7 and in 8 of variable intensity, that may contribute to the different phenotypes in patients carrying this mutation We also show that the most prevalent mutation in Gran Canaria (p.L708P), leads to a complete exon 8 skipping, indicating that the pathogenicity of this variant lies beyond the Leu to Pro substitution. Our novel approach could also be applied to other mutations not studied yet presenting variable phenotypes.
Grant number: NW24-04-00067 from the Ministry of Health of the Czech Republic.

Complejo Hospitalario Universitario Insular Materno Infantil, Las Palmas Gran Canaria, Spain
Email: lgarciavillarreal@gmail.com

Background and aims: Loss-of-function (LOF) mutations in Wilson disease (WD) have been proposed as highly penetrant, with different copper metabolism and increased risk of transplantation and death. We hence decided to study them in a large sample of our Registry.
Method: Clinical, analytical and outcome data and the presence of LOF mutations and the prevalent M645R, L708P, and H1069Q, in cases with both known alleles, were collected. We compared both homozygotes (HO) and compound heterozygotes (HE), excluding combinations among the four mutations studied. We defined biochemical response (BR) as normalization of transaminase levels or a decrease >70% at 1 or 3 years, and lack of BR or the development of cirrhosis, decompensation, transplantation or death from WD defined clinical-biochemical progression (CBP).
Results: Of 512 patients, we reviewed 322 cases: 276 had two known alleles (study group); 46 had only one (of these 46 alleles, 87% were not LOF). LOF were present in 36% of the patients (116/322) and in 23% of the alleles (138/598). There were 22 cases with double LOF (14 HO of 4 mutations and 8 with other combinations) and 94 HE. We found 35 deletions, 10 insertions, 32 terminations and 60 splicings (53 in introns). In the two-allele group, patients with double LOFs had higher ceruloplasmin concentrations and less cases with levels <10 mg/dL; higher baseline copper excretion; younger age at diagnosis, fewer cases over 40 years of age and more cases with neurological manifestations. The BR was similar among mutations, both in the HO and HE groups. Double LOF cases showed a worse CBP than the HO M645R group and similar to the HO L708P group. The HE groups behaved similarly, but without reaching statistical significance. Combining HO and HE from mutations, the LOF and L708P groups continued to show worse CBP compared to M645R group (all contrasts, $p < 0.05$). No differences in copper content in liver biopsy, presence of cirrhosis at diagnosis nor in the de novo cirrhosis were detected.
Conclusion: LOF mutations in WD are frequent in our population; since they require more complex detection techniques, this may explain some of the alleles not yet classified. These mutations exhibit certain peculiarities on copper metabolism. They do not appear to affect the biochemical response, and they present a similar CBP to penetrant mutations like L708P. These findings need to be confirmed given the great heterogeneity of existing LOF variants.

WED-290

A determination of ATP7B peptides in dried blood spots from patients with Wilson disease: a feasibility study in a high-prevalence population (Gran Canaria) and potential utility in neonatal screening

Luis García-Villarreal[1], Antonio Tugores[2], Pablo Alonso Castellano[1], Tim Grotzer[3], Kayla Croney[3], Maria Viera[1], Alberto Monescillo[1], Paola Saiz Udaeta[1], Elena Jimenèz Mutiloa[1], Ana Cruz[1], Ildefonso Quiñones-Morales[4], Jiwoon Park[5], Claire Klippel[5], Sihoun Hahn[6]. *[1]Digestive Service, Complejo Hospitalario Universitario Insular Materno Infantil, Las Palmas de Gran Canaria, Spain; [2]Research Unit, Complejo Hospitalario Universitario Insular Materno Infantil, Las Palmas Gran Canaria, Spain; [3]Seattle Children's Research Institute, Seattle, United States; [4]Hospital Universitario Dr Negrín, Las Palmas de Gran Canaria, Spain; [5]Key Proteo, Seattle, United States; [6]Seattle Children's Hospital/University of Washington, Seattle, United States*
Email: lgarciavillarreal@gmail.com

Background and aims: Wilson disease is a genetic disease that meets the clinical requirements for neonatal screening (NS): available treatments and excellent outcomes with early treatment,but still with no accepted method for NS. Recently (1), quantification of peptides (P) from the ATP7B protein in DBS has been proposed as a technique applicable to NS.
Method: The blood samples from patients and family members (all genotyped) were processed according to the protocol published (1), and the cutoff points (CP) for peptides 887 and 1056 were obtained from the samples corresponding to 9 controls without mutations. A positive result was with considered when one or two P were below the cutoff point (CP) and negative when both were above CP, in each patient.
Results: Fifty patients, 21 carriers and 9 controls were included. The most frequent mutations were: p.L708P (18 homozygotes, 17 compound heterozygotes, and 9 carriers); p.M645R (8 heterozygotes), and c.-436-422del15 (3 homozygotes, 7 heterozygotes, and 5 carriers). Five false negatives (FN) and 9 false positives (FP) were obtained, with a sensitivity of 90.0%, a specificity of 70%, a PPV of 83.3%, and a NPV of 80.8%. Among the FPs, 5/9 were carriers of the p.L708P mutation. The FNs were compound heterozygotes with mutations of very low allele frequency (AF <0.0003): 2 p.N1270S, p.M769V, and p.T1031. All but one patient with the most frequent mutations (p.L708P and p.M645R) were correctly detected, as were the case who only had one known mutant allele in ATP7B.
Conclusion: It is critical to account for the expected variability when establishing the range for the cell-based proteomic assay. Although the CP might be not very reliable yet, the feasibility study shows that in our population the technique has very high sensitivity, although low specificity; its implementation will be decided after establishing a reliable control range in the region, followed by the cost-effectiveness and cost-utility studies. In other populations the specificity and sensibility may vary and the screening program will depend on these results. It is necessary to increase the number of healthy controls to better adjust the CP for any population.

Neutrophil extracellular traps activation in porto-sinusoidal vascular disorder: a novel mechanism linking intestinal permeability to vascular damage

Stefania Gioia[1], Oliviero Riggio[1], Diletta Overi[1], Roberto Carnevale[1], Silvia Nardelli[1], Graziella Basili[1], Lorenzo Ridola[1], Valerio Giannelli[2], Giulia d'Amati[1], Andrea Baiocchini[2], Alessio Aghemo[3], Luca Di Tommaso[3], Luigi Terracciano[3], Guido Carpino[1], Nicola Pugliese[3]. *[1]Sapienza, Università di Roma, Roma, Italy; [2]Azienda*

Ospedaliera San Camillo Forlanini, Roma, Italy; [3]Humanitas University, Rozzano, Italy
Email: stensgioia@hotmail.com

Background and aims: Etiopathogenesis of porto-sinusoidal vascular disorder (PSVD) is poorly understood. Our previous studies indicated the crucial role of endotoxemia in PSVD vascular lesions, demonstrating that patients exhibit increased intestinal permeability, bacterial translocation as well as pro-aggregating/pro-thrombotic state before portal hypertension (PH) onset. However, the mechanisms linking endotoxemia to vascular injury downstream have not been completely elucidated. Neutrophil extracellular traps (NETs)-web-like chromatin structures released by activated neutrophils in response to infectious/inflammatory stimuli-are known to contribute to sinusoidal endothelial damage, hepatic inflammation and fibrosis, but their role in PSVD remains unexplored. This study aimed to assess circulating NETs markers and their correlation with intestinal permeability and pro-thrombotic state in PSVD.
Method: Serum levels of citrullinated histone H3 (citH3), neutrophil elastase (NE), and myeloperoxidase (MPO) were measured in 51 patients with PSVD (34 with PH, 17 without PH) and 33 healthy controls. Correlations between NETs markers and markers of intestinal permeability (zonulin and lipopolysaccharides-LPS), platelet aggregation and microvascular inflammation (soluble glycoprotein VI, soluble P-selectin, ADAMTS13, and von Willebrand factor-vWF), and hypercoagulability (factor VIII and prothrombin fragment F1+2) were analyzed.
Results: Compared to healthy controls, PSVD patients exhibited significantly higher serum levels of citH3, MPO, and NE. Mean citH3 level (ng/dl) was 2.5 ± 0.5 in controls, 3.4 ± 0.4 in PSVD without PH, and 4.8 ± 1.2 in PSVD with PH ($p < 0.0001$). MPO (ng/dl) levels were 44.4 ± 11, 56.4 ± 11, and 71.8 ± 14 ($p < 0.0001$), respectively; NE (ng/dl) levels 68.9 ± 11.9, 84 ± 9, and 128 ± 36.2 ($p < 0.0001$). Serum LPS and zonulin correlated positively with citH3 ($r = 0.32$, $p = 0.01$; $r = 0.24$, $p = 0.04$), MPO ($r = 0.37$, $p < 0.005$; $r = 0.23$, $p = 0.04$) and NE ($r = 0.53$, $p < 0.001$; $r = 0.48$, $p < 0.001$). vWF and FVIII showed positive correlations with NETs markers, whereas ADAMTS13 correlated negatively. SP-selectin correlated significantly with MPO and NE.
Conclusion: PSVD patients displayed elevated markers of NETs, detectable even before the development of PH and further amplified thereafter. Their association with increased intestinal permeability, bacterial translocation, endothelial dysfunction and pro-thrombotic features, suggests that NETosis contributes to the cascade of events leading to vascular alterations in PSVD.

WED-298
Proteomic quantification of ATP7B in dried blood spots: a feasibility study in a high-prevalence sardinian population and implications for newborn screening of Wilson disease

Sihoun Hahn[1], Kayla Croney[2], Tim Grotzer[2], Phi Duong[2], Salvatore Zaru[3], Alberto Civolani[4], Georgios Loudianos[5]. *[1]Seattle Children's Hospital, University of Washington School of Medicine, Seattle Children's Research Institute, Seattle, United States; [2]Seattle Children's Research Institute, Seattle, United States; [3]UOC Medicina Interna e Gastroenterologia, Nuoro, Italy; [4]UOC Gastroenterologia, Cagliari, Italy; [5]Microcythemic Paediatric Hospital, Cagliari, Italy*
Email: sihahn@uw.edu

Background and aims: Wilson disease (WD) is an autosomal recessive disorder of copper transport caused by pathogenic variants in the *ATP7B* gene, with an estimated global incidence of approximately 1 in 30,000. In contrast, multiple studies have reported a markedly elevated prevalence in Sardinia—approximately 1 in 2700–3000 individuals—representing one of the highest known regional prevalences worldwide. We previously demonstrated that quantification of ATP7B peptides in dried blood spots (DBS) using liquid chromatography–tandem mass spectrometry (LC-MS/MS) is a promising approach for newborn screening (NBS) of WD. Recently, Washington State added WD to its existing newborn screening panel following a large-scale pilot study that screened over 30,000 newborns, further supporting the feasibility of population-based screening.
Method: A multiplexed proteomic assay using LC-MS/MS was applied to quantify ATP7B peptides as surrogate biomarkers in DBS. Seventy-five non-Sardinian unaffected samples were used to establish control distributions and preliminary cutoff values. A total of 52 blind samples from Sardinia were analyzed, including 6 individuals homozygous for the founder deletion variant (*c.-441_472del*) and 22 compound heterozygotes carrying one founder variant and one additional rare variant. Three heterozygous carriers were included, as well as one individual in whom a second pathogenic variant had not been identified.
Results: ATP7B peptide concentrations below the established cutoff were observed in 45 of 52 WD samples. All three heterozygous carriers demonstrated peptide levels within the normal range. Six WD samples were classified as false negatives; all were compound heterozygotes carrying one founder variant and one rare variant. Two additional cases with suspected large second deletions showed markedly reduced ATP7B peptide levels, consistent with a true WD biochemical phenotype despite incomplete molecular characterization.
Conclusion: Establishing population-specific reference ranges is critical in regions with high genetic heterogeneity and prevalent founder mutations. While refinement of cutoff values is ongoing, this feasibility study demonstrated a detection rate comparable to our previously reported results. Although WD has not yet been universally adopted into newborn screening panels worldwide, our findings support continued evaluation and potential implementation of ATP7B proteomic screening as part of newborn screening programs in Sardinia.

WED-299
In vivo determination of the transport capacity of bile salt export pump: a breakthrough for testing novel drugs for progressive familial intrahepatic cholestasis type 2

Willemien Hof[1], Ione Grammatikopoulos Pallidis[1], Hilde de Vries[1], Milaine Hovingh[1], Rick Havinga[1], Niels Mulder[1], Krisztina de Bruyn[2], Folkert Kuipers[1,3], Jan Freark de Boer[1,2], Henkjan J. Verkade[1]. *[1]Groningen, Netherlands; [2]Department of Laboratory Medicine, University of Groningen, University Medical Centre Groningen, Groningen, Netherlands; [3]European Research Institute for the Biology of Aging (ERIBA), University of Groningen, University Medical Centre Groningen, Groningen, Netherlands*
Email: w.f.j.hof@umcg.nl

Background and aims: The bile salt export pump (BSEP) transports conjugated bile acids (BAs) from hepatocytes into the bile canaliculi. Mutations in the *ABCB11* gene cause BSEP deficiency, also known as progressive familial intrahepatic cholestasis type 2 (PFIC2). This cholestatic liver disease is characterized by disrupted bile formation, leading to BA accumulation and severe liver injury. Many *ABCB11* mutations have been identified, a part of which appear to be associated with residual BSEP activity. Pharmacological stimulation of residual BSEP transport activity represents a potential treatment option for patients with such mutations. However, a model system to accurately quantify BSEP-mediated BA transport capacity and assess the impact of its pharmacological stimulation *in vivo* is currently lacking. We aimed to establish an approach to quantify the BA transport capacity of BSEP *in vivo*.
Method: Male and female anaesthetized *Abcb11*$^{+/+}$, *Abcb11*$^{+/-}$ and *Abcb11*$^{-/-}$ mice (11–15 weeks old) were infused with the bile acid tauroursodeoxycholic acid (TUDCA) via the jugular vein while the secreted bile was collected to determine the maximum hepatobiliary BA secretion rate.
Results: Hepatic BSEP protein levels were ±50% lower in *Abcb11*$^{+/-}$ mice than in *Abcb11*$^{+/+}$ controls, confirming the impact of gene copy number on protein abundance. Infusing 1200 nmol/min TUDCA for

60 minutes was well-tolerated and allowed to assess the maximum hepatobiliary BA secretion rate of *Abcb11*$^{+/-}$, mice. In male mice, maximum hepatobiliary BA secretion rates of 5019 ± 606 nmol/min/100 g BW, 2984 ± 458 nmol/min/100 g BW and 512 ± 121 nmol/min/100 g BW were observed in the *Abcb11*$^{+/+}$, *Abcb1*$^{+/-}$ and *Abcb1*$^{-/-}$ groups, respectively. In female mice, maximum hepatobiliary BA secretion rates of 4793 ± 281 nmol/min/100 g BW, 2929 ± 603 nmol/min/100 g BW and 330 ± 194 nmol/min/100 g BW were observed in the *Abcb11*$^{+/+}$, *Abcb1*$^{+/-}$ and *Abcb1*$^{-/-}$ groups, respectively. Comparison with wildtype mice confirmed the impaired BA transport capacity of *Abcb11*$^{+/-}$, mice and their suitability as model for genetic insufficiency. Moreover, male and female mice of the same genotype showed similar baseline and maximum BA secretion rates.
Conclusion: We have developed a quantitative assessment model for BSEP transport capacity. The model will for allow to test candidate drugs for therapeutic correction and potentiation of BSEP variants with decreased functionality, such as found in patients with BSEP deficiency (PFIC2).

Email: h.w.hoyle@medisin.uio.no

Background and aims: Biliary atresia is a pediatric disease of the bile ducts with limited therapeutic treatments available which requires surgical intervention within months of birth for the best outcome. Due to the need to perform surgery in a short timeframe, studies of alternative treatment options are difficult to perform. Animal models can be used in the laboratory, with induction of biliary atresia through the addition of the toxin biliatresone, however these do not fully recapitulate human biology. We have previously developed an *in vitro* human bile duct on a chip which we aim to use in this work to model biliary atresia through the addition of biliatresone. Potential treatment of this *in vitro* bile duct injury can then be investigated.
Method: A microfluidic chip was 3D printed and a collagen gel containing a hollow channel formed within it. Primary human cholangiocytes were derived from endoscopic retrograde cholangiopancreatography (ERCP) brushings and propagated as organoids before being seeded into the channel as a single cell suspension. Experiments were performed at day 10 once cells had formed a mature epithelium. Treatment was performed with different doses of biliatresone (2, 5, 10 µg/mL) in the presence or absence of N-acetyl-L-cysteine. The properties of the bile duct on a chip system after treatment were investigated using brightfield and confocal microscopy along with biochemical assays.
Results: Treatment with biliatresone had a dose-dependent impact on the viability of *in vitro* bile ducts when measured using a tetrazolium reduction assay (~70% at 2 µg/mL, <10% at 5 µg/mL). The formation of organoid-like structures within the duct channel was also observed, with more such structures at higher doses of biliatresone. Within these structures, abnormal polarization of cells was observed when stained for actin. Treatment of the channels with 100 µM N-acetyl-L-cysteine led to a complete rescue of the phenotype with 2 µg/mL biliatresone treatment and partial rescue with 5 µg/mL biliatresone.
Conclusion: We have demonstrated that an abnormal phenotype is induced in an *in vitro* bile duct on a chip after treatment with biliatresone. The partial rescue of the model with N-acetyl-L-cysteine shows that this could be an effective platform for preclinical testing of novel therapeutic treatments and future studies could look into probing the mechanisms involved in biliary atresia progression in more depth.

WED-301

Heterozygous variants in NOTCH2 among a cohort of juvenile and adult patients with cholestatic liver disease: Disease modifiers or innocent bystanders?

Roman Liebe[1], Amelie Stalke[2], Hartmut Schmidt[1], Frank Lammert[3], Marcin Krawczyk[1]. [1]*Essen University Hospital, Department of Gastroenterology, Hepatology and Transplant Medicine, Medical Faculty, University of Duisburg-Essen, Essen, Germany;* [2]*Hannover Medical School, Hannover, Germany;* [3]*Center for Health Economics Research Hannover (CHERH), Hannover Medical School, Hannover, Germany*
Email: marcinjan.krawczyk@uk-essen.de

Background and aims: Genetic cholestatic liver disease is increasingly stratified using NGS, and the resulting information can be used to guide treatment with new drugs such as IBAT inhibitors, which have proven efficacious in congenital liver diseases such as Alagille Syndrome and PFIC. We hypothesised that hypomorphic variants in NOTCH2 or JAG1 may predispose affected patients for later-onset multifactorial cholestasis.
Method: We re-analysed NGS data from 128 patients with cholestatic liver disease of various aetiologies using a targeted sequencing panel of 36 candidate genes involved in hereditary cholestasis. Variants of interest were characterised by filtering allele frequencies in the gnomAD V4.1.0 database, and assessed for potential pathogenicity using various bioinformatic tools e.g. CADD, REVEL, and popEVE.
Results: Missense *NOTCH2* variants were identified in twelve patients (age range 26–83 y.o., 10 women), whereas no pathogenic variants in *JAG1* were detected. None of the private or very rare *NOTCH2* variants had been previously observed in paediatric patients with Alagille syndrome. Additional high-impact pro-cholestatic *ABCB4* variants occurred in three patients, lower-impact *ABCB4* variants in another three, and one patient carried an *ABCC2* variant associated with Dubin–Johnson syndrome. Low-impact single nucleotide polymorphisms predisposing for cholestatic conditions were identified in five patients. Among the twelve patients with *NOTCH2* variants, three exhibited phenotypes consistent with the co-inherited pathogenic *ABCB4* variants (i.e., PFIC or LPAC syndrome). Filtering allele frequencies of five *NOTCH2* variants in six patients ranged from 0.12%–5.05% suggesting that they were not associated with (a modest or highly penetrant) disease. In the remaining three patients, the predicted functional impact, low allele frequency, and absence of alternative explanatory variants support a plausible contribution of *NOTCH2* variants to the pathogenesis of episodic intrahepatic cholestasis, in line with their clinical presentations.
Conclusion: We show that rare heterozygous variants in *NOTCH2* might predispose their carriers for juvenile- or adult-onset recurrent intrahepatic cholestasis, possibly through bile duct paucity.

Email: matylda.kuzinska@charite.de

Background and aims: Biliary atresia (BA) is a common pediatric cholangiopathy in which, following hepatoportoenterostomy ("Kasai" procedure), approximately 50% of patients fail to resolve jaundice. The precise cytokine environment underlying this clinical divergence remains unidentified.
Method: Liver tissue single-nucleus RNA sequencing (snRNAseq) was stratified by clinical jaundice clearance and native liver survival at 100 days after Kasai. Controls were non-BA-cholestatic patients (total n = 12, n = 4/group). A multiplex cytokine assay using flow cytometry and tissue secretome analysis was performed by incubating liver tissue and collecting liver-conditioned media (LCM) from BA patients and controls (n = 6/group). Patient-derived intrahepatic cholangiocyte organoids (ICOs) functionally modeled epithelial phenotypes *in vitro*.
Results: Cholangiocytes from patients failing to clear jaundice enriched the expression of the receptors *IL6R, IFNAR1/2*, *IL17R,* and *IL12RB1*. On the protein level, BA-derived LCM enriched IL-6, TNFα, IFNγ, IFNα2, IL-12, and IL-17 compared with controls ($p < 0.05$). Further, cholangiocytes from patients with persistent jaundice exhibited a pronounced interferon-responsive, epithelial remodeling transcriptional state, marked by upregulation of *IFI44L, CXCL9, CXCL10, KRT17, COL2A1*, and MMP7. BA-derived ICOs demonstrated reduced epithelial lumen diameter, impaired expandability, and sustained interferon-responsive gene enrichment across passaging. Additional growth suppression occured when TNFα and IL1β were added to ICOs at concentrations in the same log-fold as native BA-LCM tissue levels, indicating that both epithelial-intrinsic and cytokine-mediated effects govern epithelial dysfunction in BA.
Conclusion: We delineated the biliary cytokine milieu and cholangiocyte transcriptional states that dictate the inability to resolve jaundice, which may inform future immune-targeting therapeutic strategies.

WED-303
Multi-omics analysis reveals ECM defects and TGF-β signaling in biliary atresia

Qiongfen Lin[1], Zuyi Ma[1], Vincent CH Lui[1,2], Pak Chung Sham[3], Paul KH Tam[4], Clara Sze-man Tang[1,2]. [1]*Department of Surgery, Li Ka Shing Faculty of Medicine, The University of Hong Kong, Hong Kong SAR, China;* [2]*Dr Li Dak-Sum Research Centre, The University of Hong Kong-Karolinska Instituted Collaboration in Regenerative Medicine, Hong Kong SAR, China;* [3]*The University of Hong Kong, Hong Kong SAR, China;* [4]*Precision Regenerative Medicine Research Centre, Medical Sciences Division, Macau University of Science and Technology, Macau SAR, China*
Email: qiongfen@hku.hk

Background and aims: Biliary atresia (BA) is a severe cholangiopathy characterized by progressive fibrosclerosing and inflammatory obstruction of the bile ducts, which is caused by genetic predisposition (e.g., *ADD3*, *PKHD1*) to developmental defects in hepatobiliary development and plausibly triggered by environmental insults (e.g., viral infections). Liver fibrosis, marked by excessive deposition of abnormal extracellular matrix (ECM), and cirrhosis are the main contributors to morbidity in BA. In this study, we aimed to utilize multi-omics approaches—including whole exome and genome sequencing, RNA sequencing, and others—to investigate the role of ECM in the development of BA.
Method: To uncover novel disease-susceptibility genetic factors, rare damaging mutations were analyzed in a dataset comprising whole exome and genome sequencing data from 303 BA patients, including 228 trios (probands and unaffected parents).
Results: This analysis revealed a significant enrichment of rare, potentially damaging mutations in ECM-related genes, with approximately 30% of cases harboring at least one ECM mutation. To explore the regulatory landscape of ECM-related genes, we performed protein-protein interaction network and hub gene analyses, which uncovered a highly interconnected network composed of structural ECM components—such as laminins and collagens—and key TGF-β signaling activators, including integrins, thrombospondin-1 (THBS1), and members of the ADAMTS family (ADAMTS2, 5, 6, ADAMTSL1, and 17). Functional studies further elucidated the role of these components: dual luciferase reporter assays showed that wild-type THBS1 activates TGF-β signaling by directly binding to latent TGF-β, whereas BA-associated THBS1 variants impair this activation. Similarly, variants in ADAMTS5 and ADAMTSL1 linked to BA were found to reduce TGF-β activation. To investigate the developmental implications, CRISPR/Cas9-mediated knockdown of *thbs1a* and *thbs1b* in zebrafish resulted in reduced liver size and decreased density of biliary epithelial cells and ducts, indicating that impaired THBS1 function disrupts biliary development.
Conclusion: Collectively, these findings suggest that genetic disruptions in ECM components may contribute to BA pathogenesis by impairing biliary development through the dysregulation of TGF-β signaling.

WED-304
Variation of management in Wilson's disease in England: results from the first national audit

James Liu Yin[1], William J. H. Griffiths[2], Oliver Bandmann[3], Aftab Ala[1]. [1]*Institute of Liver Studies, King's College Hospital, London, United Kingdom;* [2]*Cambridge Liver Unit, Addenbrooke's Hospital, Cambridge, United Kingdom;* [3]*Division of Neuroscience, University of Sheffield, Sheffield, United Kingdom*
Email: aftab.ala1@nhs.net

Background and aims: Wilson's disease (WD) is a rare genetic metabolic liver disease which affects around 1 in 30,000 people. In England, patients have been managed in specialist centres which are able to provide 2nd line therapy.
Recently guidance has been released by international and national liver associations to help standardise patient care. We undertook a national audit of specialist centres to assess the current management of WD patients, as well as use of and alignment with society guidance.
Method: We conducted an online survey from 2024–25, which gathered information on the number of patients managed with WD at the centre, the presence and staffing of their multidisciplinary team, information on their 5 most recent patients (including medication regime, symptoms, and presence of cirrhosis or neurological symptoms) and the awareness of current guidance.
Results: We had responses from 80% of the clinical commissioned centres for Trientine prescriptions in 2019. 55% of centres had multidisciplinary teams mostly including a Gastroenterologist and Neurologist. Centre-reported patient numbers were 536 in total with mean age of 34 (range 9–50). D-penicillamine was the most commonly prescribed medication with 57% also prescribed pyridoxine (75% daily dosage compared to weekly). 37% of patients were on some form of Trientine with the remaining on zinc. Side effects were reported in 13% of the audited patients and 15% reported neurological deterioration. 24hr urinary copper was performed within 12 months in 83% of patients, with one third whilst off their chelator treatment. Treatment was titrated in 15% as a result of UCE. 38% of patients were

cirrhotic with two thirds having regular ultrasound surveillance. All clinicians reported following guidance, with only 1 reporting practice outside of guidance. Clinicians reported following; British 84% European 66% and American 42%.
Conclusion: Despite the high usage of published guidance there remained significant disparity in management regimes, in particular with treatment monitoring and titration. We will engage with clinicians at participating centres to explore the rationale leading to current practice. We hope to then achieve a level of standardisation of management of WD in line with current recommendations to elevate patient care.
This WD survey and engagement framework could then be adapted in other rare liver diseases, including WD, with the aim of it being utilised internationally within the EASL-ERN.

WED-305
Exploring causes of excess mortality in the Wilson's disease psychiatric cohort in the largest psychiatric centre in the UK
James Liu Yin[1], David Okai[2], Richard Thompson[1], Aftab Ala[1]. [1]*Institute of Liver Studies, King's College Hospital, London, United Kingdom;* [2]*Institute of Psychiatry, Psychology and Neuroscience, South London and Maudsley NHS Foundation Trust, London, United Kingdom*
Email: aftab.ala1@nhs.net

Background and aims: Wilson's disease (WD) is a genetic metabolic disease that leads to accumulation of copper in the body. Copper is deposited in the brain and the liver giving rise to a number of neurological, liver and psychiatric symptoms. Preliminary work exploring the data from the largest psychiatric centre (Maudsley Hospital, London) in the UK found a significant cohort of WD patients with a mortality rate of 27%. Our work investigated the cause of death of these patients and explored any contributing factors that could be related to the mortality rate.
Method: We identified our cohort of WD patients from the Maudsley hospital, part of the South London and Maudsley trust, by using hospital episodes statistic (HES) data coded as E83.0 as well as free text mention of WD. We then further used HES data to gather mortality status, coded cause of death, co-mobidities and medications.
Results: There were 81 WD patients identified within records with 22 deaths in total. Mean time to death was 83 months from time of referral (7–204), with a raised standarised mortality ratio. Cause of death data was available on 91% of patients. We found a variable cause of death across available data. The most common cause of death was infection, followed by overdose, renal failure and cirrhosis. Within patients with infection as cause of death, 3 had been liver transplant recipients and therefore would have been on a form of immunosuppression. There was a high rate of liver disease listed as a contributory cause of death within this cohort at 30%. On review of coded co-morbidities, liver disease was the highest co-morbidity at 34%, with mental and behaviours disorders at 31%. Cerebrovascular disease, ischaemic heart disease or hypertension were present in 38% of patients. 51% of patients were on a form of antipsychotic, anxiolytic or antidepressant with >50% of patients on 4 different types of these medications.
Conclusion: Patient with psychiatric conditions can often have a high rate of mortality due to cardiovascular disease, however our cohort, despite having risk factors and presence of these co-morbidities, did not follow this trend. We observed a high rate of liver disease or alcohol as contributing factors in mortality in the WD population. A higher rate of co-existing liver disease in those presenting with psychiatric symptoms should be therefore considered. This highlights the need to screen the psychiatric population for WD, as its prevalence is underestimated, to aid in decreasing liver related mortality.

WED-306
Genetic dysregulation of methionine metabolism in the pathogenesis and progression of biliary atresia
Zuyi Ma[1], Pak Chung Sham[2], Paul Kwong-Hang Tam[3], Vincent Ch Lui[1], Clara Sze-man Tang[1]. [1]*Department of Surgery, Li Ka Shing Faculty of Medicine, The University of Hong Kong, Hong Kong SAR, China;* [2]*Department of Psychiatry, Li Ka Shing Faculty of Medicine, The University of Hong Kong, Hong Kong SAR, China;* [3]*Precision Regenerative Medicine Research Centre, Medical Sciences Division, Macau University of Science and Technology, Macau SAR, China*
Email: u3013448@connect.hku.hk

Background and aims: Biliary Atresia (BA) is a life-threatening fibroinflammatory disease of the biliary tree, with the highest incidence in Asians. Its pathogenesis remains unknown, but it is thought to result from a combination of genetic predisposition and hepatobiliary injury and immune response. Our group previously conducted a sequencing study on BA patients, whereby we identified enrichment of rare damaging mutations in multiple genes associated with methionine metabolism in BA patients. We hypothesize that genetic predisposition to methionine metabolic dysfunction is a key pathological mechanism for BA. In this study, we aim to employ *Mat1a* knockout mice to elucidate the underlying molecular mechanisms by which reduced *Mat1a* expression leads to BA.
Method: We established a BA model in *Mat1a*–/–, *Mat1a*+/–, and wild-type mice through rhesus rotavirus (RRV) inoculation to investigate if deletion of *Mat1a* increases susceptibility to RRV-induced BA and disease severity. We will also inject SAMe and/or GSH supplements to the BA mice to determine if these supplements ameliorate disease development and alleviates the morbidity and mortality in RRV-induced BA mice.
Results: BA-like phenotypes were observed in RRV-injected *Mat1a* –/–, *Mat1a*+/–, and wild-type littermates. Homozygous deletion of *Mat1a* increased susceptibility to RRV-induced BA and exacerbated disease severity, as evidenced by pale, nodular livers and an obstructed extrahepatic bile duct. Histology revealed increased inflammatory cell infiltration and fibrosis in portal areas, accompanied by significantly elevated alkaline phosphatase (ALP) and aspartate aminotransferase (AST) levels. The effect of SAMe and/or GSH supplements will be discussed.
Conclusion: Loss function of *Mat1a* increased susceptibility to RRV-induced BA and exacerbated disease severity, indicating that genetic predisposition to dysregulation of methionine metabolism may be a key pathological mechanism in BA development.

WED-307
RNA - based CRISPR/Cas9 - mediated genetic modification of the copper transporter ATP7B in Wilson disease
Moritz Marciniak[1], Andree Zibert[1], Oksana Nadzemova[1], Hartmut Schmidt[2], Phil Robin Tepasse[1], Jonel Trebicka[1], Vanessa Sandfort[1]. [1]*University Hospital Münster, Münster, Germany;* [2]*University Hospital Essen, Essen, Germany*
Email: vanessa.sandfort@ukmuenster.de

Background and aims: Toxic copper (Cu) accumulations in the liver are described in Wilson disease (WD), a monogenic disorder characterized by mutations in Cu transporting protein ATP7B. H1069Q is the most common point mutation in *ATP7B* in Western Europe and the USA. A previous study by our group demonstrated the feasibility of H1069Q correction using plasmid-based CRISPR/Cas9 (Clustered Regularly Interspaced Short Palindromic Repeats/Caspase 9) molecules in WD-specific induced pluripotent stem cells (iPSCs). The corrected cells differentiated into hepatocyte-like cells (HLCs) and showed a higher resistance to high Cu concentrations (Iwan et al. in revision). However, an application of RNA-based CRISPR/Cas9 molecules would bring this technology one step closer to potential clinical application in WD.
Method: A single-guide RNA (sgRNA) targeting the ATP7B H1069Q locus was designed. HEK293 cells were lipofected with sgRNA and

Cas9 mRNA to induce a double-stranded DNA cleavage. Individual HEK293 clones were analysed by Sanger sequencing. ATP7B expression was assessed by Western blotting (WB) and quantitative PCR (qPCR), and cellular tolerance to high copper concentrations was evaluated using MTT assays. In parallel, HepG2 cells were subjected to the same CRISPR/Cas9 editing procedure, and individual clones were analysed by Sanger sequencing.
Results: In HEK293 cells, RNA-based CRISPR/Cas9 editing generated several ATP7B knockout (KO) clones with distinct homozygous and heterozygous insertions and deletions, as shown by Sanger sequencing. Reduced ATP7B expression in these clones was confirmed by WB and qPCR analysis. MTT assays indicated a functional impact on the cellular response to high Cu concentrations. In HepG2 cells, Sanger sequencing identified a first ATP7B KO clone.
Conclusion: This study demonstrates that RNA-based CRISPR/Cas9 molecules target and cleave the H1069Q-specific locus in ATP7B, leading to diverse ATP7B KOs. ATP7B loss was supported by concordant reductions in ATP7B expression by WB and qPCR. MTT assays revealed metabolic effects of Cu sensitivity in HEK293 KO clones, indicating a functional alteration of ATP7B. This RNA-based approach provides a proof of principle in terms of CRISPR/Cas9-mediated genetic modification in ATP7B. In future experiments, these molecules will also be applied to WD-specific iPSCs in combination with previously validated repair template molecules.

WED-308
New mouse strains recapitulating biliary atresia and Alagille syndrome-associated variants of JAGGED1 reveal a dual role of Jagged1 in liver development and biliatresone-induced injury response

Anna Maria Frontino[1], Daniel V. Oliveira[1,2], Mitra Tavakoli[3], Oren Gozlan[4], Eliška Trampotová[1], Kristyna Neffeova[5], Noémi K. M. Van Hul[6], Emma Andersson[6], Gabriela Pavlinková[3], Hana Kolesova[5], David Sprinzak[4], Jan Mašek[1,2]. Email: jan.masek@natur.cuni.cz

Background and aims: Therapeutic solutions for disorders with complex genetic/environmental etiology, such as biliary atresia (BA)—the most common pediatric cholangiopathy—are hindered by the lack of suitable animal models. While *JAGGED1*(*JAG1*)|*NOTCH2* loss-of-function variants are the major driver of Alagille syndrome (ALGS), several distinct JAG1 missense variants have also been identified in BA, suggesting that JAG1 may exert context- or cell-type-specific effects during liver development. This study aimed to determine how human disease-associated Jag1 variants affect development of mouse liver, extrahepatic bile duct (EHBD), and their responses to injury.
Method: We recapitulated JAG1 variants associated with ALGS (R1097W (RW)) and BA (R1213Q (RQ)) in mice using CRISPR/Cas9. Notch activity luciferase reporter *assays* using mouse and human cells were used to measure the activity of JAG1 variants. Developing liver, heart and inner ear of the control and mutant mice were assessed using immunohistochemistry. To study biliary injury responses, postnatal day 1 (P1) C57BL/6J mice were administered biliatresone (70 μg/pup), and bulk RNA transcriptomic analyses of the EHBDs were performed at P10 (n = 3 for each treatment and genotype).
Results: While neonatal *Jag1*$^{RW/RW}$ mice manifested transient cardiac defects, hepatic artery loss, and bile duct disorganization, the *Jag1*$^{RQ/RQ}$ mice bile ducts were largely unaffected, with pronounced periportal arterial hyperplasia, indicating distinctly disrupted biliary–vascular development. Interestingly, the differently expressed genes (DEGs) in EHBD of WT mice treated with biliatresone showed little overlap with transcriptomic changes observed in BA liver biopsies, or RRV- and BDL-induced EHBD injury (1 up-/9 down-regulated, 10 up-/18 down-regulated, respectively). The overlap was low also for the EHBDs of biliatresone-treated *Jag1*$^{RW/RW}$ pups (0 up/12 down, 0 up/1 down, respectively), but much higher when compared with *Jag1*$^{RQ/RQ}$ mice (26 up/57 down, 3 up/28 down, respectively), indicating disrupted integrin and Akt signaling. Of note, neither the transcriptomics nor *in vitro* reporter assays indicated a disrupted Notch activity.
Conclusion: These findings demonstrate that Jag1 variants associated with distinct pediatric cholangiopathies differentially instruct liver development and EHBD injury responses. The results advance our understanding of Jag1's role in disease pathogenesis, potentially through mechanisms that are independent of canonical Notch signaling.

WED-313
Spatially resolved transcriptomics identifies disease-specific hepatic microenvironments in Fontan-associated liver disease

Yukie Nakadai[1], Nobuhito Taniki[1], Shuhei Tanemura[1], Junko Kuramoto[1], Naofumi Sumitomo[1], Masaaki Kodaira[1], Toshiyuki Yamagishi[1], Ryosuke Kasuga[1], Makoto Ueno[1], Tabuchi Takaya[1], Haruka Okada[1], Usui Shingo[1], Keisuke Ojiro[1], Takanori Kanai[1], Nobuhiro Nakamoto[1]. [1]*Keio University, Tokyo, Japan*
Email: yukie-t.1223@keio.jp

Background and aims: Fontan-associated liver disease (FALD) is a late complication after the Fontan procedure and is characterized by progressive hepatic fibrosis and an increased risk of hepatocellular carcinoma. However, the molecular mechanisms underlying disease progression remain poorly understood. We aimed to investigate its spatial molecular landscape using high-resolution spatial transcriptomic analysis (Visium HD) of human liver tissue.
Method: We enrolled 70 patients who had undergone the Fontan procedure at our institution. Among them, patients were clinically classified as high risk for FALD based on age and laboratory abnormalities. Of those patients considered to be at high risk, liver biopsy was performed in individuals who provided informed consent (n = 16). Bulk RNA sequencing was conducted using biopsy-derived liver tissue from these FALD patients. As disease controls, liver biopsy samples from 8 patients with chronic hepatitis C who had achieved sustained virologic response were analyzed by bulk RNA sequencing. In addition, for high-resolution spatial transcriptomic analysis, representative cases were selected from both disease groups: FALD patients with mild fibrosis and advanced fibrosis, as well as fibrosis stage–matched HCV-SVR patients. Formalin-fixed paraffin-embedded liver sections from these selected cases were subjected to high-resolution spatial transcriptomic analysis using the Visium HD platform.
Results: Bulk RNA sequencing demonstrated upregulation of genes associated with fibrosis, extracellular matrix organization, and cell adhesion in FALD compared with HCV. In Visium HD analysis, spatial transcriptomic integration guided by histological assessment and zonation-informed analysis identified nine clusters across FALD and HCV liver samples. Central vein–associated hepatocyte clusters in FALD showed disease-specific upregulation of genes including HAMP, CYP1A2, and mitochondrial genes (MT-ND2 and MT-ND3), while hepatocyte clusters in both central and portal regions exhibited widespread downregulation of metabolic pathways. In addition, liver sinusoidal endothelial cell clusters displayed increased expression of IGFBP7.
Conclusion: This study reveals spatially distinct molecular features in FALD, highlighting region-specific gene programs related to hepatocyte dysfunction and the hepatic microenvironment. High-resolution spatial transcriptomic analysis may provide insights into disease-specific mechanisms underlying FALD.

WED-314-YI

Ceruloplasmin is required for hepatocellular- but not macrophage-iron export

Marlene Panzer[1], Benedikt Schaefer[1], Sonja Wagner[1,2], Elke Pertler[1,2], Maria Rosina Troppmair[1], Laura Obholzer[1], Günter Weiss[3], Heribert Talasz[4], Klaus Faserl[4], Bettina Sarg[4], Herbert Tilg[1], Heinz Zoller[1,2]. *[1]Departement of Internal Medicine I, Medical University of Innsbruck, Innsbruck, Austria; [2]Christian Doppler Laboratory for Iron and Phosphate Biology, Medical University of Innsbruck, Innsbruck, Austria; [3]Department of Internal Medicine II, Medical University of Innsbruck, Innsbruck, Austria; [4]Division of Medical Biochemistry, Protein Core Facility, Biocenter, Medical University of Innsbruck, Innsbruck, Austria*
Email: marlene.panzer@i-med.ac.at

Background and aims: Iron homeostasis relies on coordinated iron storage, transport, and recycling. Macrophages recycle iron from senescent red blood cells, a process dependent on efficient iron export. The ferroxidase ceruloplasmin (Cp) is involved in iron export, primarily from hepatocytes. In humans, recessive mutations in the CP gene cause aceruloplasminemia, characterized by iron overload in the liver and brain but not the spleen. This study aims to investigate the function of ceruloplasmin in systemic iron homeostasis, erythropoiesis and iron export from macrophages.
Method: To examine the functional interaction of ceruloplasmin and the iron exporter ferroportin (FPN), ferroportin-floxed mice carrying a macrophage-specific LysM-Cre recombinase ($FPN^{\Delta M/\Delta M}$) were crossed with ceruloplasmin knockout ($CP^{-/-}$) mice. This breeding produced $CP^{-/-}FPN^{\Delta M/\Delta M}$, $FPN^{\Delta M/\Delta M}$, $CP^{-/-}$, and $FPN^{flox/flox}$ as control mice. Female mice at the age of 2 and 9 months were analyzed for alterations in iron homeostasis and erythropoiesis. Tissue iron levels, mRNA expression, blood counts, red cell indices, and plasma iron parameters were assessed. Proteomic analyses were performed on the bone marrow, liver, and spleen, while erythropoiesis was evaluated by flow cytometry of bone marrow cells.
Results: Off all genotypes tested, $CP^{-/-}FPN^{\Delta M/\Delta M}$ mice had the highest liver iron concentrations and the lowest hemoglobin concentrations, which was associated with the lowest TSAT. Serum ferritin concentrations were not different between $CP^{-/-}FPN^{\Delta M/\Delta M}$ and $FPN^{\Delta M/\Delta M}$ mice. Increased spleen iron concentrations were only found in mice lacking FPN in macrophages, regardless of the CP-genotype. These phenotypes were more pronounced in 9-months-old mice, when compared to younger mice. Analysis of red cell precursors in bone marrow by flow cytometry did not show differences between genotypes, but all mice had mild hypochromic microcytic anemia when compared to wild type controls.
Conclusion: Differences in spleen iron concentration confirm that macrophage ferroportin, but not ceruloplasmin is important for iron export from (red-pulp) macrophages in mice. Differences in liver iron suggest that CP has an important function for hepatocellular iron export. The finding that liver iron was highest in $CP^{-/-}FPN^{\Delta M/\Delta M}$ mice could be attributed to iron export defects in hepatocytes and Kupffer cells.

Single-cell and spatial transcriptomics reveal portal vascular remodeling in porto-sinusoidal vascular disorder

Delfina Papinutti[1,2], Sarah Shalaby[3], Genís Campreciós[3], Alexandre Sayadi[4], Carla Fuster[3], Andreea Fodor[3], Alba Díaz[3], Keren Bahar Halpern[1], Juan Carlos García-Pagán[3], Pierre-Emmanuel Rautou[5], Shalev Itzkovitz[1], Virginia Hernández-Gea[3]. *[1]Weizmann Institute of Science, Department of Molecular Cell Biology, Rehovot, Israel; [2]Weizmann Institute, Molecular Cell Biology, Rehovot, Israel; [3]Hospital Clínic de Barcelona, Hepatic Hemodynamic Laboratory, Liver Unit, IDIBAPS (Fundació de Recerca Clínic Barcelona–Institut d'Investigacions Biomèdiques August Pi i Sunyer), Centro de Investigación Biomédica en Red de Enfermedades Hepáticas y Digestivas (CIBEREHD), Barcelona, Spain; [4]Université Paris Cité, Centre de Recherche sur l'Inflammation, INSERM U1149, Service de Pathologie, AP-HP Nord, Hôpital Beaujon, FHU MOSAIC, SIRIC InsiTu, Clichy, France; [5]Université Paris Cité, INSERM, Centre de Recherche sur l'Inflammation (CRI), UMR 1149, Paris, France*
Email: delfina.papinutti@weizmann.ac.il

Background and aims: Porto-sinusoidal vascular disorder (PSVD) is a rare vascular liver disorder characterized by portal hypertension in the absence of cirrhosis with poorly understood pathophysiology. Cellular drivers and the molecular and spatial mechanisms underlying PSVD remain unknown, and no comprehensive single-cell or spatial atlas has been described.
Method: We performed an integrated transcriptomic analysis combining bulk RNA sequencing (n = 76 samples), single-cell RNA sequencing (scRNA-seq; n = 16 samples), and Visium HD spatial transcriptomics (n = 3 liver samples) from human liver tissue. Single-cell data were used to construct a liver atlas and characterize disease-specific transcriptional programs across stromal, endothelial and immune compartments. Ligand–receptor interaction analysis was applied to infer intercellular signaling, and spatial transcriptomics was used to localize PSVD-associated programs within the liver architecture.
Results: PSVD was characterized by changes in endothelial cell states that included elevation of the collagen genes COL15A1 and COL4A1, metabolic–inflammatory stress signatures (FABP4/5), hypoxia-related pathways (FMO2), and B-cell involvement consistent with a stromal- and immune-rich, vessel-centered disease. Gene expression changes were most prominent in portal endothelial cells and resembled fetal signatures that were previously documented in hepatocellular carcinoma vessels. Ligand–receptor analysis identified enhanced collagen–integrin signaling from stromal to endothelial cells and increased Notch–Delta interactions at endothelial–perivascular interfaces, supporting active fibrovascular crosstalk. Spatial transcriptomics localized PSVD programs to discrete periportal and perivascular regions enriched for TIMP3 and IGFBP7, consistent with a mechanically remodeled vascular niche and chronically stressed endothelium. The patchy spatial distribution supports a vascular-triggered process with localized remodeling rather than diffuse parenchymal injury.
Conclusion: This study provides an integrated bulk, single-cell and spatial transcriptomic characterization of PSVD, highlighting altered endothelial cell states and pathways that may inform future diagnosis and targeted therapeutic strategies.

WED-316-YI

Targeting copper overload in Wilson disease – silencing ion transporter in the liver holds therapeutic potential for copper detoxification

Martha-Julia Sasula[1], Andree Zibert[2], Marcin Krawczyk[3], Hartmut Schmidt[3], Ruth Broering[3]. *[1]University Duisburg-Essen, Dept. of Gastroenterology, Hepatology and Transplantation Medicine, Essen, Germany; [2]Department of Internal Medicine B, University Hospital Muenster, Muenster, Germany; [3]Dept. of Gastroenterology, Hepatology and Transplantation Medicine, Medical Faculty, University Duisburg-Essen, Essen, Germany*
Email: martha-julia.sasula@uk-essen.de

Background and aims: Wilson disease (WD) is an autosomal recessive disorder caused by mutations in the intracellular copper transporter ATP7B. The functional impairment of ATP7B results in hepatocellular copper accumulation, which ultimately causes impaired cell viability, mitochondrial activity and autophagy that lead to the death of hepatocytes. Herein, the toxic excess of copper in WD cells will be targeted by silencing ion transporters.
Method: A transcriptomic analysis (GSE107323) and qRT-PCR validation of four ion transporters (T1–T4) was conducted in HepG2 wild-type (WT) and ATP7B-knockout (KO) cells, and in primary human hepatocytes from control and WD patients. The effects of siRNAs targeting ion transporters were evaluated for

pathophysiological improvements were evaluated using live/dead staining, CCK8 and MTT assays, as well as gene expression of copper-regulated metallothioneins (MT).
Results: Expression of selected ion transporters was copper-sensitive in HepG2 ATP7B-KO as well as in primary human hepatocytes. Silencing of T1 in HepG2 ATP7B-KO cells resulted in a significant reduction in copper toxicity by increased cell proliferation, improved cell- and mitochondrial viability, and downregulation of MT expression. Live/dead staining confirmed protective effects of T1 silencing. Conversely, the silencing of the remaining three transporters resulted in a comparatively less pronounced reduction in copper toxicity. Gene silencing led to a partial enhancement of cell and mitochondrial viability (T2) or a reduction in MT expression (T3 and T4).
Conclusion: T1 represents a most promising candidate for siRNA treatment in patients. Silencing of all four transporters will be investigated in personalised, induced pluripotent stem cells from WD patients with different ATP7B mutations in order to find new therapeutic applications.

WED-317

Challenges in the care of rare vascular liver diseases: insights from patients, health care providers, and patient organizations

Email: mguilabert@umh.es

Background and aims: Patients with rare vascular liver diseases (VLDs), including non-cirrhotic portal vein thrombosis and Budd–Chiari syndrome, may develop severe complications from an early age. Yet, little is known about their healthcare experiences and unmet needs. This study aimed to identify key challenges and needs in the care of patients with VLDs across four European countries.
Method: Semi-structured interviews were conducted with patients, members of patient advocacy organizations (PAOs), and healthcare providers (HCPs) from France, Spain, Switzerland, and the Netherlands. A standardized interview guide explored challenges and unmet needs in healthcare. Using thematic analysis, themes were first identified at the national level and subsequently synthesized internationally.
Results: Thirty-seven individuals participated: 13 patients, 7 PAO representatives, and 17 HCPs. Six core challenges and needs were identified across countries: (1) diagnostic wandering, sometimes due to insufficiently targeted imaging requests and limited radiologic experience, highlighting the need for greater VLD awareness in medical education; (2) challenges in communicating the diagnosis given the complexity and severity of the disease, suggesting the need to improve diagnosis delivery, notably through separate clinical visits and the use of visual aids; (3) scientific uncertainty regarding the etiology, progression, and treatment of VLDs, leading to difficulties for HCPs in risk interpretation and for patients in understanding and managing their condition, emphasizing the importance of addressing medical uncertainty explicitly in physician–patient communication; (4) challenges in care coordination, particularly for patients with associated diseases or comorbidities, pointing to the need for improved coordination, notably by strengthening the role of coordinating nurses; (5) insufficient supportive care, particularly in addressing mental health issues and fatigue; and (6) management of reproductive and sexual health, requiring tailored communication strategies. Empowering patients, through peer exchange, PAOs, and caregiver involvement, was considered essential to help them manage the disease and its broader impact on their lives.
Conclusion: This study highlights perceived cross-country challenges in the care of patients with rare VLDs, underscoring the need for targeted interventions in communication and care coordination to improve their healthcare experience and outcomes.

WED-318

Small molecule approach for increasing biliary phospholipid secretion in a mouse model for MDR3 deficiency (progressive familial intrahepatic cholestasis type 3)

Henkjan J. Verkade[1], Hilde de Vries[1], Willemien Hof[1], Niels Mulder[1], Milaine Hovingh[1], Rick Havinga[1], Eric Bell[2], Nathan Fuller[2], Robert Hughes[2], Folkert Kuipers[3], Jan Freark de Boer[1]. *[1]University Medical Center Groningen (UMCG), Groningen, Netherlands; [2]Rectify Pharmaceuticals, Boston, United States; [3]University of Groningen, European Research Institute for the Biology of Ageing (ERIBA), Groningen, Netherlands*
Email: h.j.verkade@umcg.nl

Background and aims: Progressive Familial Intrahepatic Cholestasis Type 3 (PFIC3) is a severe liver disease caused by mutations in *ABCB4*, encoding the biliary phospholipid transporter MDR3 in humans and MDR2 in mice. PFIC3 patients have impaired MDR3 function, leading to reduced phospholipid secretion into bile and unshielded detergent activity of biliary bile acids. Consequently, PFIC3 patients have progressive damage of the biliary system. Recently, a novel potent dual-acting MDR3/BSEP positive functional modulator has been discovered. RTY-694 increases protein function of both MDR3 and BSEP *in vitro*. We evaluated whether RTY-694 can rescue phospholipid secretion in a PFIC3 mouse model with residual phospholipid transport function (*Abcb4*$^{+/-}$ mice).
Method: We treated *Abcb4*$^{+/-}$ mice twice daily with vehicle, 30 or 60 mg/kg RTY-694 via oral gavage. Vehicle-treated WT mice served as the reference group. After 14 days all mice underwent common bile duct ligation and catherters were placed into the gallbladder and the jugular vein. Bile samples were collected under basal conditions and during IV infusion of tauroursodeoxycholic acid (TUDCA), after which bile flow and composition were determined.

Results: Treatment with RTY-694 did not affect food intake, body-weight or liver weight. Under basal conditions, bile flow was similar in all *Abcb4*$^{+/-}$ groups, as were the biliary secretion rates of bile acids and cholesterol. As expected, biliary phospholipid secretion rate was 50% reduced in untreated *Abcb4*$^{+/-}$ mice compared to WT mice. Treatment with RTY-694, however, significantly increased biliary phospholipid secretion at baseline and during stimulation by TUDCA infusion in these mice, by 35% and 22% compared to untreated *Abcb4*$^{+/-}$ mice, resp. ($p < 0.01$ ans <0.05).
Conclusion: RTY-694 increases biliary phospholipid secretion in a PFIC3 mouse model with residual phospholipid transport function. The present results strongly support the development of positive functional modulators for the treatment of PFIC3 patients.

WED-319-YI
Spatiotemporal profiling reveals the role of the microenvironment in polycystic liver disease progression
Scott Waddell[1], Elizabeth Carmichael[1], Mairi Hodge[1], Andreea Gradinaru[1], Melissa Boerrigter[2], Joost PH Drenth[3], Luke Boulter[1]. *[1]Institute of Genetics & Cancer, University of Edinburgh, Edinburgh, United Kingdom; [2]Radboud University Medical Center, Nijmegen, Netherlands; [3]Amsterdam University Medical Center, Amsterdam, Netherlands*
Email: scott.waddell@ed.ac.uk

Background and aims: Polycystic liver disease (PLD) is a relatively common genetic disorder that typically presents in midlife and is associated with severe pain/discomfort and a marked reduction in quality of life. There are currently no approved pharmacological therapies for PLD, and despite predictable Mendelian inheritance of disease-causing alleles (most commonly *PKD1*), preventative approaches are lacking. PLD cysts arise from biliary epithelial cells (BECs) and increase in number and size throughout life. The cellular and tissue-level changes that drive disease initiation and progression early in life remain poorly understood. Elucidating the molecular pathogenesis of PLD is essential to identify new therapeutic strategies. Here, we aimed to model and characterise the spatial and temporal dynamics underlying PLD development to uncover potential therapeutic targets.
Method: We generated a murine model with liver-specific deletion of *Pkd1* (Alfp-Cre; *Pkd1*). Mice were analysed from birth to six months of age using single-nuclear RNA sequencing and immunohistochemistry. To define the spatial organisation of the cyst microenvironment, human PLD liver samples with distinct genetic mutations were analysed using spatial transcriptomics and immunophenotyping.
Results: Spatial analysis of human PLD tissue revealed that CD4$^+$ memory T cells are the most abundant immune population within the cyst microenvironment in established disease. BECs displayed marked heterogeneity, forming NCAM$^-$ cystic epithelia and NCAM$^+$ ductular reactions. Notably, T cells were spatially associated with NCAM$^+$ ductular reactions rather than NCAM$^-$ cystic BECs, suggesting that mature cysts do not actively recruit immune cells. In Alfp-Cre; *Pkd1* mice, bile duct dilation was evident at birth and progressed in number and size into adulthood, recapitulating PLD. Single-nuclear RNA sequencing and immunohistochemistry of ~2 million cells across disease progression revealed dynamic recruitment and turnover of diverse immune populations, including multiple T cell subsets, consistent with human PLD. PLD mouse livers further mirrored human disease by harbouring NCAM1$^+$ BECs in close proximity to CD4$^+$ T cells.
Conclusion: PLD is a slowly progressive disease characterised by evolving spatiotemporal interactions among multiple cell types within the cyst microenvironment. While cystic BECs do not directly recruit immune cells, CD4$^+$ T cells preferentially localise near NCAM1$^+$ BECs, implicating this interaction in driving inflammation during PLD progression.

WED-320-YI
Multi-ancestry genome-wide association meta-analysis identifies novel susceptibility loci for biliary atresia
Zijing Yang[1], Shaowen Liu[1], Pak Chung Sham[1], Kenneth Ky Wong[1], Paul Kwong-Hang Tam[1,2], Clara Sze-man Tang[1]. *[1]The University of Hong Kong, Hong Kong SAR, China; [2]Macau University of Science and Technology, Macao SAR, China*
Email: u3012177@connect.hku.hk

Background and aims: Biliary atresia (BA) is a congenital disease characterized by inflammation and obstruction of the extrahepatic and intrahepatic bile ducts. BA has a higher disease prevalence among East Asians (1:5000 to 1:9000) than Europeans (1:14,000 to 1:22,000), suggesting a genetic predisposition across different populations. In this study, we aim to identify shared and/or ancestry-specific loci for BA across populations.
Method: We performed a multi-ancestry meta-analysis of genome-wide association studies including 1481 BA cases and 6372 controls of East Asian and European ancestry. To prioritize putative causal variants and effector genes, we integrated cross-population fine-mapping, regulatory annotation, colocalization analyses, and published single-cell transcriptomic datasets.
Results: In addition to the known *ADD3* locus, we identified two novel genome-wide significant loci at 1p21 and 12q23. At 1p21, the serum gamma-glutamyl transferase level and BA share the same causal variants, which were mapped to a cytoskeleton gene highly expressed in hepatoblast to fetal cholangiocyte lineage. The risk allele of the lead SNP was associated with reduced expression of the mapped gene in cholangiocytes, but not hepatocytes, suggesting a role of genetic dysregulation in cytoskeleton remodeling during cholangiocyte development in BA patients.
Conclusion: We identified a potential susceptibility locus at 1p21.2 for BA. Further experiments are required to elucidate the roles of cytoskeleton remodeling during the differentiation of hepatocytes and cholangiocytes. The target gene at 12q23.2 and its role in the pathogenesis of BA remain to be determined.

Evaluation of HEV burden and urine antigen diagnostic utility in the DZIF transplant cohort
Nora Proske[1,2], Katja Dinkelborg[1,2], Tanja Klause[1], Christine Wundes[1], Birgit Bremer[2], Benjamin Maasoumy[2,3], Heiner Wedemeyer[2,3], Lisa Sandmann[2,3], Patrick Behrendt[1,2,3]. *[1]TWINCORE, Centre for Experimental and Clinical Infection Research, Institute for Experimental Virology, Hannover, Germany; [2]Hannover Medical School, Department of Gastroenterology, Hepatology and Endocrinology, Hannover, Germany; [3]German Center for Infection Research (DZIF), Hannover, Germany*
Email: proske.nora@mh-hannover.de

Background and aims: Hepatitis E virus (HEV) is the leading cause of acute viral hepatitis worldwide. While infection is usually self-limiting, immunocompromised individuals, particularly stem cell and solid organ transplant recipients, are at risk of chronic HEV infection, which may lead to progressive liver disease and is frequently underdiagnosed. Reported prevalence estimates in European transplant cohorts vary substantially. This study aimed to determine the prevalence and burden of HEV infection in a large multicenter transplant cohort and to evaluate urine-based HEV antigen detection as a diagnostic approach.
Method: Plasma and urine samples were collected from 1066 transplant recipients at four German transplant centers. Plasma

samples were obtained at transplantation and at follow-up, in the mean 22 months post-transplantation (range 3–60 months), while urine samples were collected at follow-up. Samples were tested for anti-HEV IgG, HEV RNA, and, in a subset, anti-HEV IgM. Additionally, 1041 urine samples were analyzed for HEV antigen.
Results: Anti-HEV IgG seroprevalence was 35.7% at baseline and 34.3% at follow-up. Seroconversion occurred in 9.1% of patients, whereas 20.1% lost detectable IgG antibodies, resulting in an IgG persistence of 79.9%. HEV RNA was detected in 15 of 1060 follow-up plasma samples (1.4%). HEV antigen was identified in 19 of 1041 urine samples (1.8%). Among patients with paired samples, urine antigen testing confirmed eight HEV RNA–positive cases, while samples with very low viral loads remained antigen-negative. Conversely, 11 urine samples were antigen-positive despite RNA-negative plasma results. Notably, HEV infection at follow-up was observed in several patients with baseline anti-HEV IgG positivity.
Conclusion: This multicenter cohort study demonstrates a substantial loss of anti-HEV IgG antibodies after transplantation and identifies ongoing HEV infections despite preexisting seropositivity. Urine-based HEV antigen testing may represent a complementary screening tool, while it is less sensitive in cases of low HEV RNA, it might be more sensitive in detecting recent HEV infection.

FRI-637
Comparison of foetal and maternal outcomes of hepatitis E in pregnant versus non pregnant women
Faiza Sadaqat Ali[1], Bader Faiyaz Zuberi[2], Erum Majid[3], Amanullah Abbasi[4], Tazeen Rasheed[4]. [1]*Karachi Metropolitan University, Dow University of Health Sciences, Karachi, Pakistan;* [2]*OMI hospital, Karachi, Pakistan;* [3]*Jinnah Postgraduate Medical Centre, Karachi, Pakistan, Karachi, Pakistan;* [4]*Dow University of Health Sciences, Karachi, Pakistan*
Email: faiza.sadaqat@duhs.edu.pk

Background and aims: Hepatitis E virus (HEV) is a major cause of acute viral hepatitis in endemic regions, with pregnancy recognized as a vulnerable state. Severe maternal disease and poor foetal outcomes have been reported, yet comparative data with non pregnant women remain limited. This study aimed to determine maternal and foetal outcomes of HEV infection in pregnant women and compare them with non pregnant women.
Method: A prospective observational cohort was conducted at Jinnah Postgraduate Medical Center and Dr Ruth KM Pfau Civil Hospital Karachi between 7 February 2023 and 6 January 2025. Pregnant women presenting with jaundice were enrolled as Group A, while non pregnant women with hepatitis served as controls (Group B). Both groups were stratified by HEV status into Group Ae (pregnant HEV positive), Group Ane (pregnant HEV negative), Group Be (non pregnant HEV positive), and Group Bne (non pregnant HEV negative). HEV diagnosis was confirmed by serology. Demographic, clinical, and laboratory data were collected, and patients were followed for maternal outcomes (improvement or death) and foetal outcomes (alive healthy birth, intrauterine growth restriction, stillbirth, abortion). Statistical analysis used chi square test, with $p < 0.05$ considered significant.
Results: A total of 190 patients were included, equally distributed between pregnant and non pregnant groups (95 each). Mean age was comparable (27.0–27.8 years). Diabetes and hypertension prevalence was similar across groups ($p > 0.05$). Maternal outcomes did not differ significantly between HEV positive and negative cohorts, with mortality rates ranging from 37.8 percent to 46.6 percent. In contrast, foetal outcomes were significantly worse in HEV positive pregnant women. Group Ae had 37.9 percent alive healthy births, 12.1 percent intrauterine growth restriction, 31.0 percent stillbirths, and 18.9 percent abortions. Group Ane showed 67.6 percent alive healthy births, 5.4 percent intrauterine growth restriction, 21.6 percent stillbirths, and 5.4 percent abortions. The difference in foetal outcomes between HEV positive and HEV negative pregnant women was statistically significant ($p = 0.032$). Non pregnant HEV groups showed comparable maternal outcomes but no foetal outcomes.
Conclusion: Hepatitis E in pregnancy leads to significantly poorer foetal outcomes compared to HEV negative women, despite similar maternal results. This underscores pregnancy vulnerability and the need for prevention, early diagnosis, and close monitoring in endemic regions.

FRI-638
FIB-4 fails to identify significant liver fibrosis in people with HIV: evidence from a large multinational screening study

Email: giada.sebastiani@mcgill.ca

Background and aims: Steatotic liver disease (SLD) and liver fibrosis are major comorbidities in people with HIV (PWH). Guidelines recommend stepwise screening using the Fibrosis-4 (FIB-4) index followed by transient elastography (TE), yet its accuracy in PWH and the magnitude of FIB-4 misclassification are uncertain. We aimed to evaluate the diagnostic performance of FIB-4 against TE, quantify missed significant fibrosis cases, and assess whether adding metabolic and HIV-related factors improves risk prediction.
Method: We conducted a multinational cross-sectional study of 4917 consecutive PWH without viral hepatitis coinfection or hazardous alcohol intake from seven prospective cohorts undergoing TE-based liver health screening. SLD was defined as controlled attenuation parameter (CAP) ≥275 dB/m and classified as metabolic dysfunction–associated SLD (MASLD) or metabolic dysfunction–associated alcohol-related liver disease (MetALD). We compared FIB-4 <1.3 against liver stiffness measurement (LSM) ≥8 kPa using the area under the receiver operating characteristic curve (AUROC), identified determinants of false-negative misclassification, and evaluated the incremental value of metabolic and HIV-related predictors using discrimination and reclassification metrics.
Results: Significant fibrosis was present in 12.6% and SLD in 21.7% (20.6% MASLD; 1.1% MetALD), with higher prevalence in PWH with MASLD (25%) and MetALD (26.9%) than in those without SLD (8.6%; $p < 0.001$). 13% of fibrosis cases occurred without SLD or metabolic comorbidities. FIB-4 showed modest accuracy (AUROC 0.635, 95% CI 0.61–0.66) and misclassified 36% of LSM ≥8 kPa cases as low-risk, with poorer performance in MASLD (AUROC 0.579) compared to non-MASLD (AUROC 0.68; DeLong $p = 1.3 \times 10^{-5}$). Steatosis independently increased false-negative misclassification (risk ratio 2.01, 95% CI 1.50–2.69), whereas prior D-drug exposure reduced it (risk ratio 0.63, 95%

CI 0.44–0.91). Models incorporating metabolic factors (diabetes, SLD, dyslipidemia, hypertension, and waist circumference) improved discrimination and enhanced patient reclassification by 27% beyond FIB-4 alone, with a further 12% improvement after adding HIV-specific variables (CD4 count, HIV viral load, CD4/CD8 ratio, and prior D-drugs exposure).
Conclusion: In PWH, liver fibrosis is common and frequently missed by FIB-4-based screening, particularly in MASLD. TE-centered pathways augmented by metabolic and HIV-specific risk indicators may improve early detection and liver health management in PWH.

FRI-639
Hepatitis E seroprevalence is significantly elevated in lymphoma patients: exploring causal association or epiphenomenon
Jan Drews[1], Johannes Bannasch[1], Julia Dierlamm[1], Katja Weisel[2], Marc Luetgehetmann[3], Maria Mader[4], Samuel Huber[1], Ansgar W. Lohse[1], Julian Schulze zur Wiesch[1], Sven Pischke[1].
[1]I. Department of Medicine, University Medical Centre Hamburg-Eppendorf, Hamburg, Germany; [2]II. Department of Medicine, University Medical Centre Hamburg-Eppendorf, Hamburg, Germany; [3]Institute of Medical Microbiology, Virology and Hygiene, University Medical Centre Hamburg-Eppendorf, Hamburg, Germany; [4]III. Department of Medicine, University Medical Centre Hamburg-Eppendorf, Hamburg, Germany
Email: jdrews9247@googlemail.com

Background and aims: Hepatitis E virus (HEV) infection is associated with diverse extrahepatic manifestations including immunological abnormalities and blood count changes. A single case report suggested a potential causal link between HEV and T-cell lymphoma development, but the prevalence and significance of HEV infection in lymphoma patients remain unknown. This study investigates whether HEV exposure is enriched in lymphoma populations and whether it represents a potential pathogenic cofactor or merely an epiphenomenon.
Method: We retrospectively tested 117 lymphoma patients for HEV exposure using anti-HEV serology (IgM and IgG by Wantai enzyme immunoassay) and HEV-RNA polymerase chain reaction (Altona Diagnostics). A cohort of 1000 unselected blood donors served as controls. Positive sera were confirmed by immunoblot (Mikrogen). We extracted transfusion history from medical records to exclude passive antibody acquisition as a confounding variable.
Results: Anti-HEV IgG seropositivity was significantly elevated in lymphoma patients at 27% (n = 32/117) compared to 17% in healthy controls (p = 0.01), representing a 59% relative increase in seroprevalence. Immunoblot confirmation reduced confirmed seropositivity to 24/117 (20.5%) in lymphoma patients. Anti-HEV IgM positivity was similar between groups (2% in both). The distribution of anti-HEV IgG positivity across individual subgroups yielded the following ratio: Indolent B-cell: 7/23 (30%), aggressive B-cell 19/68 (28%), indolent T-cell 3/11 (27%), aggressive T-cell 2/8 (25%), Hodgkin 1/6 (17%), unclassified 0/1 (0%). HEV-RNA was undetectable by polymerase chain reaction in all subjects, excluding active viremia. IgG-positive and IgG-negative lymphoma patients showed no significant differences in gender distribution, age, lymphoma subtype, total immunoglobulin G levels, or transfusion exposure (mean 18 versus 23 blood products; p = not significant).
Conclusion: Hepatitis E seropositivity in lymphoma patients substantially exceeds population baseline without clear explanation by confounding variables. The absence of active viremia, similar transfusion burden, and identical immunological profiles between seropositive and seronegative patients argue against passive acquisition or acute infection. These findings warrant mechanistic investigation to determine whether prior HEV exposure represents a causative contributor to lymphomagenesis or a marker of altered immune surveillance.

Email: davidaguirre14@gmail.com

Background and aims: Hepatitis A virus (HAV) causing autoimmune hepatitis (AIH) has been previously reported but its incidence, prevalence, and natural history are largely unknown. We aim to describe a subgroup of patients with biopsy-proven AIH among a cohort of patients with acute hepatitis A infection (aHAV) and compare them to patients with aHAV that completely resolved.
Method: Multicenter, case-control study of patients diagnosed with AIH several weeks after a confirmed aHAV. AIH was suspected in patients with prolonged liver chemistry elevations (≥3 months with intermittent elevation of >1000 U/L of ALT or constant elevation of ALT), hyperglobulinemia, positive autoimmune serologies and confirmed with a liver biopsy. Cases were matched (3:1) to controls with aHAV that underwent complete resolution (defined by ALT normalization) three months after diagnosis.
Results: Of 558 patients with aHAV, 24 (4.3%) were diagnosed with biopsy-proven AIH. All patients had positive ANA titers (median 1:160) and 14 had positive ASMA titers (median 1:160). Median IgG levels were 2230 g/dL. Patients with aHAV-associated AIH had higher bilirubin levels, more likely presented with diarrhea and were hospitalized more frequently. Median time to aHAV-associated AIH LC peak was 83 days. In aHAV-associated AIH, LC showed intermittent elevations of ALT in 18, and constant elevations in 6 patients. All cases of AIH received prednisone for a median duration of 66 days (36–708), and 14 also received AZA or MMF. Of the 24 patients, 22 completely normalized ALT with no further treatment. When compared to controls, no differences in initial liver chemistries were found (ALT: 2251 vs. 2418, p = 0.78, AST 1629 vs. 1881).
Conclusion: aHAV-associated AIH is rare and requires a high degree of suspicion. Most patients have prolonged illness with intermittent ALT elevations yet a favorable clinical course and excellent response to short-term immunosuppression.

Email: garn.jonathan@mh-hannover.de

Background and aims: Hepatitis E virus (HEV) is the most common cause of acute viral hepatitis worldwide. While infection is usually self-limiting in immunocompetent individuals, immunocompromised patients are at risk of developing chronic HEV infection. The main immunogenic HEV antigen is the capsid protein (pORF2), which occurs in two forms: the pORF2c protein forms the infectious virion and the secreted, glycosylated form pORF2s, which is believed to act as an immune decoy.
The mechanisms underlying HEV chronification are not fully understood. The aim of this study was to identify clinical and serological factors associated with chronicity in order to enable earlier prediction of viral persistence and timely initiation of antiviral therapy, ultimately improving clinical outcomes.
Method: 277 longitudinal serum samples were collected from 77 patients with acute or chronic HEV infection. Samples were tested for HEV-RNA and pORF2c using an in-house ELISA that specifically detects the infectious pORF2c. Moreover, HEV-RNA polymerase sequencing was performed to assess viral population composition during acute and chronic infection. Anti-HEV IgG was quantified using ELISA and antibody functionality was assessed by neutralization assays and avidity ELISA.
Results: Tacrolimus-based immunosuppressive therapy following solid organ transplantation was identified as the main clinical risk factor driving HEV chronification. Patients with chronic HEV infection displayed higher HEV-RNA levels and significantly elevated pORF2c levels, which correlated with viral RNA concentrations. Interestingly, all patients with an pORF2c signal-to-cut-off ratio exceeding 10 at the initial sampling time point were affected by chronic infection. HEV populations were more heterogenous during chronic infection and associated with certain amino acid variants. Anti-HEV IgG levels and neutralizing capacity were reduced in chronic infection. In contrast to acute infection, antibody avidity remained persistently low in chronic patients.
Conclusion: Elevated pORF2c levels are associated with development of HEV chronicity. The in-house ELISA enables specific detection of infectious viral particles, which can be used as an early predictive biomarker for chronification. Together with assessment of the adaptive humoral immune response, this approach may allow earlier identification of patients at risk for viral persistence and guide timely initiation of antiviral therapy.

Impact of sex and age on acute hepatitis E: comparable exposure but male predominance of symptomatic disease and age-dependent mortality

Sven Pischke[1], Lara Erichsen[1], Susanne Polywka[1], Marcus Altfeld[1], Marylyn Addo[1], Marc Lutgehetmann[1], Julian Schulze zur Wiesch[1].
[1]University Hospital Hamburg Eppendorf, Hamburg, Germany
Email: s.pischke@uke.de

Background and aims: Sex and age are fixed host characteristics, but their role in hepatitis E virus (HEV) infection dynamics remains unclear. This study investigated (1) the influence of sex and age on HEV exposure in a healthy population and (2) their impact on clinical presentation and outcomes of acute hepatitis E in immunocompetent individuals in a HEV genotype 3–endemic region.
Method: The analysis consisted of two steps: HEV exposure: Anti-HEV IgG was determined using the Wantai assay in 1000 healthy blood donors (50% male, 50% female). Clinical course: Sex- and age-related differences were assessed retrospectively in 148 consecutive immunocompetent patients with PCR-confirmed (Cobas PCR, Roche) acute hepatitis E.
Results: Anti-HEV IgG was detected in 17% of blood donors (19% of men, 15% of women; p = n.s.), indicating no sex difference in HEV exposure. Donor ALT levels and age did not differ significantly between sexes (mean age 35 years, range 18–73). Hepatitis E patients were significantly older than blood donors (mean age 53 years, $p < 0.001$) and predominantly male (69% male vs 31% female, p = 0.002). Mean age did not differ between male and female patients (52 vs 56 years). Six patients (4%; 3 men, 3 women) died from acute-on-chronic liver failure; fatal cases were significantly older than survivors (mean 67 years, p = 0.01). Extrahepatic manifestations were observed in 10 patients (7%; 6 men, 4 women).
Conclusion: In an HEV genotype 3–endemic region, men and women exhibit similar lifetime HEV exposure, yet men constitute the majority of symptomatic, immunocompetent acute hepatitis E cases. Advanced age—but not sex—was the key predictor of fatal outcomes. These findings suggest biological or behavioral sex-related differences in clinical disease manifestation rather than in viral exposure risk.

FRI-643

Cross-kingdom gut microbiome signatures associate with clinical severity in hepatitis A-associated acute liver failure

Anoushka Saxena[1], Rakhi Maiwall[1], Dr Babu Lal Meena[1], Varun Suroliya[1], Guresh Kumar[1], Shiv Kumar Sarin[1], Nirupma Trehanpati[1]. *[1]Institute of Liver & Biliary Sciences, New Delhi, India*
Email: trehanpati@gmail.com

Background and aims: Hepatitis A-induced acute liver failure (ALF-A) is associated with high short-term mortality. As gut microbial perturbations may capture systemic derangements, we aimed to define integrated bacterial–fungal alterations in ALF-A patients, and explore any correlations with clinical severity.
Method: Stool samples of IgM HAV positive, ALF-A patients (n = 33, age 26 ± 9 yrs;50.7% male) age and sex matched acute viral hepatitis AVH-A (n = 27) and healthy subjects (HC,n = 20) were collected within 48 h of admission and subjected to paired 16S rRNA and Internal Transcribed Spacer (ITS) sequencing. Differential taxa were identified and correlated with clinical severity parameters like MELD, ammonia, INR and lactate. Cross-kingdom association networks were constructed using Spearman correlations ($|r|>0.5$) and co-occurrence analysis (Jaccard$\geq$0.4; co-presence $\geq$3 samples).
Results: ALF-A exhibited fungal dysbiosis with reduced diversity and significantly lower Basidiomycota: Ascomycota ratio, compared to AVH-A and HC. AVH-A showed enrichment of *Saccharomyces cerevisiae* and *Ascobolus* spp., whereas ALF-A was enriched for *Trichoderma longibrachiatum*, *Penicillium sublateritium*, *Cladosporium*, *Torula* with reported proteolytic, acidogenic and secondary-metabolite biosynthetic potential. Selected ALF-A enriched fungi correlated positively with MELD, ammonia and lactate levels ($r = 0.40–0.83$, $p < 0.05$). In parallel, ALF-A bacterial dysbiosis was characterized by enrichment of lactate and hyperammonemia-associated pathobionts (*Enterococcus*,*Ruminococcus gnavus*,*Hungatella hathewayi)* with depletion of commensal SCFA-associated genera (*Faecalibacterium*,*Roseburia*,*Agathobaculum*

butyriciproducens) compared with AVH-A. ALF-A–enriched bacteria were also correlated with MELD, ammonia, INR and lactate ($r > 0.50$, $p < 0.05$). Integrated correlation and co-occurrence networks consistently linked *Enterococcus-R. gnavus-Hungatella* bacterial core with *Trichoderma-Cladosporium-Torula-Penicillium*, indicating cross-kingdom microbial signature aligned with clinical severity in HAV-ALF.

Conclusion: In ALF-A, stool profiling identifies cross-kingdom dysbiosis. Bacterial shifts consistent with a lactate/ammonia-rich milieu may favor fungal expansion, while fungal proteolytic and acidogenic properties further altering pH, mucus integrity and bacterial community structure. Together, these bi-kingdom signatures can serve as adjunct severity markers.

FRI-644

Porcine-derived pancreatic enzyme replacement therapy as a cause of hepatitis E virus infection

Siddharth Sridhar[1], Cyril CY Yip[1], Xiaodan Ma[1], Jianwen Situ[1], Yonghao Liang[1], Nicholas Foo-Siong Chew[1], Xizhu Wang[1], Stanley Siu Fung Ho[1], Esmond Ng[1]. [1]*The University of Hong Kong, Pok Fu Lam, Hong Kong*
Email: sid8998@hku.hk

Background and aims: Hepatitis E virus (HEV) is an important cause of hepatitis which is usually acquired via consumption of undercooked pork products. Recently, porcine-derived pancreatic enzyme replacement therapy (PERT) has been proposed as a cause of HEV infection in cystic fibrosis patients after lung transplantation. We investigated PERT as a source of HEV infection in immunocompromised persons and the general population using a clinical study and advanced disease models.

Method: PERT capsules/tablets from different manufacturers were sourced for HEV RNA detection by two independent real-time RT-PCR (qRT-PCR) assays. Positive PERT products with sufficient virus loads were sequenced using Sanger sequencing. Hepatitis E patients diagnosed at our center since 2017 were retrospectively assessed for PERT intake prior to symptom onset. Immunocompromised gerbils were orally challenged with HEV inocula with virus loads simulating those found in PERT products. Effect of PERT treatment on HEV infectivity in cell culture was assessed.

Results: HEV RNA contamination was pervasive across PERT products from different manufacturers with 36/115 (31.3%) individual capsules/tablets testing positive in both HEV qRT-PCR assays. Positivity rates varied widely by manufacturer. Virus loads ranged from 8.1 copies – 4.61×10^3 copies per capsule. Only 1/92 (1.09%) hepatitis E patients had taken PERT prior to symptom onset. This was an immunocompromised patient with self-limiting acute hepatitis E with no other risk factors for hepatitis E infection. A 124-nucleotide HEV sequence fragment from this patient was 99.2% identical to PERT-derived HEV sequences from certain manufacturers. Cytotoxicity and low virus loads precluded direct assessment of HEV viability in PERT products. However, concomitant treatment with PERT did not inhibit infection of a validated HEV strain *in vitro* showing that the virus can remain viable in this matrix. Immunocompromised gerbils were susceptible to a simulated oral HEV inoculum equivalent to daily exposure from PERT in cystic fibrosis patients.

Conclusion: PERT products are frequently contaminated with HEV RNA. Although low virus loads and questionable viability indicate negligible risk for most users, immunocompromised persons may be at risk for clinically significant hepatitis E infection via this route.

VDAC1-ACSL3-mediated aberrant lipid droplet-mitochondria crosstalk drives metabolic reprogramming and HCC in CHB and MASLD coexistence

Zhe Dai[1], Guangde Zhou[2], Yin Gao[3], Jie Li[4], Ming-Hua Zheng[5], Yijin Wang[1]. [1]*Department of Pharmacology, Joint Laboratory of Guangdong-Hong Kong Universities for Vascular Homeostasis and Diseases, School of Medicine, Southern University of Science and Technology, SUSTech Homeostatic Medicine Institute, School of Medicine, Southern University of Science and Technology, Shenzhen, China;* [2]*Department of Pathology, Beijing YouAn Hospital, Capital Medical University, Department of Pathology, The Second Affiliated Hospital of Southern University of Science and Technology, Beijing, China;* [3]*Department of Biochemistry, Key Laboratory for Molecular Enzymology and Engineering of Ministry of Education, School of Life Sciences, Jilin University, Changchun, China;* [4]*Department of Infectious Disease, Nanjing Drum Tower Hospital, Affiliated Hospital of Medical School, Nanjing University, Nanjing, China;* [5]*MASLD Research Center, Department of Hepatology, the First Affiliated Hospital of Wenzhou Medical University, Key Laboratory of Diagnosis and Treatment for The Development of Chronic Liver Disease in Zhejiang Province, Wenzhou, China*
Email: wangyj3@sustech.edu.cn

Background and aims: The co-occurrence of chronic hepatitis B (CHB) and metabolic dysfunction-associated steatotic liver disease (MASLD) constitutes a "vicious synergy" linked to accelerated fibrosis and hepatocellular carcinoma (HCC). The molecular mechanisms driving this convergence—particularly how metabolic steatosis reshapes the viral liver to drive oncogenesis despite viral suppression—remain undefined.

Method: Spatial transcriptomics was performed on liver biopsies from patients with MASLD, CHB, CHB+MASLD, and controls. A murine CHB+MASLD model was established via HBV hydrodynamic injection combined with high-fat feeding. The mitochondrial-lipid droplet (LD) interactome was mapped by LC-MS/MS. Protein interactions and stability were interrogated using co-immunoprecipitation and site-directed mutagenesis. Tumorigenic potential was evaluated in an orthotopic HCC model using RIL-175 cells expressing wild-type or K365A-mutant ACSL3.

Results: Spatial profiling revealed altered immune and metabolic features in CHB+MASLD patients, characterized by marked mitochondrial dysfunction and enrichment of tumor-associated macrophages (TAMs), even during the immune-tolerant phase. Mechanistically, hepatocytes in this disease context exhibited upregulated expression and oligomerization of the mitochondrial outer membrane protein VDAC1. VDAC1 directly interacted with acyl-CoA synthetase long-chain family member 3 (ACSL3), whose protein stability was enhanced via K365-dependent deubiquitination by USP9X. The resulting VDAC1-ACSL3 complex facilitates aberrant LD-mitochondria tethering, leading to exacerbated oxidative stress, extensive mitochondrial impairment and a metabolic shift toward aerobic glycolysis with elevated lactate production, thereby fueling a procarcinogenic niche. Notably, the ACSL3-K365A mutation disrupted USP9X-dependent deubiquitination, reduced VDAC1-ACSL3 tethering, restored mitochondrial integrity and significantly suppressed orthotopic tumor growth. Furthermore, VDAC1

oligomerization triggered mitochondrial DNA release, activating cGAS-STING signaling and interferon responses that suppressed HBV replication.
Conclusion: We identify VDAC1-ACSL3-mediated LD-mitochondria tethering, regulated by USP9X, as a critical driver of metabolic stress and microenvironment reprogramming in patients with CHB complicated by MASLD. This axis represents a promising therapeutic target to mitigate hepatocarcinogenesis in this growing patient population.

The interferon-inducible protein C19ORF66 suppresses HBV reverse transcription through incorporating into viral nucleocapsid
Sheng Shen[1], Hongyan Liang[1], Ge Zeng[1], Yidan Chen[1], Wanying Liang[1], Jianlu Wang[1], Hu Zhang[2], Haitao Guo[2], Jian Sun[1]. *[1]Department of Infectious Diseases, Nanfang Hospital, Southern Medical University, Guangzhou, China, State Key Laboratory of Multi-organ Injury Prevention and Treatment, Key Laboratory of Infectious Diseases Research in South China, Ministry of Education, Guangdong Provincial Key Laboratory for Prevention and Control of Major Liver Diseases, Guangdong Provincial Clinical Research Center for Viral Hepatitis, Guangdong Institute of Hepatology, Guangdong Provincial Research Center for Liver Fibrosis Engineering and Technology, Guangzhou, China; [2]Department of Microbiology and Molecular Genetics, University of Pittsburgh School of Medicine, Pittsburgh, Pennsylvania, USA, Cancer Virology Program, UPMC Hillman Cancer Center, University of Pittsburgh School of Medicine, Pittsburgh, Pennsylvania, USA, Pennsylvania, United States*
Email: doctorsunjian@qq.com

Background and aims: The host interferon stimulated gene (ISG) C19ORF66 (also known as SHFL or UPF0515) exhibits broad-spectrum antiviral activity against a range of RNA viruses and retroviruses. However, its potential role in inhibiting Hepatitis B Virus (HBV) remains unexplored. This study aims to assess the antiviral effect of C19ORF66 on HBV replication and, if present, to delineate its mechanism of action.
Method: We employed gain-and-loss-of-function approaches in various cell culture models (HepG2, Huh7, and HepG2-NTCP) supporting HBV transfection or infection. A hepatocyte-specific *C19ORF66* knockout (KO) mouse model was generated and used for *in vivo* functional validation. Co-IP, immunofluorescence, RNA immunoprecipitation (RIP), cross-linking immunoprecipitation sequencing (CLIP-seq), and electrophoretic mobility shift assay (EMSA) were used to investigate protein and RNA interactions.
Results: Ectopic expression of C19ORF66 potently inhibited HBV replication without affecting viral RNA transcription, protein expression, or capsid assembly, but specifically blocked viral reverse transcription. Intriguingly, C19ORF66 overexpression altered the profile of encapsidated pgRNA, generating multiple shorter pregenomic RNA (pgRNA) species. Conversely, C19ORF66 knockdown/knockout enhanced HBV DNA synthesis and increased encapsidated pgRNA levels. The basal level of C19ORF66 expression was detected in hepatocytes, and its expression was further induced by IFN-α/γ/λ in vitro, and knockdown of C19ORF66 partially abrogated IFN's anti-HBV effect. In IFN-treated chronic HBV patients, higher intrahepatic C19ORF66 induction correlated with a better treatment response. Mechanistically, C19ORF66 incorporates into the viral nucleocapsid during its assembly via simultaneously binding to HBV polymerase (P) protein and pgRNA, a process dependent on a specific domain of C19ORF66 and a defined *cis*-element on pgRNA identified by CLIP-seq and EMSA. Consequently, the incorporated C19ORF66 aborted HBV reverse transcription.
Conclusion: We identified C19ORF66 as a potent and key executor of the IFN-mediated anti-HBV response. C19ORF66 exerts its inhibitory function by co-packaging with the viral P protein and pgRNA into the nucleocapsid. This unique incorporation mechanistically disrupts reverse transcription, thereby providing a novel mechanism of host-mediated viral restriction.

Discovery and preclinical profiles of a first-in-class potent hepatitis E virus inhibitor AT-587
Qi Huang[1], Dawei Cai[1], Adel Moussa[1], Nancy Agrawal[1], Jean-Pierre Sommadossi[1]. *[1]Atea Pharmaceuticals, Inc, 225 Franklin Street, Suite 2100, Boston, United States*
Email: huang.qi@ateapharma.com

Background and aims: Hepatitis E virus (HEV), the causative agent of hepatitis E, is an important public health concern in many developing countries in Asia and Africa but is also endemic in industrialized countries including the USA. Globally, an estimated 20 million people are newly infected by HEV each year, resulting in >3.3 million cases of hepatitis E and 44,000 HEV-related deaths. Currently, there are no HEV-specific antivirals, and therapeutic options for HEV infection are limited to off-label use of ribavirin (RBV) and pegylated-interferon-α. There is an urgent need for highly effective drugs for the treatment of HEV infection, which can lead to fulminant hepatitis during pregnancy, neurological sequelae and hepatic failure in transplant patients. We report here on a unique nucleotide prodrug, AT-587, that targets HEV RNA polymerase and exhibits a promising antiviral profile as a first-in-class inhibitor for the treatment of life-threatening HEV infection.
Method: A small library of pre-selected molecules was screened for anti-HEV activity utilizing a luciferase-based HEV replicon and an HEV infection system. The selectivity and specificity of the lead compound was established against other RNA viruses and human polymerases. IND enabling studies such as cytotoxicity, genotoxicity, off-target binding and DMPK were also conducted.
Results: *In vitro* compound screening against HEV in an HEV-3 Kernow-C1 p6/Gluc replicon assay identified AT-587, as a potent inhibitor of HEV replication, with EC_{50} values 86.1 nM, which was independently confirmed in an HEV-1 Sar55 replicon assay. AT-587 is >50-fold more potent against HEV than known nucleos(t)ide inhibitors such as sofosbuvir and RBV. AT-587 is also active against flaviviruses and chikungunya virus. In multi-species pharmacokinetic studies, high plasma concentrations of the surrogate of the active triphosphate (TP) metabolite were achieved across species. AT-587 also forms high levels of TP in human hepatocytes. It shows no cytotoxicity *and* its active TP does not inhibit human DNA polymerases. It is negative in *in vitro* genotoxicity assays and also shows little effect in screening hERG assays. Additional preclinical development studies, including rabbit and gerbil animal efficacy studies, are ongoing.
Conclusion: AT-587, a nucleotide prodrug, has been identified as a highly potent pan-genotypic inhibitor of HEV and nominated as an IND candidate for the treatment of life-threatening HEV infection.

DDX5 and DDX17 RNA helicases regulate HBV RNA splicing
Guillaume Giraud[1,2], Xavier Grand[1,2], Pélagie Huchon[1,2], Mélanie Roda[1,2], Audrey Diederichs[1,2], Sébastien Renaudin[1,2], Fleur Chapus[1,2], Francesca de Nicola[3], Romain Parent[1,2], Rivoire Michel[4], Cyril Bourgeois[5], Fabien Zoulim[1,2,6], Barbara Testoni[1,2]. *[1]UCBL - INSERM UMR1350 - PaThLiv, Lyon, France; [2]The Lyon Hepatology Institute, Lyon, France; [3]IRCCS Regina Elena National Cancer Institute, Rome, Italy; [4]Centre Léon Bérard, INSERM UMR1032, Lyon, France; [5]University Claude Bernard of Lyon, Ecole Normale Supérieure de Lyon, CNRS UMR 5239, INSERM U1293, Laboratory of Biology and Modelling of the Cell, Lyon, France; [6]Hepatology Department, Hospices Civils de Lyon, Lyon, France*
Email: guillaume.giraud@inserm.fr

Background and aims: HBV RNAs undergo alternative splicing generating at least 22 spliced variants (SpVs). Some of these SpVs encode proteins promoting HBV immune escape and deregulating

oncogenic signalling pathways. Interestingly, the overall proportion of SpVs appears to increase with the disease evolution. Despite their importance in HBV-induced liver pathogenesis, how HBV RNA splicing is regulated remains elusive. We recently demonstrated the role of two RNA helicases, DDX5 and DDX17 (DDX5/17), whose expression is down-regulated in CHB patients and associated with poor prognosis, in HBV RNA transcriptional fidelity.
Method: HBV-infected HepG2-NTCP cells and primary human hepatocytes (PHH) were silenced for the expression of DDX5/17. 8 days post-infection, RNAs were isolated and subjected to 5'RACE-PCR assays followed by single molecule sequencing using the MinION from Oxford Nanopore Sequencing to analyse the profile of HBV SpVs. The differential expression of SpVs upon DDX5/17 silencing were validated using droplet digital PCR. Polysome fractionation and transfection assays were used to analyse their translation status. RNA-seq experiments upon expression of a novel SpV-encoded viral protein were carried out to determine its role in hepatocytes and crossed with publicly available datasets from infected patients. Finally, phenotypical analysis were performed and correlated with the deregulation of specific pathways.
Results: We demonstrated that silencing of DDX5/17 resulted in a general increase of the SpVs using the donor site (DS) at nucleotide position 2070. In particular, SP17 was the mostly induced SpVs in infected HepG2-NTCP cells and PHH. Polysome fractionation experiments combined with transfection assays demonstrated that SP17 encodes a novel viral protein corresponding to a fusion between HBV Core and POL proteins. Transcriptome analysis of HepG2-NTCP cells expressing SP17 revealed dysregulation of pathways related to cell cycle progression and resistance to apoptosis. The same pathways were found dysregulated in publicly available gene expression databases from CHB patients in different disease phases. Functional analyses suggested that SP17 promoted cell proliferation and cell death resistance associated with the interference with the p53 pathway.
Conclusion: Altogether, this study showed the role of DDX5/17 as regulators of HBV RNA splicing and identified a novel viral protein potentially involved in HBV-induced liver pathogenesis.

TOP-645
Targeting inositol-requiring enzyme 1 alpha signaling reprograms macrophage polarization and restores CD8$^+$ T cell function in chronic hepatitis B virus infection

Jinyao Dai[1], Shuaibing Ying[1], Yuqi Hong[1], Yunqing Qiu[1], Yan Lou[1]. *[1]The First Affiliated Hospital, Zhejiang University School of Medicine, Hangzhou, China*
Email: yanlou@zju.edu.cn

Background and aims: Chronic hepatitis B (CHB) is characterized by a state of immune tolerance that severely limits the achievement of functional cure. Although anti-inflammatory macrophage polarization is central to shaping the hepatic immune microenvironment, the underlying molecular mechanisms that orchestrate this process remain unclear. This study aimed to investigate the role of endoplasmic reticulum stress sensor inositol-requiring enzyme 1 alpha (IRE1alpha) in CHB.
Method: Human liver tissues obtained from patients with CHB and controls were used to assess IRE1alpha expression. AAV-HBV models were developed in macrophage-specific IRE1alpha knockout, hepatocyte-specific IRE1alpha knockout, and wild-type mice. Transcriptomics and immunoprecipitation-mass spectrometry (IP-MS) were utilized to explore molecular mechanisms.
Results: IRE1alpha expression was markedly upregulated, accompanied by the accumulation of anti-inflammatory macrophages, in livers from patients with CHB. Macrophage-specific deletion of IRE1alpha disrupted this anti-inflammatory phenotype, restored antiviral CD8$^+$ T cell responses, and significantly reduced viral loads. Hepatocyte-specific deletion of IRE1alpha effectively promoted autophagic degradation of HBV. Pharmacological inhibition of IRE1alpha significantly reduced viral loads and reversed the immunosuppressive microenvironment. Mechanistically, hepatitis B e antigen (HBeAg) was identified as a key viral trigger that induced IRE1alpha expression in macrophages through toll-like receptor 4 (TLR4). IRE1alpha regulated macrophage function independently of its canonical RNase effector spliced X-box binding protein 1(XBP1 s). Instead, activated IRE1alpha directly interacted with and stabilized ADP-ribosylation factor 1 (ARF1), leading to suppression of PI3K-AKT-STAT1 signaling axis. Consequently, expression of the chemokine c-c motif chemokine ligand 5(CCL5) was transcriptionally downregulated, impairing the recruitment and function of HBV-specific CD8$^+$ T cells. At the same time, the IRE1alpha-ARF1 axis reinforced an anti-inflammatory macrophage phenotype, thereby promoting immune tolerance and HBV persistence.
Conclusion: This study identifies IRE1alpha as a central regulator of immune tolerance in CHB. By driving anti-inflammatory macrophage polarization and limiting antiviral CD8$^+$T cell immunity, IRE1alpha promotes HBV persistence. Thus, IRE1alpha represents a promising therapeutic target for restoring antiviral immunity in CHB.

TOP-646
Intratumoral persistence of hepatitis delta virus is associated with a PD-1–high, Th1-deficient immune-inflamed microenvironment in hepatocellular carcinoma

Orgil Jargalsaikhan[1,2], Mayuko Shimizu[1], Wenhua Shao[3], Masako Nomaguchi[4], Takaaki Koma[4], Koichi Tomita[5], Koichi Tsuneyama[1]. *[1]Department of Pathology and Laboratory Medicine, Tokushima University Graduate School of Biomedical Sciences, Tokushima, Japan; [2]Tokushima University, Pathology and Laboratory Medicine, Tokushima, Japan; [3]Department of Molecular Pathology, Tokushima University Graduate School of Biomedical Sciences, Tokushima, Japan; [4]Department of Microbiology and Infectious Diseases, Institute of Biomedical Sciences, Tokushima University Graduate School, Tokushima, Japan; [5]Department of Functional Anatomy, Tokushima University Graduate School of Biomedical Sciences, Tokushima, Japan*
Email: tsuneyama.koichi@tokushima-u.ac.jp

Background and aims: Hepatitis delta virus (HDV) infection accelerates liver disease progression and hepatocarcinogenesis in patients with chronic hepatitis B virus (HBV) infection. In HBV-related hepatocellular carcinoma (HCC), HBV antigens are frequently lost within tumor tissue; however, whether HDV persists within tumor cells and how such persistence relates to the functional immune state of tumor-infiltrating lymphocytes (TILs), including the PD-1/PD-L1 and IFN-γ axes, remains unclear. We aimed to determine intratumoral localization of HDV and HBV and to characterize the immune microenvironment associated with intratumoral HDV persistence.
Method: Seventeen surgically resected HCC specimens were analyzed (11 HBV/HDV coinfection, 6 HBV monoinfection). Immunohistochemistry for HDV antigen, HBV antigens, CD4, CD8, PD-1, PD-L1, IFN-α, and IFN-γ was performed on tumor and background liver tissues. HDV RNA localization was validated by in situ hybridization. Immune infiltration and marker expression were assessed qualitatively and semi-quantitatively.
Results: Among 11 HBV/HDV-coinfected cases, HDV-positive tumor cells were identified in 7 HCCs by both immunohistochemistry and HDV RNA in situ hybridization, whereas HBV-positive tumor cells were absent in all cases. All HDV-positive tumors showed intratumoral CD8-positive T-cell infiltration and frequent CD4-positive T-cell infiltration. In contrast, T-cell infiltration was minimal or absent in HDV-negative HBV/HDV-coinfected HCCs and in HBV-monoinfected HCCs. Despite T-cell–rich infiltrates, IFN-γ–positive lymphocytes were scarce in both background liver and tumor, with only occasional IFN-γ–positive macrophages/histiocytes observed. PD-1 was expressed on most infiltrating lymphocytes. PD-L1 expression was strong in background liver but markedly reduced or absent in tumor regions, where it was mainly confined to Kupffer cells/

histiocytes with only scattered PD-L1–positive tumor cells. IFN-α expression was heterogeneous and not restricted to HDV-positive areas.
Conclusion: HDV, but not HBV, persists within HCC tissue and defines a distinct subset characterized by abundant intratumoral CD8/CD4 infiltration with predominant PD-1 expression, a Th1/IFN-γ–deficient effector profile, and low tumor-cell PD-L1 expression. These findings suggest chronic antigen exposure leading to dysfunctional T-cell states and a myeloid-skewed checkpoint landscape, supporting the relevance of intratumoral HDV persistence for patient stratification and therapy.

Email: johannes.baecher@stud.uke.uni-hamburg.de

Background and aims: Hepatitis delta virus (HDV) infection accelerates liver disease progression in individuals co-infected with hepatitis B virus (HBV). Despite the severity of chronic hepatitis D (CHD), treatment options remain limited. As HDV relies on the HBV envelope proteins (HBsAg) for egress, small interfering RNA (siRNA)–based therapies designed to degrade HBV RNA transcripts offer an attractive approach to hinder HBsAg production and impair HDV release. To evaluate the impact of siRNA targeting all HBV transcripts on HDV-infected human hepatocytes in vivo, we used human liver chimeric mice coinfected with HBV and a patient-derived HDV strain (GT-1) (*Giersch, JHEP Rep 2023*).
Method: Mice harbouring high levels of human hepatocyte repopulation (>90%) were coinfected with HBV and HDV. 9 weeks post-infection, 5/9 animals received a 4-week treatment of LNP-encapsulated siRNA (1 mg/kg/ i.v.; *Axolabs*) that targets all HBV transcripts (*Allweiss, Gut 2022*). Viral markers in serum and liver were analysed by qPCR, ELISA (Abbott Architect), immunofluorescence and RNA in situ hybridisation.
Results: Median baseline viral titres were 5×10^7 HBV DNA copies/mL and 4×10^6 HDV RNA copies/ml. The strongest reduction in viremia was already observed after 1 week of treatment, with median decreases reaching 2 $\log_{10}$ for HBV DNA and 1.8 $\log_{10}$ for HDV RNA ($p = 0.008$) after 4 weeks of therapy, whereas viral levels in untreated controls remained stable. Median serum levels of HBsAg and HBeAg in treated mice declined by 1.6 $\log_{10}$ and 1.5 $\log_{10}$, respectively. In the liver, median HBV DNA and pgRNA levels were reduced by 1.2 $\log_{10}$ and 1.6 $\log_{10}$, respectively, after 4 weeks of therapy compared with untreated controls ($p = 0.016$). In contrast, intrahepatic HDV RNA levels were comparable between treated and untreated mice. No increase in ALT levels was observed during the 4-week treatment period.
Conclusion: SiRNA targeting all HBV transcripts rapidly reduced HDV viremia in HBV/HDV-infected mice, confirming that hindering HBsAg production promptly lowers the levels of circulating HDV. Consistent with previous studies (*Giersch, J.Hep 2014*), we demonstrate that HDV can persist in the liver for several weeks in the absence of HBV or HBsAg production. Longer treatment durations in preclinical models and analysis of patient liver biopsies are needed to determine the full impact of siRNA-based therapies on intrahepatic HDV persistence.

THU-559-YI
HDV propagates by hijacking a non-canonical, lysosome-derived exosomal pathway independent of HBV
Enkhtuul Batbold[1], Jennifer Molle[1], Artemiy Fedulov[2], Alexander Ivanov[2], Fabien Zoulim[1], Kathrin Weber[1], Birke Bartosch[1].

Email: enkhtuul.dr@gmail.com

Background and aims: EVs (Extracellular Vesicles) derived from HDV (Hepatitis D Virus) infected cells contain ribonucleoprotein and induce HDV-associated immune activation. This suggests that HDV may be transmitted by hijacking the EV pathway, independently of HBV. However, the composition and subtype of EVs remain unclear. We have previously demonstrated that exosome biogenesis is not restricted to the canonical multivesicular body (MVB) pathway, but can also originate from lysosomes. Therefore, we hypothesize that HDV hijacks a non-canonical, lysosome-derived exosomal pathway to facilitate viral dissemination independent of HbsAg.
Method: EVs were isolated from HepaRG^{NTCP} cell culture supernatant by differential ultracentrifugation, after mono- or co-infection with HDV or hepatitis B virus (HBV), respectively. The EVs were analysed by Nanosight. The infectious potential of isolated EVs was determined by transfer experiments to Huh7 cells. The subtype of EV was characterized by RT-qPCR and immunoblotting. The known executer of necroptosis, MLKL (mixed lineage kinase domain-like protein), was functionally linked to non-canonical exosome formation using the MLKL inhibitor, necrosulfonamide (NSA), or CRISPR-mediated MLKL knockout.
Results: HDV mono-infected HepaRG^{NTCP}cells secreted higher numbers of EVs compared to uninfected cells. Transferring these EVs, which contain HDV RNA and protein, resulted in active HDV replication in recipient Huh7 cells. Although the markers of MVB-derived exosomes remained unchanged between uninfected and HDV mono-infected cells, the level of late endo-lysosomal marker LAMP1 was increased in HDV mono-infected cells, indicating a lysosomal origin. The expression of MLKL, which is increased in HDV mono-infected cells, was identified as a key regulator of lysosomal ILV (intraluminal vesicle) formation. Inhibiting MLKL led to intracellular accumulation of HDV RNA and protein, suggesting impaired viral egress. Furthermore, transferring EVs derived from NSA-treated HDV mono-infected HepaRG^{NTCP} cells resulted in reduced HDV replication in recipient Huh7 cells.
Conclusion: In conclusion, our findings reveal a novel, HBsAg-independent mechanism of HDV dissemination. HDV exploits a non-canonical, lysosomal derived, MLKL-regulated EV pathway. This provides a mechanistic explanation for HDV persistence and pathogenicity beyond classical HBV-dependent virion assembly and highlights MLKL as a potential therapeutic target to limit HDV spread.

Combination immunotherapy can promote clinical cure in a model of chronic hepatitis B
Nicholas Carey[1], Jillian Jespersen[1,2], Jean Publicover[1], Lia Avanesyan[1,3], Ravi Patel[1], Nicholas Wong[1], Stewart Cooper[2,3], Gabriela Fragiadakis[1], Jody Baron[1,2]. *[1]University of California San Francisco, San Francisco, United States; [2]UCSF Liver Center, San Francisco, United States; [3]California Pacific Medical Center and Research Institute, San Francisco, United States*
Email: Nicholas.Carey@ucsf.edu

Background and aims: At least 250 million people are chronically infected with the hepatitis B virus (HBV), a major global pathogen that often leads to immune-mediated progressive liver injury, cirrhosis, and liver cancer. Clinical cure, defined by seroclearance of the surface antigen (HBsAg), reduces disease-associated risks but is rarely observed with standard-of-care nucleos(t)ide analog (NA)

treatment regimens. Using a mouse model of age-dependent HBsAg seroclearance and persistence, and longitudinal PBMC samples from our clinical trial patients who either cleared HBsAg or retained stable HBsAg levels after stopping ≥192 weeks of NA, we identified a conserved mechanism of HBsAg seroclearance. Clinical cure was associated with a sustained HBV-specific $CD4^+$ T cell response that promotes hepatic leukocyte organization and cytotoxic lymphocyte function. Motivated by this insight, we sought to identify immune-modulating agents that promote and sustain HBV-specific T-cell responses, as well as an increased rate of clinical cure, in mice that would otherwise fail to produce an effective HBV response.

Method: We investigated the effects of several agonistic monoclonal antibodies selectively targeting T cell costimulatory pathways and innate immune agonists targeting hepatic antigen-presenting cells (APCs) on hepatic leukocyte phenotypes and serological outcomes. Mice were treated during acute response (concurrent with initiation of HBV immune response) or during a chronic phase (HBsAg+ at 2+ months post-initiation). Hepatic leukocyte phenotypes were measured by spectral flow cytometry. Serological profiles following treatment were monitored for ALT, serum HBsAg, and anti-HBs.

Results: In acute response, innate immune agonists augmented expression of markers of hepatic APC function but did not significantly increase HBsAg-specific CD4+ T cell frequencies. T cell costimulatory agonists augmented HBsAg-specific CD4+ T cell frequencies but did not improve the clinical cure rate during chronic phase treatment. A combination of T cell costimulatory agonist and innate immune agonists significantly increased the rate of HBsAg seroclearance and anti-HBs production in chronic phase mice.

Conclusion: When used in combination, T cell costimulatory agonists and innate immune agonists were able to safely promote clinical cure in mice that would otherwise remain HBsAg+. These preclinical studies establish proof of concept to inform future therapeutic approaches for promoting clinical cure of chronic hepatitis B.

Cellular NEDD4 family ubiquitin ligase AIP4 ubiquitinates HGS to facilitate HBV naked capsid egress

Sheng Shen[1,2,3,4], Ge Zeng[1], Hongyan Liang[1], Yidan Chen[1], Dawei Cai[2], Hu Zhang[2,3,4], Yuanjie Liu[2,3,4], Haitao Guo[2,3,4], Jian Sun[1]. *[1]Department of Infectious Diseases, Nanfang Hospital, Southern Medical University, Guangzhou, China, State Key Laboratory of Multi-organ Injury Prevention and Treatment, Key Laboratory of Infectious Diseases Research in South China, Ministry of Education, Guangdong Provincial Key Laboratory for Prevention and Control of Major Liver Diseases, Guangdong Provincial Clinical Research Center for Viral Hepatitis, Guangdong Institute of Hepatology, Guangdong Provincial Research Center for Liver Fibrosis Engineering and Technology, Guangzhou, China; [2]Department of Microbiology and Immunology, Indiana University School of Medicine, Indianapolis, Indiana, USA, Indianapolis, United States; [3]Department of Microbiology and Molecular Genetics, University of Pittsburgh School of Medicine, Pittsburgh, Pennsylvania, USA, Pittsburgh, United States; [4]Cancer Virology Program, UPMC Hillman Cancer Center, University of Pittsburgh School of Medicine, Pittsburgh, Pennsylvania, USA, Pittsburgh, United States*
Email: doctorsunjian@qq.com

Background and aims: HBV-replicating cells nonlytically release non-enveloped (naked) capsids in addition to virions, but the detailed secretory mechanism remains elusive. We have previously reported that NEDD4 E3 ligase AIP4 stimulates naked capsid secretion through its E3 ligase activity. The current study aims to identify the potential substrate(s) of AIP4 for promoting naked capsid egress.

Method: The expression levels of host proteins of interest in hepatocyte-derived cells were depleted by CRISPR/Cas9 system and over-expressed by plasmids transfection. The intracellular HBV capsids and the extracellular viral particles were analyzed by particle gel assay.

Results: Previous studies reported that the ESCRT accessory protein Alix and the ESCRT-0 component HGS facilitate HBV naked capsid secretion. However, we demonstrated that Alix ubiquitination is not required for AIP4-induced naked capsid secretion (PMID: 39259704). In this study, we showed that both HGS and its ubiquitin interaction motif (UIM, aa258-277) deletion mutant are capable of stimulating naked capsid secretion through binding to intracellular capsid. We further found that the ubiquitinated HGS binds to the K96 residue of capsid protein through its C-terminal domain (aa278-777). Through exogenous overexpression and endogenous knockout of AIP4, we demonstrated that AIP4 interacts with HGS and promotes its ubiquitination even in the absence of UIM domain, and AIP4 is essential for HGS-mediated naked capsid secretion. Moreover, AIP4 binds to both the N- and C-terminal domains of HGS, but it only ubiquitinates the lysine(s) in the FYVE domain (aa159-221) within the N-terminal portion (aa1-257) via K27-linked ubiquitination. Mutagenesis study revealed that K207 of HGS is the major ubiquitination site catalyzed by AIP4, and its ubiquitination is important for naked capsid egress. Furthermore, we found that HGS and Alix bind to each other and interdependently promote naked capsid secretion through forming an intracellular complex.

Conclusion: Taken together, our study demonstrates that NEDD4 E3 ligase AIP4 interacts with HGS to promote HBV naked capsid egress in an HGS ubiquitination-dependent manner, which sheds new light on the mechanism of HBV naked capsid egress in viral life cycle.

THU-562

Study on the immunomodulatory effects and mechanisms of the traditional chinese medicine formula Tiaoganbuxuyidu against HBV in mice

Fan-E Cheng[1], Size Li[1], Qiuyue Wang[1], Wenying Qi[1], Yaxi Zhang[1], Shihao Zheng[1], Xinyu Zhao[1], Chunfeng Mei[1], Xiaobin Zao[2], Yong'an Ye[3]. *[1]Dongzhimen Hospital, Beijing University of Chinese Medicine, Beijing, China; [2]Key Laboratory of Chinese Internal Medicine of Ministry of Education and Beijing, Dongzhimen Hospital, Beijing University of Chinese Medicine, Beijing, China; [3]Institute of Liver Diseases, Dongzhimen Hospital, Beijing University of Chinese Medicine, Beijing, China*
Email: 18801020531@163.com

Background and aims: Chronic hepatitis B (CHB), caused by HBV infection, remains a serious global health burden and can progress to cirrhosis or hepatocellular carcinoma if uncontrolled. The traditional Chinese medicine formula TiaoGanBuXuYiDu (TGBX) shows clinical efficacy against CHB, yet its mechanisms are not fully understood. This study uses an AAV-HBV mouse model to investigate how TGBX inhibits HBV replication and reduces liver injury through immunomodulation, aiming to clarify its molecular mechanisms.

Method: After establishing an HBV-infected mouse model via tail vein injection of AAV8-HBV vectors, successfully modeled mice were randomly divided into the following groups: AAV-HBV group, TGBX-L group, TGBX-M group, TGBX-H group, and an ETV-positive control group, with a normal control group also included. Each group received the corresponding treatment via oral gavage for 12 consecutive weeks. Ultra performance liquid chromatography mass spectrometry/mass spectrometry (UPLC-MS/MS)profiling delineated the principal constituents of TGBX.The therapeutic effect of TGBX on CHB and its immunomodulatory role were evaluated by measuring serological virological and biochemical indicators, performing liver H&E staining, and conducting flow cytometry. Furthermore, mouse liver transcriptomics was employed to investigate the anti-HBV mechanism of TGBX, with differential expression genes functionally annotated and enriched through GO and KEGG analyses.

Results: UPLC-MS/MS profiling revealed 158 bioactive constituents in TGBX, among them berberine, paeoniflorin and jatrorrhizine. TGBX dose-dependently suppressed serum HBsAg and HBeAg, with TGBX-

H showing sustained inhibition from week 2. From week 4, TGBX also reduced ALT/AST levels and alleviated liver injury (edema, ballooning, inflammation), most notably in the TGBX-H group. Flow cytometry indicated TGBX restored hepatic $CD4^+/CD8^+$ T-cell balance, reduced exhausted $CD8^+$ T cells ($PD\text{-}1^+$, $CXCR6^+$), and demonstrated liver-targeted immunomodulation. Proteomics identified 288 differentially expressed proteins linked to immune-inflammatory and metabolic processes. KEGG analysis highlighted immunomodulatory pathways including AMPK signaling, alcoholic liver disease, and amino acid metabolism.
Conclusion: TGBX acts against HBV by suppressing viral antigens, improving liver function, and modulating hepatic T-cell balance—notably reversing $CD8^+$ T-cell exhaustion. This study offers mechanistic insights into its immunomodulatory role in chronic hepatitis B.

Mathematical modeling of HBV infection and HEPLISAV-B treatment in rAAV-HBV mouse model
Aarim Khan[1], Louis Shekhtman[1], Adquate Mhlanga[1], Ashish Goyal[1], Jiapeng Wu[2], Lydia Tang[2], Shyamasundaran Kottilil[2], Lishan Su[2], Harel Dahari[1], James Ahodantin[3]. *[1]Program for Experimental and Theoretical Modeling, Division of Hepatology, Department of Medicine, Loyola University Chicago, Maywood, IL, United States; [2]University of Maryland School of Medicine, Baltimore, United States; [3]Department of Pharmacology and Experimental Neuroscience, University of Nebraska Medical Center, Omaha, United States*
Email: harel.dahari@gmail.com

Background and aims: Heplisav-B (Dynavax Technologies) is a newly FDA approved prophylactic 2-dose hepatitis B vaccine with a CpG adjuvant and a high seroprotection rate. We sought to understand the kinetics of serum hepatitis B viral genome (HBV DNA), hepatitis B surface antigen (HBsAg), hepatitis B e-antigen (HBeAg), and anti-HBs antigen IgG (IgG), in rAAV-HBV infected mice, with and without Heplisav-B, during a 25-week period using mathematical modeling.
Method: Ten rAAV-HBV infected mice were included. Heplisav-B was administered in 6 mice at weeks 4 and 8. Blood samples were collected every 2–4 weeks. We developed a multiscale mathematical model, where cells are assumed to be instantly infected after rAAV-HBV injection and the number of infected cells is fixed. In each infected hepatocyte, three products are produced from cccDNA: intracellular HBV RNA, HBsAg, and HBeAg. Intracellularly, HBV RNA is converted to HBV DNA, and HBsAg is either converted to HBsAg subviral particles or incorporated into virus-like particles containing HBV RNA or HBV DNA during secretion. IgG follows a logistic growth model and is cleared when it forms a complex with serum HBsAg, HBV RNA, or HBV DNA. The effects of Heplisav-B were modelled by an immediate reduction in HBsAg, HBV RNA, and HBeAg synthesis and increase in IgG synthesis.
Results: The model recapitulated the increase and plateau in serum HBV DNA, HBeAg, and HBsAg in unvaccinated mice. It also captured IgG, which remained undetectable or low in unvaccinated mice. By assuming a vaccine efficacy of 99.99% in blocking HBsAg synthesis, the model captured the rapid decrease in serum HBV DNA and its subsequent slow increase in vaccinated mice, as well as the rapid decline in serum HBsAg to below detection until the end of the experiment (EOE). Simultaneously, the model captured the slight decrease in serum HBeAg until EOE by assuming a 77% reduction in HBeAg synthesis. A 99.9% reduction in intracellular HBV RNA synthesis was able to explain the observed ~1 log in intracellular HBV RNA decline relative to unvaccinated mice at week 25. The model fits the gradual increase and plateau in IgG, with negligible effect on serum HBV DNA, HBsAg, and HBeAg clearance.
Conclusion: Modeling suggests a significant suppression of HBsAg synthesis, which in turn reduces HBV DNA secretion, along with a moderate to high suppression of intracellular HBV RNA and HBeAg synthesis from Heplisav-B treatment in the AAV-HBV mouse model. Further experimental validation is required.

THU-564
Understanding early hepatitis B virus kinetics in primary human hepatocytes using an agent-based modeling approach
Ari Dobos[1], Zhenzhen Shi[1], Yuji Ishida[2], Chise Tateno[2], Mikaru Yamao[2], Masaki Takahashi[2], Alexander Ploss[3], Kazuaki Chayama[4], Harel Dahari[1]. *[1]Program for Experimental and Theoretical Modeling, Division of Hepatology, Department of Medicine, Loyola University Chicago, Maywood, IL, United States; [2]PhoenixBio Co., Ltd., Hiroshima, Japan; [3]Department of Molecular Biology, Lewis Thomas Laboratory, Princeton University, Princeton, United States; [4]RIKEN Center for Integrative Medical Sciences, Yokohama, Hiroshima Institute of Life Sciences, Hiroshima, Japan*
Email: harel.dahari@gmail.com

Background and aims: Understanding of early dynamics of hepatitis B virus (HBV) covalently closed circular DNA (cccDNA) accumulation in primary human hepatocytes (PHHs) is limited. Recently, we developed a differential equations-based model to explain the dynamics of cccDNA accumulation in PHH at the well level (PMID 40236628). Here we aim to develop an agent-based modeling (ABM) approach to understand early HBV dynamics in the PHHs of a single cell level via modeling the interplay between extracellular HBV DNA (exHBV), total intracellular HBV DNA (termed relaxed circular DNA, rcDNA), and cccDNA.
Method: PHHs were inoculated with HBV, and infection was monitored with the entry inhibitor Myr-preS1 present as recently reported (PMID 40236628). Myr-preS1 treatment (6.25 lg/ml) was initiated 1 day post inoculation (p.i.). ExHBV, rcDNA, and cccDNA were frequently measured during the 12 days post inoculation. In the ABM rcDNA, cccDNA and exHBV are represented as individual agents, attempting to recapitulate the in vitro kinetics at a single cell level. Initial ABM conditions and parameters are assumed based on the in vitro experimental design.
Results: Multiphasic exHBV and rcDNA kinetics were observed with cccDNA levels rapidly increased until day 2 p.i. followed by plateau. Modeling predicts that the recycling of rcDNA into cccDNA stops when cccDNA reaches a maximum, and rcDNA secretion rate is dependent on the intracellular concentration of rcDNA. The ABM reproduced well the HBV kinetic patterns observed and predicted that rcDNA production rate from cccDNA increased over time, starting with a slow production cycle of 1 rcDNA copy per 15 hours, which gradually accelerated to 1 rcDNA copy per 3 hours after 5 days and continued to gradually accelerate up to 1 rcDNA copy per 1.25 hours by day 12 p.i.
Conclusion: The ABM provides novel insights into the early accumulation of cccDNA and rcDNA in PHH. Further experimental and theoretical efforts are needed to validate these results.

The mechanism of HSP90AB1 binding to hepatitis B surface antigen driving the progression of HBV-related hepatocellular carcinoma through chaperone-mediated autophagy
Muqi Wang[1], Yikai Wang[2], Meng Zhang[2], Chenrui Liu[2], Yaping Li[2], Xiaoli Jia[2], Shuangsuo Dang[2]. *[1]The Second Affiliated Hospital of Xi'an Jiaotong University, Xi'an, China; [2]The Second Affiliated Hospital of Xi'an Jiaotong University, Xi'an, China*
Email: 18710964067@163.com

Background and aims: heat shock protein 90-beta (HSP90AB1) is highly expressed in hepatocellular carcinoma (HCC), which is implicated in viral infections, yet its role in HBV pathogenesis remains undefined. We investigated the role of HSP90AB1 in the occurrence and development of HBV-related HCC and explore the possible mechanism by which it regulates autophagy.
Method: Serum HSP90AB1 levels were measured by ELISA in 132 HBV-HCC patients, 60 chronic hepatitis B patients (CHB) and 36

healthy controls, and clinical parameters (HBV serological markers, liver function, tumor biomarkers) were collected to perform correlations between HSP90AB1 and clinical variables. ELISA, Western blot and RT-PCR were used to detect HSP90AB1 expression in 40 paired tumor tissues and adjacent tissues of patients with HBV-related HCC. Hep3B with HSP90AB1 knockdown were constructed by lentivirus transfection to verify the effects of HSP90AB1 knockdown and HSP90AB1 inhibitors on the proliferation, migration, invasion abilities and the changes in autophagy. Bioinformatics analysis and molecular docking technology were used to predict the interacting proteins and binding sites of HSP90AB1, which were verified by the bidirectional co-immunoprecipitation experiment.
Results: Serum HSP90AB1 levels were significantly elevated in CHB patients (294.1 [125.90–663.20] compared to HBV-related HCC (86.22 [46.01–164.60] ng/mL; $P < 0.001$) and healthy controls (50.94 [42.95–131.80] ng/mL; $P < 0.001$). High HSP90AB1 expression correlated with higher HBsAg ($r = 0.414$, $P < 0.001$), higher HBeAg ($r = 0.319$, $P < 0.001$) and higher HBV pre-S1 antigen levels ($r = 0.481$, $P < 0.001$). In 40 paired tissues of HBV-HCC patients, HSP90AB1 expression in tumor was significantly higher than in adjacent, and was significantly positively correlated with pathological grade and HBsAg. Knockdown of HSP90AB1 and HSP90AB1 inhibitors significantly reduced proliferation, migration and invasion abilities of Hep3B, as well as the chaperone-mediated autophagy (CMA). Bioinformatics analysis and molecular docking techniques predict and the bidirectional co-immunoprecipitation experiments of HSP90AB1 and HSPB8 in Hep3B validated that the formation of HSP90AB1-HSPB8-HSC70 complex regulates CMA activity.
Conclusion: HSP90AB1 is elevated in HCC tumor tissues and is significantly correlated with the pathological grade of the tumor and HBsAg. The HSP90AB1-HSPB8-HSC70 protein complex may participate in regulating the CMA activity, and it can also affect the proliferation and invasion of HBV-related HCC.

THU-570
ALG-001075, the parent of pevifoscorvir sodium, exhibits potent in vitro antiviral properties compared to other HBV capsid assembly modulators in clinical development

Yannick Debing[1], Jordi Verheyen[1], Hannah Vanrusselt[1], David McGowan[1], Tse-I Lin[1], Lawrence Blatt[2], David Smith[2], Julian Symons[2], Andreas Jekle[2]. *[1]Aligos Belgium, Leuven, Belgium; [2]Aligos Therapeutics, South San Francisco, United States*
Email: ydebing@aligos.com

Background and aims: The hepatitis B virus (HBV) capsid is an attractive target for the treatment of chronic HBV infection. Pevifoscorvir sodium (pevy, ALG-000184) is a prodrug of ALG-001075, a novel capsid assembly modulator leading to the formation of empty capsids (CAM-E). Pevy has demonstrated potential best-in-class reductions of HBV DNA, RNA, HBsAg, HBeAg and HBcrAg in subjects with chronic HBV infection and is currently progressing through a phase 2 clinical trial. The aim of this study was to compare the activity of ALG-001075 to canocapavir and neracorvir, two other CAMs in clinical development.
Method: HBV DNA antiviral activity (primary CAM mechanism) was determined in HepG2.117 cells using quantitative PCR. Effects on cccDNA establishment (secondary CAM mechanism) were assessed in HBV genotype D-infected HepG2-NTCP cells or primary human hepatocytes (PHH) by adding compound together with viral inoculum and measuring HBsAg as an indirect read-out. Direct effects on HBeAg (third CAM mechanism) were investigated in HBeAg-overexpressing cells. Further characterization was performed using immunofluorescent HBc staining.
Results: ALG-001075, canocapavir and neracorvir inhibited HBV DNA production in HepG2.117 cells with EC_{50} values of 0.64, 5.8 and 24 nM, respectively. The establishment of cccDNA in HepG2-NTCP cells or PHH was efficiently blocked by ALG-001075 ($EC_{50} = 18$ nM, as measured by HBsAg in HepG2-NTCP cells), but less so by neracorvir ($EC_{50} = 3350$ nM) and canocapavir ($EC_{50} = \sim 1000$ nM in PHH and >5000 nM in HepG2-NTCP). ALG-001075 was also more potent in the direct inhibition of HBeAg secretion ($EC_{50} = 855$ nM) than canocapavir and neracorvir. The HBV core protein mutation T33N is a major viral resistance mutation for 1st generation CAMs and reduces the activity of ALG-001075 in vitro: 27- and 23-fold for HBV DNA and HBeAg, respectively. However, to date, it has not been detected in subjects with chronic HBV infection treated with pevy for up to 96 weeks. Interestingly, canocapavir was not affected by T33N but was sensitive to Y118F (18-fold shift). ALG-0001075 was not affected by Y118F. All 3 CAMs showed the typical CAM-E phenotype (no nuclear aggregates, some cytoplasmic accumulation) in immunofluorescent HBc staining assays.
Conclusion: ALG-001075, the parent of pevy, displayed a highly potent in vitro antiviral profile, confirming its potential as a best-in-class CAM. Pevy is currently being developed as a monotherapy for the suppression of chronic HBV infection.

THU-571
Temporal transcriptional dynamics in HBV-specific CD8 T cells during long-term NUC therapy in HBeAg- chronic hepatitis B

Sara Doselli[1], Benedetta Farina[1], Camilla Ceccatelli Berti[2], Ilaria Montali[1], Angelo Ruggieri[3], Valentina Reverberi[1], Anna Montali[1], Andrea Vecchi[4], Marzia Rossi[1], Alessio Pelagatti[1], Silvia Ampollini[1], Francesca Ferraglia[4], Amalia Penna[4], Carolina Boni[1,4], Marco Morselli[2], Gabriele Missale[1,4], Paola Fisicaro[4]. *[1]Department of Medicine and Surgery, University of Parma, Parma, Italy, Parma, Italy; [2]Department of Chemistry, Life Sciences and Environmental Sustainability (SCVSA), University of Parma, Parma, Italy, Parma, Italy; [3]Department of Biology, University of Puerto Rico, Rio Piedras, Puerto Rico, Rio Piedras, Puerto Rico; [4]Laboratory of Viral Immunopathology, Unit of Infectious Diseases and Hepatology, Azienda Ospedaliero-Universitaria di Parma, Parma, Italy, Parma, Italy*
Email: pfisicaro@ao.pr.it

Background and aims: Virus-specific CD8 T cell dysfunction is a hallmark of chronic hepatitis B (CHB), and its restoration represents a key strategy toward HBV cure. This study aims to define transcriptional changes in HBV-specific CD8 T cells associated with viral persistence and control in HBeAg-negative chronic patients undergoing long-term nucleos(t)ide analogue (NUC) therapy, with the ultimate goal to identify potential targets for efficient T cell restoration.
Method: We performed a transcriptome study by low-input RNA-seq on core- and polymerase-specific CD8 T cells, isolated from nine patients with HBeAg-negative chronic hepatitis B and high viral loads, prior to the start of NUC therapy and longitudinally at 1 and 4 years after treatment initiation. Five patients who achieved functional cure with HBsAg loss after long-term NUC treatment (rNUC) were included as control group. Transcriptomic data were analyzed using Weighted Gene Co-expression Network Analysis (WGCNA) to investigate the dynamics of gene cluster expression over time. Virological parameters including HBV RNA, HBcrAg and HBsAg levels were assessed at the same time points.
Results: Principal component analysis (PCA) of longitudinal transcriptomic profiles revealed a distinct clustering of core-specific CD8 T cells, with chronic patients after 4 years of therapy aligning with rNUC patients. Conversely, polymerase-specific samples displayed greater heterogeneity and lacked a comparable clustering pattern. WGCNA analysis further highlighted distinct transcriptional profile changes over time in virus-specific CD8 T cells, identifying gene clusters that were modulated early (1 year), late (4 years), or remained unchanged.
Conclusion: Our longitudinal analysis identifies distinct gene programs in HBV-specific CD8 T cells that progressively normalize or remain dysregulated during therapy, providing candidate targets for interventions aimed at restoring T cell function and achieving functional cure in CHB.

Differential interferon responses in HDV infection reveal USP18-driven IFN-α resistance and novel ISG candidates

Claudie Eber[1], Roxanne Fouillé[2], Pauline Casetta[1], Charlotte Bach[1], David Durantel[2], Thomas Baumert[1,3,4], Julie Lucifora[2], Eloi Verrier[1,2]. *[1]Institute for Translationnal Medicine and Liver Disease, Strasbourg, France; [2]Centre International de Recherche en Infectiologie, Lyon, France; [3]Institut hospitalo-universitaire (IHU), Service d'hépato-gastroentérologie, Strasbourg, France; [4]Institut Universitaire de France, Paris, France*
Email: claudie.eber@etu.unistra.fr

Background and aims: Hepatitis D virus (HDV) causes the most severe form of chronic viral hepatitis, for which curative therapies remain unavailable. In Europe, treatment options include bulevirtide and pegylated interferon-alpha (PEG-IFN-α), although the latter shows limited efficacy. The molecular mechanisms underlying HDV resistance to IFN-α as well as IFN-α molecular mechanism against HDV replication remain poorly understood. This study aimed to decipher the interplay between HDV replication and interferon signaling pathways in hepatocytes.
Method: RNA sequencing was performed to compare the transcriptional responses to IFN-α and IFN-λ in hepatocyte-derived cell lines infected with HDV. Key findings were validated using loss- and gain-of-function approaches.
Results: HDV infection selectively impaired the antiviral response to IFN-α, while IFN-λ activity remained intact. Mechanistically, HDV induced the expression of USP18, a potent negative regulator of IFN-α signaling, which binds IFNAR2 and inhibits JAK1-mediated STAT phosphorylation. USP18 knockdown restored IFN-α-induced ISG expression and enhanced its antiviral efficacy against HDV. Aiming at understanding how IFN-α affects HDV replication, comparative transcriptomic analyses across hepatocyte models responding differentially to IFN-α treatment in HDV-infected cells identified 79 interferon-stimulated genes (ISGs) potentially involved in HDV restriction. Among them, IRF1 and SAMD9L, previously implicated in antiviral responses, emerged as strong candidates.
Conclusion: HDV evades IFN-α antiviral activity through USP18-mediated inhibition of JAK–STAT signaling, providing a mechanistic explanation for the limited clinical efficacy of IFN-α in HDV infection. In contrast, IFN-λ antiviral activity remains unaffected. These findings identify USP18 as a key determinant of IFN-α resistance and highlight novel ISG candidates with potential anti-HDV activity, offering new insights for therapeutic strategies.

THU-573

Characterization of viral integrations in cancer driver genes in non-tumor tissues of HBV-associated HCC via RAISING-sequencing

Kento Fukano[1], Nao Naganori[2], Akihito Tsubota[3], Hideki Aizaki[1], Masumichi Saito[1], Kazuyoshi Hosomichi[4], Takahiro Matsudaira[5], Moto Kimura[1], Koichi Watashi[1], Masanori Isogawa[1], Wataru Sugiura[1], Masamichi Muramatsu[6], Kousho Wakae[1]. *[1]Japan Institute for Health Security, Tokyo, Japan; [2]Hokkaido University, Sapporo, Japan; [3]The Jikei University School of Medicine, Tokyo, Japan; [4]Tokyo University of Pharmacy and Life Sciences, Tokyo, Japan; [5]FASMAC Co., Ltd., Kanagawa, Japan; [6]Foundation for Biomedical Research and Innovation at Kobe, Kobe, Japan*
Email: wakae.k@jihs.go.jp

Background and aims: Integration of hepatitis B virus (HBV) DNA into host genes, such as the TERT gene/promoter and KMT2B (MLL4), is frequently detected in HBV-associated hepatocellular carcinoma (HBV-HCC) and is considered a key factor in hepatocarcinogenesis. However, the timing at which these integrations occur during disease progression remains unclear. We previously established RAISING (Rapid Amplification of Integration Site without Interference by Genomic DNA contamination), a PCR-based method that is more sensitive and versatile than hybrid capture-sequencing (HCS) for amplifying viral-host chimeric sequences. In this study, we employed RAISING-sequencing to characterize HBV DNA integration profiles in paired tumor and adjacent non-tumor tissues from HBV-HCC patients.
Method: Paired tumor and adjacent non-tumor liver tissues from 18 HBV-HCC patients were analyzed using RAISING. The RAISING products were further analyzed by next-generation sequencing (NGS) to identify viral-host junction sequences and their frequencies. Junction-specific PCR and droplet digital PCR (ddPCR) were used for validation and quantification of HBV-integrants.
Results: HBV DNA integration was detected in both tumor and adjacent non-tumor liver tissues in 11 of the 18 cases using RAISING-sequencing. Five cases showed integration into the TERT gene/promoter region, and three cases into the KMT2B gene. Interestingly, RAISING-sequencing identified these HCC-driver integration sites in adjacent non-tumor tissues, as well as in tumor tissues in four cases, whereas HCS identified them only in the tumor, except for one case. ddPCR revealed lower copy numbers in adjacent non-tumor tissues than in tumor tissues, suggesting a higher sensitivity of RAISING-sequencing than HCS for determining HBV integration sites.
Conclusion: These findings suggest that HCC-driver integrations occur in a precancerous state, highlighting their potential role in the early stages of HCC initiation.

Monoclonal anti-HBs antibody, tobevibart, induces myeloid expansion and activation through phago-lysosomal processes

Yanal Ghosheh[1,2], Loghman Salimzadeh[1,2], Stuti Shah[1,2], Jenny Chen[2], Danie La[2], Todd Correll[3], Scott K. Fung[2,4], Jordan J. Feld[2,4], Adam Gehring[1,5]. *[1]Schwartz-Reisman Liver Research Centre, University Health Network, Toronto, Canada; [2]Toronto Centre for Liver Disease, University Health Network, Toronto, Canada; [3]Vir Biotechnology, Inc., San Francisco, United States; [4]The Toronto Viral Hepatitis Care Network (VIRCAN), Toronto, Canada; [5]Department of Immunology, University of Toronto, Toronto, Canada*
Email: yanal.ghosheh@uhn.ca

Background and aims: The Hepatitis B virus surface antigen (HBsAg) is present at very high levels in the circulation of chronic hepatitis B (CHB) patients, contributing to immune dysfunction. Monoclonal antibodies targeting HBsAg have emerged as a promising avenue to rapidly reduce viral antigen in the circulation, which could facilitate restoration of immunity. These antibodies form immune complexes (IC) with HBsAg, which are then cleared via Fc-mediated phagocytosis by myeloid cells. We used single cell RNA-sequencing (scRNA-Seq) to characterize changes in the frequency and transcriptional profile of liver myeloid cells from CHB patients receiving tobevibart therapy.
Method: We collected liver fine needle aspirate (FNA) samples from three HBeAg-, CHB patients on nucleoside analogue therapy at baseline and 3 days after the first dose of 300 mg of tobevibart. We measured HBV DNA, Alanine Aminotransferase (ALT) and HBsAg levels in plasma. FNA samples were subjected to scRNA-Seq to measure transcriptional changes in liver myeloid cells.
Results: All patients exhibited sharp declines (mean 2.1 $\log_{10}$ IU/mL) in HBsAg levels at day 3. The HBsAg decline was not associated with changes in ALT levels. Our analysis of scRNAseq data focused on myeloid cells based on their ability to carry out antibody-dependent phagocytosis. We identified 12 myeloid clusters in the liver including neutrophils, monocytes, macrophages and dendritic cells (DCs). Fc receptor expression varied across myeloid populations, with FCGR3A/B and FCGR2A being the most prominently expressed. Intermediate Monocytes and myeloid DCs (mDCs) increased in abundance, whereas neutrophil subset (Neutrophils 1) decreased after tobevibart treatment. While changes in gene expression were largely patient-specific, we identified a core set of differentially expressed genes in Intermediate monocytes, mDCs and macrophages. Pathway enrichment analysis of this core gene set highlighted genes associated with

cytoskeletal remodeling, lysosomal trafficking, vesicle fusion associated with antigen processing and presentation, and myeloid activation. These pathways are highly consistent with Fc-mediated uptake of ICs and subsequent HBV antigen degradation in activated myeloid lineages.
Conclusion: Tobevibart-mediated HBsAg reduction induces activation of phago-lysosomal pathways as a precursor for HBV antigen degradation in myeloid cell lineages in the liver of CHB patients.

THU-575
Immunometabolic stress drives persistent bystander activation of innate-like CD8$^+$ T cells and hepatocyte HBV transcription despite antiviral therapy
Lung Yi Loey Mak[1,2], Corinna Pade[1], Shue Xiong[1], Chanelle Fernandes[1], Yu Lei[1,3], Gerard Hernandez-Mir[1], Anna Riddell[4], Apostolos Koffas[1,5], Sebastian Deschler[6], Katrin Boettcher[6], Patrick Kennedy[1,5], Upkar Gill[1,5]. Email: u.gill@qmul.ac.uk

Background and aims: Chronic hepatitis B (CHB) remains a major cause of inflammatory liver disease worldwide. Increasingly, CHB coexists with metabolic dysfunction-associated steatotic liver disease (MASLD), a combination associated with heightened hepatic inflammation, immune dysregulation, and delayed virological responses to antiviral therapy (AVT). Metabolic stress may therefore reshape intrahepatic immune responses and drive bystander innate-like T-cell activation, sustaining liver injury despite viral suppression.
Method: Peripheral and intrahepatic CD8$^+$ T cells from healthy controls and patients with CHB (treatment-naïve and AVT-treated) were analysed using multi-parameter flow cytometry. Cellular activation, natural killer receptor (NKR) expression, effector function, and sensitivity to free fatty acids (FFAs; palmitic acid, oleic acid, docosahexaenoic acid [DHA], and arachidonic acid [AA]) were assessed. CD8$^+$ T cells were also isolated for transcriptomic profiling. In parallel, HepG2-NTCP models of HBV infection were used to assess the impact of lipid overload on HBV transcription and antiviral efficacy.
Results: Activated (CD38$^+$HLA-DR$^+$) CD56$^+$ CD8$^+$ T cells were significantly expanded in CHB, particularly in immune-active disease, with increased expression of NKRs including NKG2A and NKp30. Although AVT reduced their overall frequency, elevated NKR expression and innate-associated transcriptional signatures (including KLRK1 and NCR3) persisted. Functionally, CD56$^+$ CD8$^+$ T cells showed comparable IFN-gamma production following TCR-dependent and TCR-independent stimulation, but enhanced TNF-alpha production following IL-15 stimulation (TCR-independent), indicating a differential functional profile consistent with bystander activation. These cells were also more susceptible to functional suppression following FFA exposure. Complementary in vitro studies demonstrated that FFA exposure increased HBV transcriptional activity in infected HepG2-NTCP cells and this effect was not fully abrogated by AVT.
Conclusion: CHB is characterised by persistent expansion of metabolically sensitive, innate-like CD56$^+$ CD8$^+$ T cells with bystander inflammatory potential in the context of metabolic dysfunction. In parallel, lipid overload sustains HBV transcription despite AVT. Together, these findings identify a convergent immunometabolic axis linking MASLD, immune-mediated liver injury, and incomplete viral suppression in CHB.

THU-576
Drug-mediated transcriptional readthrough of HBV RNAs triggers antiviral effects in infected hepatocytes
Guillaume Giraud[1,2], Xavier Grand[1,2], Audrey Diederichs[1,2], Anaëlle Dubois[1,2], Maud Michelet[1,2], Fabien Zoulim[1,2], Barbara Testoni[1,2]. [1]*UCBL - INSERM UMR1350 - PaThLiv, Lyon, France;* [2]*The Lyon Hepatology Institute, Lyon, France*
Email: guillaume.giraud@inserm.fr

Background and aims: Current treatments against chronic hepatitis B (CHB) infection, albeit efficient in maintaining the infection under control, fail to completely eradicate hepatitis B virus (HBV). Thus, even treated patients have a higher risk of severe liver disease. HBV persistence is due to its minichromosome, the so-called covalently closed circular (ccc)DNA. It serves as the template for the transcription by the host RNA polymerase II of the six main viral transcripts. HBV RNAs are polyadenylated at their 3' end extremity, a process that is initiated by the recognition of a common polyadenylation signal (cPAS) that is linked to transcription termination. We previously identified a significant proportion of transcripts showing a transcriptional readthrough and stopping at a distal PAS. We demonstrated that this transcriptional readthrough destabilises HBV RNAs and is associated with a lower replication rate. This study thus functionally linked HBV transcription termination and replication opening the door to the usage of novel compounds to trigger this transcriptional readthrough. This can be achieved by inhibiting the termination factor CPSF3 by molecules such as JTE-607 prompting us to determine its antiviral effect in infected hepatocytes.
Method: We performed 3'RACE-PCR combined with single molecule sequencing using the Oxford Nanopore Technology to appreciate the ability of JTE-607 treatment of HBV-infected HepG2-NTCP cells to induce HBV transcriptional readthrough. HBV RNAs were quantified by RT-qPCR and viral protein levels were assessed by Western blot and ELISA experiments. Finally, viral replication was assessed by the quantification of HBV viremia in the supernatant of HepG2-NTCP cells.
Results: First, we performed 3'RACE-PCR assays combined with Oxford Nanopore single molecule sequencing to demonstrate that, indeed, as for host transcripts, JTE-607 treatment induced HBV transcriptional readthrough. Furthermore, the quantification of viral parameters demonstrated that JTE-607 treatment significantly decreased the levels of secreted antigens, HBV viremia and intracellular HBsAg and HBc proteins. As expected, these changes were associated with the significantly decreased HBV RNA levels due to their destabilisation. These results were further confirmed in primary human hepatocytes.
Conclusion: Altogether, these data demonstrated that HBV transcriptional termination might represent a new target for emerging antiviral strategies.

THU-577
Spatially clustered capsid substitutions distinguish human-tropic from zoonotic hepatitis E viruses
André Gömer[1,2], Anja Boekmann[3], Eike Steinmann[1,2]. [1]*Department of Molecular and Medical Virology, Ruhr University Bochum, Bochum, Germany;* [2]*Hepatitis E Virus Research Hub (HepE-Hub), Bochum, Germany;* [3]*Molecular Microbiology and Structural Biochemistry, CNRS/ Université de Lyon, Lyon, France*
Email: andre.goemer@rub.de

Background and aims: Hepatitis E virus (HEV), the leading cause of acute viral hepatitis worldwide, belongs to the family *Hepeviridae*, a genetically diverse group of positive-sense RNA viruses infecting a wide range of vertebrate hosts. Human infections are caused primarily by *Paslahepevirus balayani*, which comprises eight genotypes (HEV-1 to HEV-8) displaying marked differences in

epidemiology, host range, and clinical outcome. HEV-1 and HEV-2 are human-restricted, transmitted via the fecal–oral route, and predominantly cause acute hepatitis, whereas HEV-3 to HEV-8 are zoonotic, maintained in animal reservoirs including pigs, wild boar, and camels, and can cause both acute and chronic infection. Despite these pronounced phenotypic differences, overall genomic divergence among genotypes is only modest, raising the possibility that a limited number of substitutions drive host adaptation, though their identity and functional relevance remain unclear.

Method: To investigate the molecular basis of this divergence, we performed a comprehensive comparative analysis of ~800 full-length ORF2 capsid protein sequences across the *Hepeviridae* family, integrating phylogenetic reconstruction, sequence variability profiling, and three-dimensional structural mapping.

Results: ORF2 was highly conserved in the shell (S) and middle (M) domains but showed substantial diversification in the protruding (P) domain and terminal regions, which mediate receptor interaction and immune recognition. Within *Paslahepevirus*, maximum-likelihood phylogeny on ORF2 sequences resolved eight genotypes, and Jensen–Shannon divergence analysis identified a discrete set of residues that consistently distinguished human-tropic HEV-1 to HEV-2 from zoonotic HEV-3 to HEV-8 lineages. Notably, these substitutions were enriched on the protein surface, with several mapping to the P domain and overlapping known antibody-binding sites.

Conclusion: Together, these findings demonstrate that minor, structurally localized variation in the HEV capsid protein correlates with host tropism and may contribute to viral emergence. This study provides an evolutionary and structural framework for understanding *Hepeviridae* host adaptation.

THU-578

HBV-Specific T cell responses during early PEG-IFN α therapy

Yifei Guo[1], Yuqi Liu[1], Xiaoting Zhao[1,2], Haoxiang Zhu[1], Jiming Zhang[1,3]. [1]*Department of Infectious Diseases, Shanghai Key Laboratory of Infectious Diseases and Biosafety Emergency Response, Shanghai Institute of Infectious Diseases and Biosecurity, National Medical Center for Infectious Diseases, Huashan Hospital, Fudan University, Shanghai, China;* [2]*The First Affiliated Hospital of Xinxiang Medical University, Xinxiang, China;* [3]*School of Infection and Health, Xinxiang Medical University, Xinxiang, China*
Email: yfguo21@m.fudan.edu.cn

Background and aims: Prior studies have demonstrated that PEG-IFN α modulates HBV-specific T-cell functionality, which correlates with therapeutic outcomes. However, the temporal dynamics of HBV-specific T cell responses during the initial phase of PEG-IFN α therapy (12 weeks) and their relationship with the magnitude of HBsAg decline remain unexplored.

Method: This single-center prospective study enrolled 34 HBeAg-negative CHB patients undergoing PEG-IFN α therapy. Participants were stratified into three groups based on baseline HBsAg levels: the ENL group (HBsAg≤100 IU/mL), ENI group (100 IU/mL<HBsAg≤1000 IU/mL), and ENH group (HBsAg>1000 IU/mL). Additionally, patients were categorized into a good response group (>0.5 $\log_{10}$ IU/mL reduction in HBsAg from baseline) and a poor response group (≤0.5 $\log_{10}$ IU/mL reduction) at week 12 to compare intergroup differences in HBV-specific T cell responses. Core- and Env-specific T cells were quantified using ELISpot and ICS.

Results: Heterogeneous patterns emerged during treatment: the ENL group maintained baseline-level Core-specific T-cell responses, whereas the ENI group exhibited a marked decline. T-cell subset analysis revealed HBV-specific immune responses were predominantly mediated by CD4+ T cells. Comparative analysis of good response and poor response groups demonstrated stronger HBV-specific T-cell reactivity in good responders, characterized by significantly higher IFN-γ, IL-2, and TNF-α secretion levels from Core-specific CD4+ T cells at weeks 8 and 12. Additionally, Env-specific CD4+ T cells in good responders sustained robust IFN-γ and TNF-α production from baseline through week 12. Longitudinal individual-level analysis further highlighted a strong correlation between dynamic HBV-specific T-cell response trajectories and clinical outcomes: at week 4, 60.0% of good responders maintained or enhanced HBV-specific T cell response, significantly surpassing poor responders (38.9%), with this disparity widening over time.

Conclusion: Patients with early favorable responses to PEG-IFN α therapy demonstrated not only enhanced baseline IFN-γ and TNF-α secretion by Env-specific CD4+ T cells but also sustained maintenance or augmentation of HBV-specific CD4+ T cell reactivity throughout treatment. Consequently, early dynamic changes in HBV-specific T cell profiles may serve as predictive biomarkers for identifying optimal candidates for PEG-IFN α-based therapeutic strategies.

THU-579-YI

USP37 restricts hepatitis E virus infection by deubiquitinating ORF1 and promoting tollip-dependent autophagic degradation of ORF2

Jikai Zhang[1], Dan Liu[1], Wenshi Wang[1], Hongbo Guo[1]. [1]*Xuzhou Medical University, Xuzhou, China*
Email: hongbo.guo@xzhmu.edu.cn

Background and aims: Hepatitis E virus (HEV) is a leading cause of acute viral hepatitis globally, yet the host-virus interactions governing its life cycle remain poorly understood. Ubiquitin-specific peptidase 37 (USP37) is a deubiquitinase that regulates protein stability and cellular signaling, often acting as a critical node in host-virus interactomes. This study aims to elucidate the potential role of USP37 in HEV infection.

Method: We evaluated HEV replication using luciferase reporter assays, qRT-PCR, western blotting, and indirect immunofluorescence. Protein-protein interactions were characterized using co-immunoprecipitation (co-IP) assays.

Results: USP37 was identified as a key host restriction factor that suppresses HEV replication and progeny production. Mechanistically, USP37 exerts dual antiviral effects: 1) Replication Inhibition: USP37 directly interacts with the HEV ORF1 polyprotein and removes its K29-linked polyubiquitination, thereby impairing viral RNA replication. 2) Assembly and Secretion Blockade: USP37 cleaves K11-linked ubiquitin chains of autophagy receptor Tollip, enhancing its stability and facilitating the formation of a USP37-ORF2-Tollip complex. This promotes the autophagic degradation of both secreted ($ORF2^S$) and capsid ($ORF2^C$) proteins in a Tollip-dependent manner. Notably, the deubiquitinase-inactive mutant USP37(C350A) failed to inhibit ORF1 or degrade ORF2 proteins, demonstrating that these anti-HEV effects require USP37's catalytic protease activity.

Conclusion: Our findings reveal that USP37 acts as a vital host restriction factor against HEV by simultaneously disrupting ORF1-mediated replication and triggering Tollip-dependent autophagic degradation of ORF2 proteins. These results provide new insights into HEV pathogenesis and highlight USP37 as a potential target for novel antiviral therapies.

THU-580

MDL-001, an oral direct-acting Thumb-1 polymerase inhibitor, demonstrates efficacy against HCV/HBV co-infection in vitro, and achieves HCV and HBV preclinical proof-of-concept, including equivalence to sofosbuvir

Virgil Woods[1], Tyler Umansky[1], Sean Russell[1], Asha Goodman[2], Michael Bobardt[2], William Brubaker[3], Philippe Gallay[2], Davey Smith[4], Daniel Haders[1]. [1]*Model Medicines, San Diego, United States;* [2]*The Scripps Research Institute, La Jolla, United States;* [3]*Farmington Pharma, Cheshire, United States;* [4]*University of California San Diego, La Jolla, United States*
Email: virgil@modelmedicines.com

Background and aims: MDL-001 is a first-in-category oral direct-acting non-nucleoside inhibitor that binds a previously

underexploited allosteric pocket in the Thumb-1 domain of viral polymerase. We assessed inhibition of hepatitis C virus (HCV) and hepatitis B virus (HBV) in mono- and co-infection in vitro, established HCV and HBV proof-of-concept in vivo, and summarized nonclinical pharmacokinetic (PK) and safety data supporting clinical translation.
Method: HCV activity was measured in genotype 1b Con1 (Huh-luc/neo-ET) and genotype 2a JFH1 (Huh7.5.1) subgenomic replicons. HBV (AD38 ayw) activity was measured in HepAD38 cells, and HCV JFH1/HBV AD38 ayw co-infection was assessed in Huh7.5.1 cells. In vivo efficacy was evaluated in humanized MUP-uPA-SCID/Beige mice infected with HCV (JFH1/J6) or HBV (AD38). Resistance was selected by 8 weeks of serial passaging in an HCV replicon and characterized by genomic profiling. PK and safety data were compiled from completed nonclinical studies.
Results: MDL-001 inhibited HCV mono-infection in vitro with EC50/90 of 164/460 nM and 72/300 nM in Con1 and JFH1 replicons, respectively, and inhibited HBV mono-infection with an EC50/90 of 52/88 nM. MDL-001 suppressed an in vitro HCV-HBV co-infection model with similar potency. In vivo, oral MDL-001 reduced plasma HCV RNA by 3.27 $\log_{10}$ on day 28 compared with vehicle, achieving efficacy equivalent to that of sofosbuvir, with both treatments achieving viral load levels within the assay's limit of detection. In vivo, oral MDL-001 reduced plasma HBV rcDNA by 1.8 $\log_{10}$ on day 28. Pharmacokinetic studies demonstrated that Cmax and C24 drug concentrations in liver tissue were far in excess of EC90 s. An 8-week HCV resistance-mutation study yielded three MDL-001-resistant colonies with a convergent P495S mutation in the NS5B Thumb-1 domain. Safety data from >400 animals dosed in vivo at up to 16-fold the minimum efficacious dose (1.0 log10 reduction in plasma viral load in HCV) in a single-dose study and at 6-fold the minimum efficacious dose at 28 days reported no observed adverse events.
Conclusion: MDL-001 directly targets the Thumb-1 cryptic allosteric site that is present across RNA-dependent viral polymerases, delivering dual preclinical efficacy against HCV and HBV, as well as activity against HCV/HBV co-infection, with a safety and pharmacokinetic profile consistent with oral dosing. These data support completion of IND-enabling studies and clinical evaluation in chronic hepatitis B and C, including co-infected cohorts.

THU-585-YI
Bulevirtide treatment reduces bystander activation of CD8+ T cells in chronic hepatitis D virus infection

Email: chowdhury.shruti@mh-hannover.de

Background and aims: Infection with the hepatitis D virus (HDV) causes the most severe form of chronic viral hepatitis. This has been associated with bystander activation of $CD8^+$ T cells, which contribute to liver disease pathogenesis in chronic HDV infection. Improvement in liver function tests has been observed in HDV-infected patients treated with bulevirtide. Here, we aim to identify immunological correlates associated with improved liver function in virological responders under bulevirtide treatment.
Method: Peripheral blood mononuclear cells (PBMCs) and plasma samples were isolated from HDV-infected patients (n = 21) before (baseline) and at week 48 of bulevirtide treatment (TW48). Single-cell RNA sequencing and 34-color spectral flow cytometry were performed to assess the gene expression and the immune-cell phenotypes and function over time. A 48-plex immunoassay was performed on plasma samples to study the expression of cytokines. Viral response was defined as an HDV RNA decline ≥2 log10.
Results: Under bulevirtide treatment, HDV-infected patients show a significant decline in liver transaminases, aspartate transaminase to platelet ratio index (APRI) and fibroscan values. This is accompanied by a significant reduction of CXCL9, CXCL10 and CCL3 in the plasma of responders, reflecting decreased inflammation and type I interferon signaling. Importantly, when looking at interferon-stimulated genes (ISGs), these get significantly downregulated under bulevirtide treatment in responders, especially in the $CD4^+$ and $CD8^+$ T cell subsets. This is reflected by decreased frequencies of $CD4^+$ and $CD8^+$ central memory T cells (TCM) at baseline, which though show a capacity to recover at TW48. Interestingly, although reduced in numbers, these cells display higher levels of activation and cytotoxicity at the transcriptomic and proteomic level at baseline, accompanied by an increased bystander activation score in $CD8^+$ T cells before treatment initiation. This score is improving in all $CD8^+$ T cell subsets under bulevirtide treatment, which is also reflected by a significant reduction in NKG2D expression at the protein level.
Conclusion: Bulevirtide therapy reduced bystander activation of $CD8^+$ T cells at TW48, explaining the improvement in liver function. This improvement is more pronounced in virological responders compared to non-responders.

THU-586
Sequential mRNA vaccine-enabled quadruple therapy induces functional cure of HBV in rAAV8-1.3HBV carrier mice

Yuqi Hong[1], Shaohua Dong[1], Jinyao Dai[1], Yan Lou[2], Yunqing Qiu[2]. [1]*Zhejiang University School of Medicine, the First Affiliated Hospital, Hangzhou, China;* [2]*Zhejiang University School of Medicine, the First Affiliated Hospital, Hangzhou, China*
Email: yanlou@zju.edu.cn

Background and aims: Chronic hepatitis B functional cure remains difficult to achieve with current treatments, primarily due to HBV-induced multilayered immune tolerance. We proposed a sequential therapeutic strategy designed to gradually reduce viral antigen load, enhance antigen presentation, and promote cytotoxic T-cell memory formation to overcome this immune barrier.
Method: We designed a staged quadruple therapy: (1) Viral suppression using antisense oligonucleotides (ASO) and entecavir (ETV); (2) Dendritic cells (DCs) priming with IFNα to enhance antigen presentation; (3) Administration of a codon-optimized mRNA vaccine (encoding full-length HBV large S protein) delivered via chitosan nanoemulsions (mRNA@CNE) to induce cytotoxic memory T-cell responses.
Results: In rAAV8-1.3HBV carrier mice, this regimen induced durable functional cure in 50% of mice for over 17 weeks. A key finding was that functional cure depended on achieving HBsAg levels below 100 IU/mL before IFNα administration. This threshold was necessary to permit IFNα-mediated DC activation, which in turn enabled vaccine-expanded and functionally restored HBV-specific CD8+T cells, alongside dissolution of immunosuppressive networks. Non-responders (pre-IFNα HBsAg >100 IU/mL) displayed impaired DC-T cell interactions.
Conclusion: These results support a biomarker-guided sequential therapeutic framework with clear clinical applicability, providing a mechanistic and staged strategy to overcome HBV immune tolerance and advance toward functional cure.

THU-587

The potentially best-in-class HBV ASO ALG-170674 demonstrates additive to synergistic antiviral activities when combined with other anti-HBV modalities

Jin Hong[1], Vivek Rajwanshi[1], Hyunsoon Kang[1], Min Luo[1], Dinah Misner[1], Kusum Gupta[1], Antitsa Stoycheva[1], Kellan Passow[1], Jacquelyn Sousa[1], Dana Cho[1], John Cortez[1], Shane Daguison[1], Jieun Song[1], Lillian Adame[1], Cheng Liu[1], Sarah Stevens[1], Aneerban Bhattacharya[1], Rostom Ahmed-Belkacem[2], Susan Luong[1], Lawrence Blatt[1], Leonid Beigelman[3], David Smith[1], Julian Symons[1].
[1]Aligos Therapeutics, Inc., South San Francisco, United States; [2]Former Employee of Aligos Therapeutics, Inc., South San Francisco, United States; [3]Pacifica, United States
Email: jhong@aligos.com

Background and aims: Chronic hepatitis B (CHB) patients can achieve a modest rate of functional cure after monotherapy with antisense oligonucleotides (ASO) e.g. bepirovirsen (GSK-836) and AHB-137. To enhance the rate of functional cure, it will be important to combine HBV ASOs with other modalities of HBV drugs. ALG-170674 is a next generation HBV ASO that showed superior in vivo RNase H-mediated activity as well as PK compared to GSK-836 in an AAV-HBV mouse model. ALG-170674 also exhibited improved binding over GSK-836 to human TLR8 protein. ALG-001075 is the parent of the CAM-E prodrug, pevifoscorvir sodium (pevy, ALG-000184). In a 96-week study in CHB patients, ALG-000184 demonstrated the ability to dramatically reduce HBV viral load in all patients, as well as HBsAg in HBeAg+ patients. In this study, we demonstrate the antiviral effects of ALG-170674 in monotherapy and in combination with ALG-001075 or its analog in HBV cell and animal models. The effects of ALG-170674 in combination with other modalities such as nucleos(t)ide analogs (NAs), HBV siRNA and pegylated interferon (IFN) were also studied.
Method: In vitro HBV cell models such as HepG2.2.15, HepG2.117 and Emulate 3-D liver chips were used for ASO characterization and for combination studies in vitro. In vivo combination studies utilized the AAV-HBV mouse model.
Results: When dosed at 25 mg/kg in AAV-HBV mice, ALG-170674 showed a >0.6 $\log_{10}$ IU/mL additional maximum HBsAg reduction compared to GSK-836. ALG-170674 bound more tightly to human TLR8 protein with a Kd of 0.4 nM vs. 1.0 nM for GSK-836. Further, cytokine (IL6) induction was modestly higher than GSK-836 in a human PBMC assay. In PXB mice with humanized livers, ALG-170674 showed good liver safety when dosed at 50 mg/kg. In HepG2.2.15 cells as well as in 3-D human liver chips, combination of ALG-170674 and ALG-001075 demonstrated additive effects in HBsAg reduction. In AAV-HBV mice, analogs of ALG-170674 and ALG-001075 showed additive to synergistic effects in reducing HBV DNA in mouse plasma. Combinations of ALG-170674 with NAs, pegylated IFN and HBV siRNA are ongoing.
Conclusion: ALG-170674 exhibited potential to be a best-in-class HBV ASO. Additive to synergistic effects were observed when combining ALG-170674 and ALG-001075 (or close analogs) in preclinical studies. Combination of ALG-170674 and ALG-000184 could potentially improve functional cure rates in CHB patients, particularly in patients with higher baseline levels of HBsAg.

THU-588

Acute hepatitis E virus infection in asymptomatic blood donors is characterized by constrained intra-host diversity and temporal mutational signatures

Saskia Janshoff[1,2,3,4], Ricarda Plümers[3], Alina Kohl[2,4], Maximilian Nocke[1,2,4,5], Rui Costa[2,4], Tanja Vollmer[3], Daniel Todt[1,2,4,5], Eike Steinmann[2,4], André Gömer[2,4]. *[1]Department of Translational and Computational Infection Research (TRACiR), Ruhr University Bochum, Bochum, Germany; [2]Department of Molecular and Medical Virology, Ruhr University Bochum, Bochum, Germany; [3]Institut für Laboratoriums- und Transfusionsmedizin, Herz- und Diabeteszentrum Nordrhein-Westfalen, Universitätsklinikum der Ruhr-Universität Bochum, Universitätsklinikum der Universität Bielefeld, Bad Oeynhausen, Germany; [4]Hepatitis E Virus Research Hub (HepE-Hub), Ruhr University Bochum, Bochum, Germany; [5]European Virus Bioinformatics Center (EVBC), Jena, Germany*
Email: saskia.janshoff@rub.de

Background and aims: The hepatitis E virus (HEV) is the most common cause of acute viral hepatitis worldwide. RNA viruses like HEV can establish viral populations with high intra-host variability, which enables them to rapidly adapt to changing immune responses, as observed in chronic infections. To which extent intra-host diversity plays a role during acute infection remains unknown. This study aimed to characterize early intra-host evolutionary dynamics of HEV-3 during acute self-limiting asymptomatic infection. To understand early selective forces, we identified enriched variants in the RNA-dependent RNA polymerase (RdRp), quantified mutational signatures, and assessed the *in vitro* fitness of discovered variants.
Method: We sequenced the RdRp domain of viral populations in 82 asymptomatic blood donors with acute HEV-3 infection. Intra-host diversity was analyzed using Tanoti and DiversiTools. Variant frequency shifts were tracked in longitudinal samples. Recurrently enriched variants were characterized *in vitro* using replicon and trans-complementation assays.
Results: The overall HEV diversity within the host was constrained, however, several recurrent substitutions were identified, and four mutations in the polymerase region were found to be enriched among the donors. Despite being markedly replication-deficient *in vitro*, their replication defects could be rescued by Kernow/C1-p6 strain in a trans-complementation assay. Longitudinal sampling in a subset of donors revealed temporal shifts in variant frequencies, indicating ongoing early selection dynamics. In contrast to chronic HEV infection in immunosuppressed patients, acute phase populations exhibited a significantly lower number, and an absence of high-frequency variants. Similarly, premature stop codons and replication deficient variants were primarily detected in patients with acute infection, but not in patients with chronic infection.
Conclusion: Although HEV diversity is markedly restricted during acute infection, the early evolutionary landscape is highly dynamic but constrained even within the short window of acute, self-limiting and asymptomatic disease. These findings offer mechanistic insights into early intra-host evolution, highlight conditions under which deleterious variants can transiently persist, and lay the groundwork for linking genotypic features to clinical outcomes and treatment responsiveness.

THU-589-YI

Seroprevalence and viral biomarker characterization of hepatitis D infection in treatment naive-infected blood donors with hepatitis B in Cameroon

Rodrigue Kamga Wouambo[1], Nadesh Ashukem Taku[2,3], Noel Simon Ateba[2,4], Maria Pfefferkorn[1], Shirin Nkongolo[5,6,7], Gnimah Eva Gnouamozi[6,7], Madlen Matz-Soja[1], Stephan Urban[6,7], Thomas Berg[1], Florian van Bömmel[1], Francoise Ngo Sack[2,8]. *[1]Division of Hepatology, University of Leipzig Medical Centre, Leipzig, Germany; [2]Blood Bank, Yaounde Central Hospital, Yaounde, Cameroon; [3]Faculty of Health Science, University of Buea, Buea, Cameroon; [4]Faculty of Medicine and Biomedical Sciences, University of Yaounde I, Yaounde, Cameroon; [5]Internal Medicine IV (Gastroenterology, Hepatology, Infectious Diseases), University Hospital Heidelberg, Heidelberg, Germany; [6]University Hospital Heidelberg, Department for Infectious Diseases, Molecular Virology, Heidelberg, Germany; [7]German Center for Infection Research (DZIF), partner site Heidelberg, Heidelberg, Germany; [8]Faculty of Medicine and Pharmaceutical Sciences, University of Douala, Douala, Cameroon*
Email: rodrigue.kamgawouamba@medizin.uni-leipzig.de

Background and aims: Hepatitis delta virus (HDV) infection causes the most severe form of chronic viral hepatitis, yet it remains

significantly under-researched in Sub-Saharan Africa (SSA). In Cameroon, data on HDV prevalence and its interaction with hepatitis B virus (HBV) biomarkers are scarce, hindering effective public health interventions and clinical trials. Our study investigated the HDV seroprevalence and HBV biomarker characterization of HDV infection among HBsAg positive blood donors in Yaoundé, Cameroon.

Method: A cross-sectional study was conducted on HBsAg-positive serum samples collected from 2023 to 2025 at the blood bank of the Yaounde Central Hospital in Cameroon (ethical approval n°: 002382/CRERSHC/2025). A rapid screening of anti-HDV antibodies was conducted by lateral flow immunoassay (HDV rapid test, Heidelberg). Molecular and serological assays were undertaken for HBV biomarker assessment (HBV DNA, HBV RNA, total HBsAg; detection limits 157.5 cp/mL, 280 cp/mL and 0.05 IU/mL). HBV DNA (Log UI/mL) and HBsAg (Log UI/mL) were classified in low and intermediate/high: ≤3.3, >3.3 and ≤3, >3, respectively.

Results: Out of 126 HBsAg-positive blood donors, 92.8% men, median age: 29 [15–61] years, overall seroprevalence of anti-HDV was 24.6% (31/126; 95% CI: 17.6%–33.0%). HDV prevalence was 25.6% in males compared to 11.1% in females (p = 0.45). HBV DNA and HBV RNA could be quantified in 62.7% (79/126) and 38.1% (48/126) of patients. Globally, 85.7% exhibited low viral loads (HBV DNA <3.3 Log IU/mL). Intermediate/high HBsAg levels (>3 Log IU/mL) were found in 84.9%. Median HBV DNA, RNA levels were 1,7 [0.0–8.1] Log IU/mL, 0.7 [0.0–8.4] Log cp/mL, and 3.9 [0.0–5.6] Log IU/mL, respectively. Notably, anti-HDV carriers showed significantly lower HBV DNA levels compared to anti-HDV negative subjects (4.9 ± 5.7 vs. 6.5 ± 7.8 Log IU/mL; p = 0.04), suggesting HDV-mediated suppression of HBV replication. No significant differences were observed in HBV RNA or HBsAg levels between the two groups. Anti-HDV seropositivity was also markedly higher in subjects presenting with jaundice (100% vs. 24.2%; p = 0.08).

Conclusion: Our pilot data reveal a substantial seroprevalence of anti-HDV antibodies (24.6%) in apparently healthy blood donors in Cameroon. These findings underscore the urgent need to implement systematic HDV screening and establish specialized treatment pathways in Cameroon to mitigate the severe health outcomes associated with hepatitis delta.

THU-590

Development of a novel TLR-7 agonist SA-5 as a therapeutic option for chronic hepatitis B: a multimodal biomarker scoring for safety and efficacy in the first-in-human study

Tatsuya Kanto[1], Takahiro Kodama[2], Shokichi Takahama[3], Sachiyo Yoshio[4], Takuya Yamamoto[3]. *[1]The Research Center for Hepatitis and Immunology, National Institute of Global Health and Medicine, Japan Institute for Health Security, Ichikawa, Japan; [2]Department of Gastroenterology and Hepatology, Graduate School of Medicine, The University of Osaka, Suita, Japan; [3]Laboratory of Precision Immunology, Center for Intractable Diseases and Immuno-Genomics, National Institutes of Biomedical Innovation, Health and Nutrition, Suita, Japan; [4]Department of Human Immunology and Translational Research, National Institute of Global Health and Medicine, Japan Institute for Health Security, Tokyo, Japan*
Email: kanto.t@jihs.go.jp

Background and aims: Various new drugs, including immune modulators, are under development to achieve a functional cure in patients with chronic hepatitis B (CHB). We are developing a novel TLR7 agonist (SA-5) with enhanced in vivo targeting to the liver. SA-5 is specifically designed as a substrate for the organic anion-transporting polypeptides OATP1B1 and OATP1B3, which are expressed on hepatocyte sinusoidal membranes. To prepare the investigator-initiated First-in-Human (FIH) study of SA-5, we examined the safety and efficacy of SA-5 in HBV mouse models and cynomolgus monkeys and assessed the feasibility of biomarkers in the clinical trial.

Method: To clarify the in vivo safety and anti-HBV activity, SA-5 was administered orally once a week for 4 to 12 weeks to HBV mouse models and cynomolgus monkeys. Safety was evaluated through hematologic, biochemical, and flow cytometric profiling, while efficacy was assessed via Interferon (IFN)-alfa production, gene expression of IFN-stimulated genes (ISGs), and plasmacytoid dendritic cell activation. A principal component analysis-based composite scoring system was used to integrate multimodal parameters.

Results: We established a novel HBV mouse model in which mouse hepatocytes were replaced by FAH-HBV-expressing hepatocytes using the Sleeping Beauty transposon system (CMGH 2025). Short-term administration of SA-5 resulted in a transient increase in ALT, and HBV DNA and HBV pgRNA levels were significantly reduced. Compared to the control IFN-alfa-treated group, ISG expression was increased in the SA-5-treated group, and the cytotoxic activity of intrahepatic NK cells and CD8+ T cells was stronger. Additionally, intrahepatic T cells differentiated into effector memory T cells. These results indicate that SA-5 exerts not only activating innate immunity but also on adaptive immunity. In cynomolgus monkeys, SA-5 treatment for 12 weeks induced a dose-dependent type I IFN response, accompanied by limited systemic inflammation. SA-5 had comparable immunostimulatory activity to GS9620 but with reduced adverse biomarker shifts. We are in the process of regulatory approval and aim to start an investigator/physician-initiated FIH study of SA-5 in 2Q of 2026.

Conclusion: SA-5 is a safer, next-generation TLR-7 agonist for chronic HBV infection, highlighting the importance of integrated biomarker profiling in preclinical immunomodulatory anti-HBV drug development.

THU-591

Immune-metabolic dysregulation and systemic inflammation drive accelerated liver disease in HBV/HDV coinfection

Arshi Khanam[1], Furkan Kaysin[2], Cihan Yurdaydin[2], Shyamasundaran Kottilil[1]. *[1]Institute of Human Virology University of Maryland, Baltimore, United States; [2]Koc University School of Medicine, Istanbul, Türkiye*
Email: arshigbpant@gmail.com

Background and aims: Chronic hepatitis B virus (HBV) infection and HBV/hepatitis D virus (HDV) coinfection are major global drivers of liver disease and hepatocellular carcinoma. Coinfected individuals experience accelerated liver damage and poor clinical outcomes despite antiviral therapy, posing a critical barrier to mitigating end-stage liver disease. The mechanisms driving disease acceleration remain unclear, underscoring an urgent need to define molecular and immunological pathways that can be targeted to mitigate disease progression.

Method: Peripheral blood samples from individuals with chronic HBV-monoinfection and HBV/HDV-coinfection underwent high-throughput transcriptome sequencing to reveal HDV-driven alterations in gene expression. In parallel multiplex cytokine profiling quantified levels of plasma inflammatory and fibrogenic mediators, revealing signatures of immune dysregulation, heightened inflammatory signaling associated with accelerated liver disease progression.

Results: Transcriptomic profiling of peripheral blood mononuclear cells revealed a dual signature of activated immune system and suppressed metabolic function in HBV/HDV-coinfected patients compared to HBV alone. Upregulated genes included pattern recognition receptors (TLR1, TLR4, TLR8), inflammasome component (NLRC4), TNF receptor family members (TNFRSF8, TNFRSF10C), metabolic regulators (NAPRT, SLC28A3), lipid and oxidative stress mediators (CYBB, CD36), transcriptional regulator (MECOM) and antigen-presenting molecules (HLA-DQB1). These changes indicate activation of NF-kB driven inflammatory pathways, caspase-1 dependent cell death, enhanced reactive oxygen generation, and increased immune activation. Conversely, downregulated genes

included those involved in metabolic regulation (G0S2, SLC2A14), immune homeostasis (NR4A3), stress response (DNAJB5), and oxygen transport (HBA2, HBB), suggesting impaired energy metabolism, reduced immune regulation and diminished stress tolerance. Plasma cytokine profiling revealed elevated levels of proinflammatory and fibrogenic mediators including IFN-γ, TNF-α, IL-17, IL-22, CXCL2, CXCL13 and TGF-β, in HBV/HDV-coinfection than HBV alone, confirming systemic inflammation in these patients.
Conclusion: Collectively, these findings highlight systemic inflammatory activation coupled with metabolic dysfunction, contributing to immune dysregulation and accelerated liver disease progression in HBV/HDV-coinfection.

Email: mara.kloehn@rub.de

Background and aims: Hepatitis E virus (HEV) remains an important but largely understudied zoonotic pathogen. A universally available vaccine is lacking, and current treatments are limited by severe side effects, teratogenicity, and frequent therapeutic failures. Drug repurposing may therefore accelerate the discovery of effective anti-HEV therapies. This study aimed to identify and characterize nucleos(t)ide analogs with antiviral activity against HEV.
Method: A library of 496 nucleoside and nucleotide analogs was screened for inhibitory effects on HEV replication while monitoring cell viability. Compounds demonstrating strong antiviral efficacy were further assessed for dose–response relationships, activity across HEV genotypes and cell types, and potential mechanisms of action. In silico docking simulations were conducted to evaluate the interaction between candidate compounds and the HEV polymerase. In vivo efficacy was tested in an athymic nude rat model of HEV infection.
Results: Ten compounds inhibited HEV replication by more than 60% while maintaining cell viability above 75%, including four that showed clear dose–response relationships. Among these, 4′-fluorouridine (4′-FlU) exhibited potent antiviral activity in both replication (EC50 ≈ 5 µM) and infection (EC50 ≈ 10 µM) assays against HEV-Kernow-C1/p6 and HEV-1 Sar55 strains. The compound also demonstrated efficacy in extrahepatic cell lines (placental JEG-3, intestinal Caco-2, and renal HEK293 T) and in primary human hepatocytes. Combination treatment with ribavirin resulted in an additive antiviral effect. In silico docking indicated binding of 4′-FlU to the HEV RNA-dependent RNA polymerase. Furthermore, exogenous uridine reversed the inhibitory effect of 4′-FlU on HEV-3 replication, suggesting that UTP competes with the active metabolite 4′-FlU-5′-triphosphate for incorporation by the polymerase. In vivo, daily administration of 20 mg/kg 4′-FlU to HEV-infected rats significantly reduced viral titers in feces, liver, kidney, intestine, and spleen.
Conclusion: Ongoing studies are evaluating 4′-FlU in treatment and combination settings with ribavirin in rats, as well as in HEV-1 infected mice. Altogether, these findings identify 4′-FlU as a promising candidate for HEV therapy.

THU-593
Replication assessment of chimeric HEV-3 subtypes demonstrate enhanced replication fitness of HEV-3f isolates
Alina Kohl[1,2], Rui Da Costa[1,2], Michelle Jagst[1,2], Daniel Todt[1,2,3], Eike Steinmann[1,2], André Gömer[1,2]. *[1]Department of Molecular und Medical Virology, Ruhr University Bochum, Germany, Bochum, Germany; [2]Hepatitis E Virus Research Hub (HepE-Hub), Bochum, Germany, Bochum, Germany; [3]Department of Translational and Computational Infection Research (TRACiR), Ruhr University Bochum, Germany, Bochum, Germany*
Email: alina.kohl@rub.de

Background and aims: Hepatitis E virus (HEV) remains an underestimated global health concern, causing an estimated 20 million infections and up to 70,000 deaths annually. While infections are often asymptomatic, HEV can become chronic in immunocompromised individuals and is associated with mortality rates of up to 25% in pregnant women. In Europe, genotype 3 (HEV-3) is the most common and comprises 15 subtypes grouped into three clades: Clade 1 (3e–3g), Clade 2 (3a–3c, 3h–3o) and Clade 3 (3ra). In particular, clade 1 has been associated with more severe disease outcomes, although the underlying mechanisms remain unclear - likely due to the lack of suitable cell culture systems.
Method: To address this gap, we performed a phylogenetic analysis of HEV-3 subtypes and generated a library of 15 primary isolate-derived polymerase chimeras, each inserted into the backbone of the Kernow-C1 p6 subgenomic replicon. We evaluated replication kinetics and antiviral responses to ribavirin and sofosbuvir.
Results: Phylogenetic analysis revealed considerable diversity among the HEV-3 polymerases, with up to 21 amino acid substitutions relative to p6. 13 of the 15 chimeras demonstrated replication comparable to the parental p6 construct. The HEV-3f subtype showed significantly enhanced replication kinetic, with up to a 5-fold increase. All chimeras remained sensitive to antiviral drugs, with only minor variations in ribavirin susceptibility.
Conclusion: Our findings highlight the genomic flexibility of HEV-3, which allows for efficient replication of diverse chimeric constructs. This model provides a robust platform for assessing intra-genotypic variability in antiviral responses and advances our mechanistic understanding of replication fitness. Such insights are critical for optimising treatment strategies and understanding the burden of disease in HEV-infected patients.

THU-594
Detailed molecular profiling of intrahepatic and serum viral markers in HBeAg-positive chronic hepatitis B patients without clinical cirrhosis
Jung Hyun Kwon[1], Hye Seon Kim[2], Soon Kyu Lee[1], Jeong Won Jang[3].
[1]College of Medicine, The Catholic University of Korea, Division of Hepatology, Department of Internal Medicine, Incheon St. Mary's Hospital, Incheon, Korea, Rep. of South; [2]College of Medicine, The Catholic University of Korea, Department of Biomedicine & Health Sciences, Seoul, Korea, Rep. of South; [3]College of Medicine, The Catholic University of Korea, Division of Hepatology, Department of Internal Medicine, Seoul St. Mary's Hospital, Seoul, Korea, Rep. of South
Email: doctorkwon@catholic.ac.kr

Background and aims: In HBeAg-positive chronic hepatitis B (CHB) patients, managing those not meeting classic immune-active (IA) criteria is an area of active investigation. While clinical trends suggest broader antiviral therapy (AVT) application, the molecular characteristics of the expanded immune-tolerant (IT) spectrum are not fully elucidated. We aimed to compare intrahepatic and serum viral markers between an Expanded IT group and the IA group to identify predictors of disease progression in clinically non-cirrhotic patients.

Method: We enrolled 78 HBeAg-positive, clinically non-cirrhotic CHB patients. The IA group (ALT >80 U/L and HBV DNA >20,000 IU/ml) was compared with the Expanded IT group (all non-IA patients). Within the Expanded IT group, a subgroup meeting Strict IT criteria (ALT <40 U/L and HBV DNA >7 log IU/ml) was separately analyzed. We analyzed intrahepatic cccDNA, pgRNA, and S RNA, along with serum HBsAg, HBV DNA, HBcrAg, and HBV RNA. Clinical events (LC or HCC) were monitored during follow-up.
Results: The Expanded IT group exhibited significantly higher serum HBV DNA and HBsAg levels compared to the IA group. Although serum HBV RNA was higher in the IA group, intrahepatic cccDNA and pgRNA levels were comparable between groups, indicating substantial viral replication potential across the expanded spectrum. In a focused sub-analysis, patients meeting Strict IT criteria showed significantly higher intrahepatic pgRNA and total HBV RNA levels than the IA group, demonstrating that intrahepatic viral transcriptional activity is most robust in the strictest IT phase. Regarding clinical outcomes, histological and clinical progression was notably absent in the Strict IT subgroup. In contrast, the majority of clinical events (LC or HCC) were concentrated in patients within the Expanded IT group who did not meet the strict IT criteria, whereas no events occurred in the IA group where AVT was initiated after enrollment.
Conclusion: HBeAg-positive patients in the Expanded IT spectrum harbor substantial intrahepatic viral activity equivalent to or exceeding that of IA patients. Clinical progression is predominantly concentrated in those who fail to meet strict IT criteria. Our findings suggest that any deviation from the Strict IT profile should be considered a high-risk indicator, warranting earlier therapeutic intervention in the expanded IT spectrum.

THU-595

Reduced apoptosis in HBV/HDV-expressing hepatocytes due to HDV-specific modulation of EphA signaling

Pia Lembeck[1], Keerthihan Thiyagarajah[2,3], Mirco Glitscher[2], Jannik Sonnenberg[1], Laurin Büning[1], Jonel Trebicka[1], Eberhard Hildt[2,4], Kai-Henrik Peiffer[1]. *[1]University Hospital Münster, Medical Clinic B, Münster, Germany; [2]Paul-Ehrlich-Institute, Research Group 2, Langen, Germany; [3]Hospital of the Goethe University Frankfurt, Internal Medicine I, Frankfurt, Germany; [4]Hasso-Plattner-Institute, Digital Health Cluster, Potsdam University, Potsdam, Germany*
Email: pia.lembeck@ukmuenster.de

Background and aims: HDV co-infection in chronic hepatitis B (CHB) patients is associated with severe liver disease and HCC development. Despite elevated TNFalpha levels, HDV persists, suggesting modulation of host cell death pathways. This study investigated the impact of HDV on TNFalpha-dependent (NF-kappaB/AP-1) and -independent (EphA) apoptotic pathways in HBeAg-positive and -negative HBV-expressing hepatocytes.
Method: Huh7 cells were co-transfected with HBeAg-positive or -negative HBV genotype A genomes and HDV full genome or HDV-specific proteins expressing plasmids. TNFalpha-mediated apoptosis was induced with TNFalpha/cycloheximide or DMSO control. Apoptosis was quantified by Annexin V/PI flow cytometry, NF-kappaB and AP-1 promoter activities by luciferase reporter assays, and deregulated kinases were identified by kinome profiling of HDV-transfected hepatocytes.
Results: Basal apoptosis was elevated in HBeAg-negative HBV-expressing hepatocytes. HDV co-transfection reduced apoptosis in both HBeAg-positive and -negative cells under both TNFalpha-stimulated and unstimulated cells, with strongest effect in HBeAg-negative cells. While HBV reduced, HDV increased cell viability. NF-kappaB and AP-1 promoter activities were greatly suppressed by HDV, S-HDAg or L-HDAg. Kinome profiling revealed downregulation of multiple Ephrin type-A receptor kinases (EPHA1, EPHA3, EPHA4, EPHA5, EPHA7) in cells expressing full-length HDV genome.
Conclusion: HDV promotes hepatocyte immortalization by modulating apoptotic and stress-response pathways. Suppression of NF-kappaB and AP-1 activity and downregulation of pro-apoptotic EphA signaling, potentially involving EphA-associated caspase-8, suggest coordinated and balanced regulation of programmed cell death. By enabling hepatocyte survival, these mechanisms may facilitate viral persistence, dominance in HBV/HDV-crosstalk, and contribute to pathophysiology and HCC development. EphA-related signaling emerges as a potential therapeutic target.

THU-596

4-1BB costimulation restores T follicular helper 1 cell function to augment hepatitis B virus-specific humoral immunity in chronic infection

Yanchen Ma[1], Xiaoyi Liu[1], Haonan Lou[1], Hui Zhang[1], Jinyan Jiang[1], Libo Tang[1], Yongyin Li[1]. *[1]Department of Infectious Diseases, Nanfang Hospital, Southern Medical University, Key Laboratory of Infectious Diseases Research in South China (Southern Medical University), State Key Laboratory of Multi-organ Injury Prevention and Treatment, GuangZhou, China*
Email: 767895970@qq.com

Background and aims: Chronic HBV infection is closely associated with dysregulated humoral immunity. Although our study demonstrated that Mother-to-child transmission could be dramatically reduced by the comprehensive interventions among HBV-infected pregnant women (Nature Medicine, 2024), how intrauterine HBV antigen exposure shapes host humoral immunity remains unclear. Here, we investigated the humoral immune profile in cord blood from neonates born to HBV-infected mothers to identify potential therapeutic targets and validate if targeting these pathways restores HBV-specific humoral immunity in chronic infection cohorts.
Method: We analyzed cord blood samples from 73 neonates born to HBsAg-positive mothers and 24 counterpart controls (HBsAg-negative mothers). B cell and $CD4^+$ T cell phenotypes and transcriptomes were analyzed by flow cytometry and RNA-seq. HBV-specific B cells were quantified via ELISPOT and ELISA. Additionally, peripheral blood from 85 untreated chronic HBV patients (aged 1–65 years) was evaluated by full-spectrum flow cytometry to determine Tfh1-cell functional dominance and age-related distribution.
Results: Cord blood from HBV-exposed neonates exhibited enhanced HBV-specific B cell responses along with significantly elevated frequencies of type 1 follicular T helper cells (Tfh1) compared to controls. In vitro, HBsAg could induced naïve $CD4^+$ T cells to differentiate into Tfh1 cells, but not Th1/Th2/Th17 or Tfh2/Tfh17 subsets. Tfh1 cells secrete both IFN-γ and IL-21, which synergistically enhanced HBsAb production by B cells via the activation of mTORC1-STAT1/STAT3 pathway. These data demonstrate that primary HBV antigen exposure preferentially induces a Tfh1-polarized immune response that initiates HBV-specific humoral immunity. To assess Tfh1 dynamics in chronic infection, we performed full-spectrum flow cytometry on a clinical HBV cohort, revealing an age-dependent decline in both Tfh1 frequency and 4-1BB expression, which positively correlated with HBsAb-secreting B cell counts. Strikingly, 4-1BB stimulation in vitro restored Tfh1 function, rescuing IFN-γ and IL-21 production and enhancing B cell help.
Conclusion: Tfh1-derived IFN-γ and IL-21 potentiate HBsAb production by activating mTORC1-STAT1/STAT3 signaling in B cells. The age-dependent decline in Tfh1 frequency and 4-1BB expression suggests progressive immune dysfunction in chronic HBV infection. Targeting 4-1BB may rejuvenate Tfh1 activity, offering a novel strategy to restore HBV-specific humoral immunity.

THU-597

CX-5461 exerts pangenotypic anti-hepatitis E virus effect in preclinical models

Yuebao Li[1], Tianxu Liu[1], Lin Wang[1]. [1]*Peking University Health Science Center, Beijing, China*
Email: lin_wang@pku.edu.cn

Background and aims: Hepatitis E virus (HEV) is one of the common causes of acute hepatitis worldwide. Clinically, HEV infection presents as either acute or chronic disease. Acute infection mainly occurs in immunocompetent individuals, especially in vulnerable populations is associated with high mortality. Chronic infection mainly develops in immunocompromised patients and carries the risk of progressing to liver fibrosis and cirrhosis. Specific antiviral drugs targeting HEV are still lacking, and the use of ribavirin is limited by adverse effects or treatment failure. Therefore, there is an urgent need for novel antiviral strategies to address future clinical demands.
Method: Potential G-quadruplex (G4) forming sequences in the HEV genome were predicted using bioinformatics analysis and validated through *in vitro* experiments. The antiviral activity of three known G4 ligands was evaluated using *in vitro* infection assay. Mongolian gerbil models of HEV infection were used to evaluate the antiviral effect of CX-5461 against acute HEV-1, -3, and -4 infection. A tacrolimus-induced rabbit model of chronic HEV infection was used to examined the antiviral effect of CX-5461 against HEV-3ra chronic infection.
Results: Bioinformatic and *in vitro* analyses identified 4 highly conserved, G4-forming sequences in the HEV genome. Among three G4 ligands tested *in vitro*, CX-5461, a drug in clinical trials for cancer showed potent antiviral activity (IC_{50} = 19.36 nM). In gerbils infected with HEV-1, -3, or -4, fecal viral shedding was reduced within 2 days post-treatment, along with significantly lowered viral RNA loads and antigen levels in the liver, kidney, and intestine. Notably, in HEV-3-infected gerbils, hepatic viral RNA loads and antigen levels were reduced by 224-fold and 8-fold, respectively. In chronic HEV-3ra-infected rabbits, CX-5461 treatment consistently reduced fecal viral shedding, reaching levels comparable to the ribavirin group by 30 days post-treatment. Hepatic viral RNA was reduced to a level similar to that in the ribavirin group.
Conclusion: These findings demonstrate that the HEV genome contains G4s, and the CX-5461 exhibits robust antiviral activity both *in vitro* and *in vivo*. CX-5461 showed promising pangenotypic efficacy in multiple preclinical models. These results support CX-5461 as a novel strategy for treating acute and chronic HEV infection.

THU-601-YI

Targeting host cell metabolism via the pentose phosphate pathway blocks hepatitis B virus surface antigen release and hepatitis D virus replication

Qiudi Li[1], Hongbo Guo[1], Zhenfeng Zhang[2], Wenshi Wang[1]. [1]*Jiangsu Key Laboratory of Immunity and Metabolism, School of Basic Medical Sciences, Xuzhou Medical University, Xuzhou, China;* [2]*School of Public Health and Emergency Management, Southern University of Science and Technology, Shenzhen, China*
Email: liqiudi1209@163.com

Background and aims: Chronic hepatitis D virus (HDV) infection represents the most severe form of viral hepatitis. Besides its dependence on HBV envelopment, HDV heavily depends on cellular machinery and metabolites to complete its obligate parasitic replication life cycle. Herein, we aim to identify critical metabolic components or pathways essential for HDV replication.
Method: We conducted systematic metabolite profiling using an in vitro cell model that stably supports HDV replication, alongside a replication-defective control model.
Results: HDV replication markedly reduced the levels of most cellular carbohydrates and their metabolites. Notably, inhibition of the pentose phosphate pathway (PPP)—but not other glycolytic pathways—suppressed HDV replication. Mechanistically, the suppression of HDV replication was due to the inhibition of de novo biosynthesis of guanine and cytosine, which are downstream of the PPP. Inhibitors targeting PPP–guanine/cytosine biosynthesis axis exhibited potent antiviral activity against different genotypes of patient-derived HDV isolates. The efficacy of these inhibitors was influenced by HDV replication status. However, the combination of guanine/cytosine biosynthesis inhibitors with IFN-α synergistically inhibited HDV replication. Notably, besides the suppressive effect on HDV replication, PPP inhibition also reduced HBsAg secretion derived either from cccDNA or HBV integrates. Nonetheless, the blockage of HBsAg secretion was independent of its downstream guanine and cytosine biosynthesis pathway.
Conclusion: Targeting host cell metabolism via PPP exerts a dual effect-inhibiting HDV replication and blocking HBsAg release, highlighting its therapeutic potential against both HBV infection and HBV/HDV coinfection.

THU-602

Deciphering the mechanistic underpinnings of hepatitis E severity: a tale of T cell exhaustion and maladaptive cDC2 activation at single-cell resolution

Jian Wu[1], Xiaoman Liu[2], Yijin Wang[2]. [1]*Department of Clinical Laboratory, The Affiliated Suzhou Hospital of Nnjing Medical University, Suzhou Municipal Hospital, Gusu School, Nanjing Medical University, 242 Guangji Rd, Suzhou, China;* [2]*Department of Pharmacology, Joint Laboratory of Guangdong-Hong Kong Universities for Vascular Homeostasis and Diseases, School of Medicine, Southern University of Science and Technology, Shenzhen, China*
Email: wangyj3@sustech.edu.cn

Background and aims: Hepatitis E virus (HEV) represents a major global cause of acute viral hepatitis, typically self-limiting yet capable of advancing to life-threatening acute liver failure (ALF). The immunological determinants of disease severity remain poorly defined. We therefore profiled the peripheral immune landscape to uncover mechanisms underlying progression to HEV-induced ALF.
Method: PBMCs from 20 subjects, including acute hepatitis E (AHE, n = 8), HEV-induced ALF (HEV-ALF, n = 8), and healthy controls (HCs, n = 4) were analyzed by single-cell RNA sequencing. Integrated analysis encompassed differential expression, pathway enrichment, pseudotemporal trajectory reconstruction, and cell-cell communication mapping to delineate immune heterogeneity and dynamics across disease severity.
Results: Unsupervised clustering delineated 23 transcriptomic clusters across six immune lineages. HEV infection triggered a broad IFN-γ response across all immune compartments. Compared to AHE, ALF was characterized by marked activation of inflammatory pathways, including NOD-like receptor, TNF, NF-κB, IL-2-STAT5, and IL-17 signaling. T and NK cells partitioned into nine functionally discrete subsets. While IL-17 signaling was confined to naïve T cells in AHE, it became pervasive across all NK/T cells in ALF. Although $CD8^+$ effector memory T cells (TEM) expanded in both AHE and ALF, $HLA\text{-}DR^+CD38^+CD8^+$ TEM predominated in AHE. Strikingly, $CD8^+$ TEM displayed profound downregulation of cytotoxic effectors (GZMA, GZMH, GNLY, PRF1) in ALF. GSEA further revealed suppression of CTLA4 and antigen presentation pathways, alongside activation of TID, TNF-JNK, JAK-STAT, and TGF-β signaling in ALF TEM. Pseudotime analysis positioned $CD8^+$ TEM at a terminally differentiated state in ALF, with key differentially expressed genes including elevated JUN and reduced IFI16, ISG15, GBP1. Conventional type 2 dendritic cells (cDC2) were decreased in both disease stages. In ALF, cDC2 demonstrated hyperactive MHC-II machinery, upregulation of all eight HLA class II genes, and the highest myeloid HLA-II module score, indicating maladaptive antigen-presenting capacity.
Conclusion: HEV-induced ALF were characterized by widespread inflammatory activation, functionally paralyzed $CD8^+$ TEM, and maladaptive cDC2-mediated antigen presentation. The coexistence of hyperinflammation and effector T cell impairment elucidates the

immunological basis of disease severity and identifies actionable targets for rebalancing immunity in severe hepatitis E.

Divergent immune resolution and protracted immuno-metabolic memory in hepatitis E revealed by cross-species multi-omics

Yining Liang[1], Tianxu Liu[2], Xiaoman Liu[1], Lin Wang[2], Yijin Wang[1]. [1]*Department of Pharmacology, Joint Laboratory of Guangdong-Hong Kong Universities for Vascular Homeostasis and Diseases, School of Medicine, Southern University of Science and Technology, Shenzhen, China;* [2]*Department of Microbiology and Infectious Disease Center, School of Basic Medical Sciences, Peking University Health Science Center, Beijing, China*
Email: wangyj3@sustech.edu.cn

Background and aims: Hepatitis E virus (HEV) infection represents a growing global health burden. Emerging evidence suggests that liver injury is primarily immune-mediated rather than resulting from direct viral cytopathy. This study aims to delineate the longitudinal immuno-metabolic landscape of HEV infection and to identify pathogen-specific immune signatures through cross-species comparison.
Method: We established a longitudinal rabbit model infected with HEV genotype (gt) 3, collecting liver and serum samples at baseline (HEV-BL), first viremia (HEV-F), peak viremia (HEV-P), and viral clearance (HEV-N) stages. Multi-omics profiling included transcriptomic and proteomics from liver tissues, alongside serum metabolomics. For cross-species validation, we analyzed public transcriptomic data from HEV gt1- and hepatitis C virus (HCV)-infected chimpanzees (GSE22160).
Results: Integrated transcriptomic and proteomic analyses in HEV gt3-infected rabbits revealed sustained activation of the adaptive immune system throughout infection, which persisted beyond viral clearance, as evidenced by ongoing T cell infiltration and antigen presentation. Metabolomic profiling further indicated a pronounced T cell-related signature at peak viremia and a prolonged innate inflammatory response during clearance. Cross-species analysis in HEV gt1-infected chimpanzees identified a robust but transient type I interferon response that rapidly subsided after viral clearance. Strikingly, comparative analysis with HCV infection in chimpanzees revealed that HEV triggers a more rapid immune activation followed by significantly quicker resolution, as evidenced by the swift downregulation of interferon-stimulated genes post-clearance in HEV, contrasting with their sustained activation in HCV.
Conclusion: Our study unveils a protracted immuno-metabolic memory post-HEV clearance, characterized by unresolved innate activation and metabolic reprogramming. These findings redefine the paradigm of HEV immunopathogenesis, highlighting a distinct immune resolution profile compared to HCV. The insights gained offer novel avenues for biomarker development and immunomodulatory interventions in high-risk populations.

Background and aims: Chronic hepatitis delta represents the most severe form of viral hepatitis, marked by rapid progression to cirrhosis and hepatocellular carcinoma. Understanding the molecular interactions between hepatitis delta virus (HDV), hepatitis B virus (HBV), and the liver microenvironment is crucial for developing preventive and therapeutic strategies.
Method: Liver biopsies from four HBV/HDV-coinfected patients (two HDV-RNA positive, two negative) and two HBV-monoinfected patients were analyzed for HBsAg and HDAg expression using dual chromogenic immunostaining (Bond RX, Leica). These samples, along with liver tissues from healthy controls (HC), were further examined using spatial transcriptomics with the CosMx™ Spatial Molecular Imaging platform (NanoString; 1000-plex RNA). In parallel, bulk RNA sequencing was performed on liver samples from 21 coinfected patients (14 HDV-RNA positive, 7 HDV-RNA negative), seven HBV patients, and ten healthy controls using the nCounter™ Digital Analyzer.
Results: Compared with HBV monoinfection, HDV coinfection induced a distinct transcriptional signature associated with immune evasion, extracellular matrix remodeling, and progression toward a tumor-permissive state. In HDV-RNA negative samples, many of these alterations were attenuated or reversed, suggesting partial restoration of hepatocyte homeostasis. Spatial neighborhood analysis revealed that HDV-RNA negative tissues displayed an intermediate cellular organization between healthy and infected livers, showing partial recovery of normal cell-cell architecture. Pseudotime trajectories confirmed a restoration trend characterized by normalization of genes linked to ECM remodeling (COL4A1, FN1), oncogenic signaling (TWIST1), inflammatory response (IL6, STAT3), and metabolic regulation (FASN, SERPINA3). Intra-sample comparisons of HDAg+ versus HDAg- regions in HDV-RNA positive patients showed that local expression of HDAg correlated directly with microenvironmental disruption.
Conclusion: In conclusion, HDV coinfection induces deep but potentially reversible transcriptional and structural remodeling of the liver. Viral clearance appears to restore hepatic architecture and metabolic balance, reducing oncogenic risk and identifying potential biomarkers and therapeutic targets for hepatitis delta.

Sequential combination of antisense oligonucleotide AHB-137 followed by HBV vaccine leads to HBsAg loss and seroconversion in the AAV-HBV mice

Tingting Lu[1], Jihai Lei[1], Ruixia Hou[1], Weiguo Zhang[1], Yang Bai[1], Shujie Hao[1], Yipeng Wang[1], Lisha Zhang[1], Yujia Zhao[1], Chunxi Li[1], Guofeng Cheng[1,2], Cheng Yong Yang[1,2]. [1]*Ausper Biopharma Co., Ltd., Hangzhou, China;* [2]*Aupserbio Therapeutics Inc., Foster City, United States*
Email: tingting.lu@ausperbio.com

Background and aims: There is a strong consensus for achieving durable HBV control and functional cure requires breaking host immune tolerance, inducing profound and sustained viral suppression, and eliciting effective antiviral immune responses. AHB-137 is an unconjugated antisense oligonucleotide, has demonstrated significant antiviral activity and achieved unpreceded function cure rate in the CHB patients (AASLD2025 Poster 5022, HEP-DART2025). Recombinant HBV vaccine was approved by NMPA for prevention of HBV infection. This study evaluated the antiviral activity and immunogenicity of sequential combination of AHB-137 followed by HBV vaccine in the AAV-HBV mice, providing preclinical rationale to inform clinical combination therapy strategy.
Method: C57BL/6 mice infected with rAAV8-1.3HBV were administered subcutaneously AHB-137 at 60 mg/kg for six doses (D1, D4, D8, D11, D15, D22), followed by intramuscular HBV vaccine at 1.5 μg or

5.0 μg per animal for five doses (D29, D43, D57, D71, D90). Serial serum collections were tested for HBsAg, HBeAg, HBV DNA, HBsAb. Terminal serum samples were assayed for neutralization of HBsAb by HBV infected NTCP-HepG2 cells. Mouse liver was stained for HBsAg and HBcAg using IHC. HBsAg-specific B cell responses in the liver and spleen were evaluated using ELISpot.
Results: AHB-137 monotherapy significantly reduced serum HBsAg, HBeAg, and HBV DNA to below the LLOQ, after which serum HBsAg began to rebound on Day 50. In contrast, followed by HBV vaccine continue maintain HBsAg loss till the study termination (Day106). During the sustained HBsAg loss period, high-titer HBsAb with neutralizing activity was rapidly induced, the HBsAg-specific B cells in the liver and spleen were detected. Interestingly, HBV vaccine alone also induced serum HBsAb while with lack of neutralizing activity and minimal change in HBsAg. Additionally, the levels of HBsAg, HBeAg, HBV DNA and HBV RNA in the liver also significantly decreased under the AHB-137 sequential regimen, whether potential immune cytotoxicity was activated is under evaluation. All animals were well tolerated without any treatment-related abnormalities in clinical observation and clinical pathology.
Conclusion: Sequential combination of AHB-137 with HBV vaccine in the AAV-HBV mice effectively sustain serum HBsAg loss by concomitantly activating HBsAg-specific B cells to produce high-titer neutralizing HBsAb. This result demonstrated a potential combination therapy strategy for achieving higher functional cure rate in CHB patients.

THU-606
Antisense oligonucleotide-based strategy to target hepatitis delta virus infections

Yannick Debing[1], Caroline Pons[2], Faustine Bernardin[2], Lars Degrauwe[1], Kellan Passow[3], Isabel Heremans[1], Aneerban Bhattacharya[3], Antitsa Stoycheva[3], Lawrence Blatt[3], Julian Symons[3], Andreas Jekle[3], Vivek Rajwanshi[3], David Smith[3], Eloi R. Verrier[4], David Durantel[2], Julie Lucifora[2]. *[1]Aligos Belgium BV, Gaston Geenslaan 1, 3001, Leuven, Belgium; [2]CIRI, Centre International de Recherche en Infectiologie, Univ Lyon, Inserm, U1111, Université Claude Bernard Lyon 1, CNRS, UMR5308, ENS de Lyon, F-69007, Lyon, France; [3]Aligos Therapeutics, Inc., 1 Corporate Drive, South San Francisco, CA 94080, San Francisco, United States; [4]CIRI, Centre International de Recherche en Infectiologie, Univ Lyon, Inserm, U1111, Université Claude Bernard Lyon 1, CNRS, UMR5308, ENS de Lyon, F-69007, Lyon, France*
Email: julie.lucifora@inserm.fr

Background and aims: Currently approved treatments for chronic hepatitis delta virus (HDV) infection (Peg-IFN-α and bulevirtide) rarely cure patients in a finite treatment regimen. New direct-acting agents (DAA), targeting HDV replication, could therefore be a valuable addition to the current therapeutic arsenal. Since HDV is an RNA virus replicating its genome via a rolling-circle process in the nucleus, and antisense oligonucleotides (ASOs) are known to act both in the cytoplasm and the nucleus (in contrast to siRNA), we hypothesized that ASOs targeting HDV genome may potently and specifically inhibit intracellular HDV RNA amplification irrespective of helper HBV.
Method: We synthesized 112 different 5-10-5 gapmer ASOs targeting HDV and screened them for their antiviral effect on HDV. The HBV-directed ASO, bepirovirsen, was used as a non-targeting ASO control since screening was performed in HDV mono-infected differentiated HuH7-NTCP cells. ASOs were transfected prior to HDV infection and a high-content imager approach was used to analyze the antiviral effect and cytotoxicity.
Results: Eighteen anti-HDV ASO candidates exhibited a ≥80% reduction in HDAg+ cells at 1 μM without associated toxicity. Among these hits, we selected six anti-HDV ASOs that displayed high efficacy against HDV for further confirmation of their antiviral effect at different doses in two different cell lines. The corresponding calculated IC_{50} values reached the single digit nanomolar range, demonstrating a very potent efficacy of the anti-HDV ASOs compared to other ASOs, which are typically active at higher concentrations. Moreover, we established the first, and to date the only, *in vitro* system that supports a *bona fide* HDV spreading in cell culture conditions and showed that anti-HDV ASOs strongly impair HDV propagation, slightly faster than a presS1 peptide equivalent to bulevirtide. Finally, similar to bepirovirsen, anti-HDV ASO may stimulate innate responses (at least human toll like receptor 8) and thereby be also considered as host targeting agents (HTA).
Conclusion: We provided the first proof of concept that ASO-based strategies, directed against HDV replication intermediates, may be effective for targeting HDV infection as both DAA and HTA, in a single drug, double bullet strategy.

Hepatitis B surface antigen directly alters Dendritic cell-mediated natural killer cell responses

Lucile Dumolard[1], Marie-Noëlle Hilleret[1,2], Thomas Decaens[1,2], Philippe Saas[1,3], Evelyne Jouvin-Marche[1], Patrice Marche[1], Caroline Aspord[1,3], Zuzana Macek Jilkova[1,2]. *[1]Univ. Grenoble Alpes, Inserm U 1209, CNRS UMR 5309, Institute for Advanced Biosciences, Grenoble, France; [2]Hepato-Gastroenterology and Digestive Oncology Department, CHU Grenoble Alpes, Grenoble, France; [3]Etablissement Français du Sang Auvergne-Rhone-Alpes, R&D Laboratory, Grenoble, France*
Email: lucile.dumolard@univ-grenoble-alpes.fr

Background and aims: Hepatitis B, caused by the Hepatitis B virus (HBV), is a significant global health concern, often leading to chronic hepatitis B in individuals unable to mount an effective immune response. Chronic HBV substantially increases the risk of severe liver diseases, including cirrhosis and hepatocellular carcinoma. Dendritic cells (DC) and Natural killer (NK) cells play crucial roles in the early immune response to HBV, but their function is compromised in chronic hepatitis B patients. The precise mechanisms through which HBV disrupts immune responses remain unclear.
Method: We investigated how Hepatitis B surface antigen (HBsAg) influences the interplay between DC subpopulations and NK cells. Blood-derived DC subsets were pre-exposed to HBsAg and then co-cultured with NK cells under various stimulation conditions. We subsequently evaluated the modulations of DC, and the phenotypic and functional responses of NK cells. Similarly, DC subsets were exposed to serum from HBV-infected individuals with varying levels of HBsAg to assess their ability to stimulate NK cell responses.
Results: Our findings show that exposure to HBsAg selectively impairs NK cell activation, phenotype and degranulation in co-cultures with plasmacytoid DC, in a Toll-like receptor-9 (TLR9)-dependent manner. HBsAg also disrupts cDC2-mediated NK cell activation via TLR7/8-dependent pathways and cDC1-mediated NK cell degranulation via TLR3-dependent pathways. Such impairment was reproduced with serum of HBV patients in a HBsAg level-dependent manner.
Conclusion: These findings deepen our understanding of immune dysregulation in chronic HBV infection, highlighting the critical role of all DC subsets in orchestrating effective cross-talk with NK cells. By uncovering the mechanisms underlying DC-NK cell interactions, this work underscores the therapeutic potential of targeting DCs to restore immune competence.

Email: rui.marquesdacosta@rub.de

Background and aims: Hepatitis E virus (HEV) remains an understudied global health concern, causing an estimated 20 million infections and up to 70,000 deaths annually. While infections are often asymptomatic, HEV can become chronic in immunocompromised individuals and is associated with mortality rates of up to 30% in pregnant women. As a neglected disease, little is known about the steps that follow viral entry, uncoating and replication. Given the viral genome comprises a 5′-m7G cap and a polyadenylated tail, similar to host mRNAs, we hypothesized that HEV may be susceptible to cleavage by the host Argonaute proteins dampening replication and thus inhibiting the innate immune response.
Method: We employed *in vitro* HEV replication and infection assays in Ago2 knock down (KD) HepG2/C3A cells to assert the effect of viral RNA cleavage by Ago2 during the HEV replication cycle. We further employed a JAK inhibitor, baricitinib, to assess whether any Ago2 elicited effects would be additive to the interferon response. Finally, we aim to perform Argonaute 2 RNA co-precipitation to identify, if any, miRNA seed sites present in the HEV genome and describe the viral-host HEV miRNA interactome.
Results: Inhibition of Ago2 during HEV infection resulted in an enhancement of HEV viral infection as shown via ORF2 staining. Further, we could show that in Ago2 KD cells infected with HEV, there is an up to 2-fold increase in HEV RNA replication when compared to the non-targeting control. Interestingly, in the Ago2 KD model, baricitinib appears to work in tandem with siAgo2_2 to enhance replication. Finally, the miRNA interactome of HEV is currently being investigated via AgoCLIP (cross-linking and immunoprecipitation) and should highlight viral regions responsible for the recruitment of the host mRNA degradation machinery.
Conclusion: Together, these data suggest that HEV uses the host RISC (RNA-induced silencing complex) system. We hypothesize this functions as an innate immune response evasion mechanism. Further, replication data suggests that Ago2 interacts with the viral nucleic acids at multiple timepoints during infection. Importantly, given HEV infection may also occur as a zoonoses, further questions about differential regulation of viral replication by host small RNAs, depending on host tropism, remain to be addressed. Our data highlight the importance novel research avenues into an understudied virus and open the possibility for counterstrategies to control infection and better understand HEV pathogenesis.

THU-609
In vitro antiviral activity of the cyclophilin inhibitors against hepatitis delta virus infection

Rola Matar[1], Hakim Ahmed-Belkacem[1], Stéphane Chevaliez[1,2], Jean-Michel Pawlotsky[1,2], Daniel Candotti[1]. *[1]"Viruses, Hepatology, Cancer" Research Team Institut de Recherche Biomédicale, INSERM U955, Créteil, France; [2]Department of Virology, French National Reference Center for Hepatitis B, C and D Viruses, Hôpital Henri Mondor (AP-HP), Université Paris-Est, Créteil, France*
Email: rola.matar99@gmail.com

Background and aims: Hepatitis Delta Virus (HDV) causes the most severe form of viral hepatitis, with limited therapeutic options. Cyclophilin inhibitors (CypIs) have demonstrated broad antiviral activity against hepatotropic viruses. This study aimed to evaluate *in vitro* the antiviral activity of the well-characterized CypI Alisporivir (ALV) and a new prototype CypI, F832, against HDV infection in Huh106 cells, using Bulevirtide (BLV) as an inhibition control of viral infection.
Method: Huh106 cells were infected with HDV and treated with increasing concentrations of ALV or F832. Cytotoxicity (CC50) and antiviral activity (IC50 and therapeutic index, TI) were determined by monitoring intracellular HDAg expression. Intracellular HDAg levels were measured by Western blot, immunofluorescence, and HDAg-specific ELISA, while HDV RNA levels were measured by RT-qPCR.
Results: ALV inhibited HDAg expression in Huh106 cells in a dose-dependent manner, with an IC50 of 0.25 ± 0.03 µM, CC50 >10 µM, and TI >40. Intracellular HDAg became undetectable at concentrations ≥2.5 µM. F832 treatment also reduced HDAg levels but proved less effective, showing an IC50 of 0.56 ± 0.16 µM, CC50 >20 µM, and TI >35.7. Quantitative analysis by Western blot, ELISA, and immunofluorescence confirmed significant decreases in HDAg expression. Starting at 5 µM, ALV and F832 reduced the level of intracellular HDV RNA significantly.
Conclusion: ALV demonstrated significant antiviral activity against HDV in vitro, providing a rationale for further preclinical evaluation. F832 compound appeared promising, but further analyses are needed.

THU-610
Discovery of novel HDV entry inhibitors with selectivity over bile acid inhibition

David McGowan[1], Isabel Heremans[1], Lars Degrauwe[1], Frederick Degroote[1], Kusum Gupta[2], Lawrence Blatt[2], Julian Symons[2], David Smith[2], Yannick Debing[1]. *[1]Aligos Belgium, Leuven, Belgium; [2]Aligos Therapeutics, South San Francisco, United States*
Email: ydebing@aligos.com

Background and aims: Chronic hepatitis delta virus (HDV) infection affects about 4.5% of patients chronically infected with hepatitis B virus (HBV), corresponding to an estimated 12 million people. HDV is a satellite virus of HBV and is only found as a co-infection with HBV due to its dependence on the HBV surface antigen (HBsAg) for viral particle assembly. HBV and HDV enter hepatocytes via the sodium taurocholate cotransporting polypeptide (NTCP) receptor. A peptide inhibitor blocking NTCP, bulevirtide (BLV), was recently approved by the European Medicines Agency for chronic HDV infection. Two potential drawbacks of BLV are the required daily subcutaneous administration and the inhibition of bile acid (BA) transport, the natural function of NTCP. An entry inhibitor that is selective for antiviral inhibition over BA transport blockade could provide patients with a potentially superior antiviral treatment.
Method: Inhibition of HBV and HDV entry was evaluated in HepG2-NTCP cells by adding compound with the inoculum and measuring secreted HBeAg or intracellular HDAg and HDV RNA as read-outs. Inhibition of BA transport was assessed using a fluorescently labeled BA derivative. Entry specificity was confirmed using a time-of-addition setup where compound as added before, during or after infection. Competitive binding with BLV was investigated using flow cytometry with fluorescently labeled BLV as a probe. Liver microsome stability was measured in several species. In vivo pharmacokinetics were studied in rats after intravenous bolus dosing at 2 mg/kg.
Results: Screening of focused compound libraries for HBV entry and BA transport led to the identification of a hit series with limited antiviral potency but clear selectivity over BA transport. Exploration of the structure-activity relationship and further chemical optimization yielded a lead series with submicromolar EC_{50} antiviral potency and pronounced selectivity (>100-fold). Selected molecules demonstrated entry inhibition with EC_{50} values under 100 nM for HBV entry. Entry specificity was confirmed in HDV infection and time-of-addition assays. The lead series was shown to bind competitively with BLV. Representative examples were stable in human and rat liver microsomes and exhibited a PK profile upon IV dosing suitable for further optimization.
Conclusion: A lead series of entry inhibitors with potent antiviral activity and pronounced selectivity (>100-fold) over BA transport was identified. Further optimization of activity, selectivity and ADME is ongoing.

Functional characterization of urine-associated hepatitis E virus mutations: effect on kidney infection and antiviral efficacy

Avista Wahid[1], Nele Meyer[1], Christine Wundes[1], Saskia Janshoff[2,3,4], Michelle Jagst[2], Martina Friesland[1], Katja Dinkelborg[1,5,6], Markus Cornberg[5,6,7,8], Benjamin Maasoumy[5,6], Daniel Todt[2,4,9], Heiner Wedemeyer[5,6], Thomas Pietschmann[1,6], Eike Steinmann[2], André Gömer[2], Patrick Behrendt[1,5,6]. *[1]Institute for Experimental Virology, TWINCORE, Centre for Experimental and Clinical Infection Research, a joint venture between the Helmholtz Centre for Infection Research and the Hannover Medical School, Hannover, Germany; [2]Department of Molecular and Medical Virology, Ruhr University Bochum, Bochum, Germany; [3]Herz- und Diabeteszentrum Nordrhein-Westfalen, Bad Oeynhausen, Germany; [4]Department for Translational and Computational Infection Research, Ruhr University Bochum, Bochum, Germany; [5]Department of Gastroenterology, Hepatology, Infectious Diseases and Endocrinology, Hannover Medical School, Hannover, Germany; [6]DZIF, Partner Site Hannover-Braunschweig, Hannover-Braunschweig, Germany; [7]Center for Individualised Infection Medicine (CiiM), Hannover, Germany; [8]German Center for Infection Research (DZIF), HepNet Study-House/German Liver Foundation, Hannover, Germany; [9]European Virus Bioinformatics Center, Jena, Germany*
Email: nele.meyer@twincore.de

Background and aims: Hepatitis E virus (HEV) is a major cause of acute viral hepatitis globally. In immunocompromised patients, it can lead to chronic infection and severe liver disease. Therapeutic options are limited; ribavirin (RBV), used off-label, is not always effective. Extrahepatic manifestations, including renal impairment, have been reported, but mechanisms and impact of compartment-specific variants remain poorly understood.
This study aimed to investigate whether various HEV strains are able to complete their replication cycle in kidney cell lines and to characterize urine-specific, patient-derived HEV variants in vitro, focusing on replication dynamics and antiviral responses.
Method: Two HEV-3 isolates and one HEV-1 strain were used to study replication and antiviral susceptibility in liver and several human kidney cell lines. To identify compartment-specific viral variants, HEV sequences from urine, stool, and plasma samples of chronically infected patients were analyzed. Urine-associated mutations were cloned into subgenomic reporter constructs and full-length HEV-3 p6 backbones. Replication efficiency, infectivity and RBV susceptibility were compared between liver and kidney cells. Ongoing work includes testing of additional antivirals and screens a 5-year Hannover Medical School (MHH) outpatient cohort for similar urine variants.
Results: Several kidney cell lines supported complete replication of HEV-3 p6 and replication of HEV-3 83-2 and HEV-1 Sar-55. Introduction of urine-specific, patient-derived mutations resulted in distinct phenotypes, affecting replication efficiency in a cell-type dependent manner (liver versus kidney cell lines) and altering RBV susceptibility. Overall, kidney cells showed a reduced RBV response compared to liver cells. Consistent trends in replication and drug response were observed in subgenomic and full-length constructs. Screening of the MHH cohort and testing of additional antivirals are ongoing.
Conclusion: Our data demonstrate that HEV can complete its replication cycle in kidney-derived cell lines in vitro and urine-specific, patient-derived variants can modulate replication efficiency and RBV susceptibility in a cell-type dependent manner. This supports a potential viral contribution to renal HEV manifestations and underscores the importance of compartment-specific viral evolution for antiviral efficacy. Ongoing cohort analyses and broader antiviral testing aim to define the clinical prevalence and therapeutic significance of urine-associated HEV variants.

THU-612-YI

Differential roles of HBc depending on its translation from spliced or unspliced HBV RNA

Dang Hoan Nguyen[1], Pierre Bablon[1], Clément Iriart[1], Jonathan Pol[2], Hélène Strick Marchand[3], Patrick Soussan[1], Jesus Brunetti[1]. *[1]Sorbonne Université, Inserm, Centre de Recherche de Saint-Antoine (CRSA), Paris, France; [2]INSERM UMR1138, Centre de Recherche des Cordeliers, Paris, France; [3]Innate Immunity Unit, Institut Pasteur, Université Paris Cité, Inserm U1223, Paris, France*
Email: patrick.soussan@inserm.fr

Background and aims: The hepatitis B virus (HBV) core protein (HBc) is involved in capsid assembly, virus-host interactions, and epigenetic regulation. An HBc isoform lacking Cys183 (HBc^{-Cys}), translated from spliced viral transcript sp1RNA, was shown to be critical for HBV wild-type (HBV^{wt}) infection in liver-humanized mice[1]. Furthermore, liver HBc^{wt} expression (translated from pgRNA) was markedly low in the liver of mice expressing HBV-invalidated for sp1RNA ($HBVsp1^{mut}$)[2]. Regulation of HBc^{wt} and HBc^{-Cys} expression was investigated *in vitro* and *in vivo*.
Method: Differentiated HepG2-NTCP and PHH cells were infected with either recombinant $HBVsp1^{mut}$ or HBV^{wt}. *In vivo* HBc expression was addressed by transduction of AAV expressing either HBV^{wt} or $HBVsp1^{mut}$ in C57Bl6, immune-deficient (NSG), and HBSP transgenic mice (10^{11} Geq AAV/mouse). Samples were studied by immunohistochemistry, western blot and PCR analyses.
Results: HBc^{wt} was easily detected in $HBVsp1^{mut}$-infected hepatic cells contrary to *in vivo* findings[1–3], suggesting an *in vivo* dependent regulation. *In vivo* comparison with HBV^{wt}, $HBVsp1^{mut}$ transduction revealed: 1) poor expression of HBc^{wt} and high levels of pgRNA in the liver; 2) slight reduction of viral load and similar amounts of HBcAg, HBsAg and HBeAg in blood. These data suggested that HBc^{-Cys} is mainly accumulated in liver while HBc^{wt} is mainly secreted in blood. The low level of HBc^{wt} liver-expression in AAV-$HBVsp1^{mut}$ remained unaffected by immune suppression or HBSP trans-complementation but was partially recovered by antiviral treatment. At higher transduction inoculum, HBc^{wt} accumulation in $HBVsp1^{mut}$ mice was partially restored only in mid-lobular hepatocytes while, in HBV^{wt} mice, all hepatocytes were positive along the liver lobule. The differential regulation of HBc expression resulted from the outcome of HBV transcripts. In HBV^{wt} mice, pgRNA represented only 40% of (sp1+pg) RNAs while almost all intracellular packaged HBV DNA forms resulted from pgRNA, suggesting that sp1RNA is mainly translated. Finally, the differential distribution of HBc isoforms was also related to the zonal transcriptomic profiles of the hepatic lobule.
Conclusion: HBV sp1RNA invalidation revealed that: 1) pgRNA is preferentially encapsidated compared with sp1RNA which is mainly translated into HBc^{-Cys} in mice; 2) viral egress is mainly driven by HBc^{wt}; 3) liver zonation is involved in HBc isoforms expression.

Email: maximilian.nocke@rub.de

Background and aims: Most hepatitis E virus (HEV) infections are asymptomatic and self-limiting, while immunocompromised or other risk group patients may develop chronic courses. The hypervariable region (HVR) within HEV's first open reading frame (ORF1) is known to integrate sequences of human origin. Genomic rearrangements are discussed to be involved in disease severity and chronicity. Therefore, an automated and standardized method of insertion identification is required in diagnostics. Our aim was to develop and provide an automated approach for insertion identification to standardize the analysis of human and viral gene snippets integrated into the HEV genome. Furthermore, we elucidated potential dynamics of insertions within a viral population on longitudinal scale. Thereby, we would obtain critical knowledge about the nature of insertions.
Method: We collected longitudinal samples of a chronic infected patient experiencing ribavirin treatment failure.
To gather insights into insertions over the course of disease, we performed Illumina sequencing on the patient's samples. We applied our bioinformatics tool Hyper-EINS to identify insertions. These were compared between different timepoints based on sequence identity to assess potential evolutionary relations.
Results: The overall most frequent insertions found in the patient's data are derived from the genes SERPINA1 and TRIM22. Insertions of numerous genes were found to be present pretreatment. All insertions were eliminated from the viral population during early treatment, except for the SERPINA1 insertion, which persisted in lower frequency. During later treatment, multiple insertions were introduced into the viral population, while especially SERPINA1 and TRIM22 insertions rose in frequency and diversity. In our previous work, we identified two of those diverse insertions as replication-enhancing.
Conclusion: In this study we were able to show dynamic shifts of HVR insertions for the first time. We observed those shifts both during and after treatment. This emphasizes that insertions are subject to complex mechanisms within the viral population. While the SERPINA1 insertion associated with treatment failure was already present in the viral population before treatment, the currently available data does not allow failure prediction. Still, the observation of sudden diversification of insertions might be a possible indicator to halt treatment.

THU-617

Deep genomic analyses of database farmed hepatitis E virus genomes uncover genotype specific features

Maximilian Nocke[1,2,3], Eike Steinmann[3,4,5], Daniel Todt[1,2,3].
[1]Department for Translational and Computational Infection Research, Ruhr University Bochum, Bochum, Germany; [2]European Virus Bioinformatics Center (EVBC), Jena, Germany; [3]Hepatitis E Virus Research Hub (HepE-Hub), Bochum, Germany; [4]Department for Molecular and Medical Virology, Ruhr University Bochum, Bochum, Germany; [5]German Centre for Infection Research, External Partner Site, Bochum, Germany
Email: maximilian.nocke@rub.de

Background and aims: Open access virus databases provide an extensive amount of data harboring a valuable potential for meta-analyses. Hepatitis E virus (HEV) is organized in the taxonomic family *Hepeviridae*, with the species *Paslahepevirus balayani* covering the typical human pathogenic strains. Since HEV genotypes are associated with disease severity and course and reservoir host, a broader understanding of genomic commonalities and (sub-)genotypic specific features would result in more directed diagnostics and treatment development. In previous work, we developed a novel and runtime efficient typing algorithm to close gaps in publicly available sequence metadata. This laid the foundation for investigating diverging and shared genomic features of HEV genotypes and subgenotypes. Our aim was to identify subgenotype specific genomic regions or sequential patterns. By identifying potential marker regions of varying genomic positions, HEV typing in diagnostics and scientific context could become more precise and efficient. Furthermore, we aim to define a novel and consistent genome nomenclature to define amino acid positions and single nucleotide variants in a unified way.
Method: 1268 full genome *Hepeviridae* sequences were downloaded from the NCBI genbank. We developed an algorithm to ensure the quality of taxonomic labels for full genome HEV sequences farmed from public databases. Using this method, we investigated genome conservation on different taxonomic and genotype levels, performed k-mer sequence clustering and Shannon entropy analyses. Resulting data was combined, while taking all taxonomic and genotype labels into account.
Results: Alongside genotype specific patterns and marker regions, we were able to identify length polymorphisms unique to sub-genotypes. While those genomic features could ease the typing of viral populations, especially the latter make developing a unified nomenclature more complex but also more important.
Conclusion: In this study we found genetic patterns in all HEV open reading frames as well as length polymorphisms unique to HEV (sub-)genotypes. Thereby, those features indicate a link to severity and transmission route, which requires further testing for validation. Still, those genetic markers bear potential advantages for typing HEV both in diagnostics and research. Taking the identified features into account makes the development of a unified HEV nomenclature and amino acid numbering scheme more feasible.

Distinct hepatic transcriptional programmes in chronic hepatitis B are reshaped by metabolic dysfunction

Eva Parisi[1], Chanelle Fernandes[1], Jantarika Arora[1], Corinna Pade[1], Apostolos Koffas[1,2], Patrick Kennedy[1,2], Upkar Gill[1,2]. *[1]Centre for Immunobiology & Infection, The Blizard Institute, Barts and The London Faculty of Medicine & Dentistry, Queen Mary University of London, London, United Kingdom; [2]Department of Hepatology, Barts Health NHS Trust, London, United Kingdom*
Email: u.gill@qmul.ac.uk

Background and aims: Chronic hepatitis B (CHB) is a major global cause of liver cancer, and metabolic dysfunction-associated steatotic liver disease (MASLD) increasingly co-exists with CHB, potentially accelerating liver disease progression. The molecular interaction between metabolic dysfunction and hepatitis B virus (HBV) remains incompletely understood. We characterised paired hepatic and peripheral gene expression patterns associated with metabolic dysfunction in HBV to identify pathways and candidate gene targets relevant to disease stratification and therapeutic development.
Method: Paired liver biopsy and PBMC samples were obtained from patients with untreated CHB with and without co-existing MASLD (n = 20). Bulk RNA sequencing was performed, and differential gene expression analysis was conducted using DESeq2 in R (v4.5.1). Differentially expressed genes were identified and subjected to pathway-level interpretation focusing on metabolic-associated transcriptional programmes.
Results: Comparative analysis identified a distinct hepatic gene expression profile in CHB-MASLD compared with CHB alone. CHB-MASLD was characterised by relative upregulation of stress-responsive genes implicated in nutrient sensing and inflammatory signalling, including ARRDC4, alongside downregulation of genes central to hepatocyte metabolic homeostasis. These included genes

involved in amino acid metabolism (TAT), urea cycle function (ASS1), growth hormone-IGF signalling (IGF1), and lysosomal metabolic regulation (RNF152), which were significant after multiple hypothesis testing (adjusted $p < 0.05$ and $|\log_2$ fold change$| > 1$). Pathway-level interpretation indicated coordinated alterations across metabolic, nutrient-sensing, and stress-associated transcriptional programmes. Overall, the hepatic transcriptomic profile in CHB-MASLD was consistent with altered metabolic regulation accompanied by relative enrichment of stress and inflammatory signalling pathways.
Conclusion: Untreated CHB with co-existent MASLD displays a hepatic gene expression profile distinct from CHB alone, marked by coordinated changes in metabolic pathways and relative enrichment of stress-associated and inflammatory transcriptional programmes. These findings support metabolic dysfunction as an important modifier of the hepatic molecular landscape in HBV infection and highlight pathways contributing to disease heterogeneity. Earlier therapeutic intervention in CHB-MASLD may therefore be important to mitigate or rebalance adverse transcriptional programmes.

Plasma THC is inversely associated with insulin resistance before and after HCV cure in people with HIV–HCV coinfection (ANRS CO13 HEPAVIH and ELICSIR study)

Tangui Barre[1], Camelia Protopopescu[1], Alexandr Gish[2], Fabienne Marcellin[1], Morgane Bureau[1], Patrick Miailhes[3], Karine Ory[4], Vincent Di Beo[1], Florian Hakim[2], Jean-Michel Gaulier[2], Patrizia Carrieri[1]. *[1]Aix Marseille Univ, Inserm, IRD, SESSTIM, Sciences Economiques & Sociales de la Santé & Traitement de l'Information Médicale, ISSPAM, Marseille, France; [2]CHU Lille, Unité Fonctionnelle de Toxicologie, Lille, France, Univ. Lille, ULR 4483—IMPECS—IMPact de l'Environnement Chimique sur la Santé humaine, Lille, France; [3]Hôpital de Fleyriat, Service de Maladies Infectieuses et Tropicales, Bourg en Bresse, France; [4]Université Bordeaux, INSERM, MART, UMS 54, Bordeaux, France*
Email: camelia.protopopescu@inserm.fr

Background and aims: In HIV-HCV co-infection, chronic immune activation contributes to insulin resistance (IR), a key factor in steatosis, fibrosis progression, cardiometabolic and other extrahepatic complications. HCV cure may improve IR, while self-reported cannabis use has been associated with reduced steatosis and IR in both the general population and HIV–HCV coinfected people. Using data from the ANRS ELICSIR study, we investigated the associations between plasma cannabinoids, HCV cure, and insulin resistance defined by the Homeostatic Model Assessment for Insulin Resistance (HOMA-IR $\geq$2.77).
Method: ELICSIR study included participants from the ANRS CO13 HEPAVIH cohort of people with HIV–HCV coinfection, who achieved HCV cure and had available plasma samples and HOMA-IR measures in the 36 months before and after HCV cure (defined by sustained virological response 24 weeks after treatment end). Plasma exocannabinoids (cannabidiol, tetrahydrocannabinol (THC), and THC-COOH metabolite), endocannabinoids, other xenobiotics, and inflammatory markers were measured using high-resolution liquid chromatography–tandem mass spectrometry. Associations between cannabinoids and IR were evaluated using a multivariable mixed-effects logistic regression model, adjusted for HCV cure and other factors.
Results: The study included 270 participants (71.1% men) contributing 518 measurements. At baseline visit (i.e., before cure), median age was 50 (IQR: 45–54) years, 20% had advanced liver fibrosis (FIB-4 >3.25), IR was present in 46.3%, while THC-COOH was detected in 27.1% of participants. Higher IR prevalence was found among participants without detectable THC-COOH (51.1% vs 33.3%, p = 0.012). In multivariable analysis, among cannabinoids, only THC-COOH was independently associated with lower odds of IR (OR: 0.36, 95% CI: 0.16–0.81). Besides, IR was associated with older age, overweight/obesity, longer time since HIV diagnosis, and higher C-reactive protein levels, and inversely associated with HCV cure.
Conclusion: For the first time, plasma THC-COOH detection was found independently associated with lower insulin resistance in HIV–HCV coinfected people, irrespective of HCV cure and overweight/obesity. Although the underlying mechanisms remain to be elucidated, these findings support further investigation in randomized clinical trials of cannabinoids—particularly more acceptable non-psychoactive compounds and smoke-free formulations—to reduce insulin resistance and related metabolic complications in at-risk populations.

Preclinical characterization of ALG-093940, a potent and orally bioavailable small molecule PD-1/PD-L1 inhibitor for the treatment of chronic hepatitis B infection and liver cancer

Heleen Roose[1], Kristina Rekstyte-Matiene[1], Sarah Stevens[2], Kusum Gupta[2], Sandra Chang[2], Nour Fayyad[1], Nega Gerard[3], Cheng Liu[2], Vladimir Serebryany[2], Lillian Adame[2], Kha Le[2], Antitsa Stoycheva[2], Dinah Misner[2], Lawrence Blatt[2], Leonid Beigelman[2], Sushmita Chanda[2], Adam Gehring[3,4], David Smith[2], Julian Symons[2], Andreas Jekle[2], Tongfei Wu[1]. *[1]Aligos Belgium, Leuven, Belgium; [2]Aligos Therapeutics, South San Francisco, United States; [3]Schwartz Reisman Liver Research Centre, University Health Network, Toronto, Ontario, Canada; [4]Department of Immunology, University of Toronto, Toronto, Ontario, Canada*
Email: hroose@aligos.com

Background and aims: PD-1/PD-L1 antibody-based therapies have demonstrated success in the treatment of liver cancer and have exhibited potential for reversing immune tolerance in chronic hepatitis B (CHB). Recently, PD-L1 small molecule inhibitors have been developed, e.g., INCB086550 which demonstrated clinical response in cancer, and AB-101 that demonstrated a transient HBsAg decline in 2 out 10 CHB patients in a phase I study. Here, we report the characterization of ALG-093940, a potent and orally bioavailable small molecule PD-1/PD-L1 inhibitor that binds to PD-L1 and promotes PD-L1 dimerization, internalization and degradation, offering a distinct mechanism of action with potential advantages over PD-1/PD-L1 antibody therapeutics.
Method: Inhibition of PD-1/PD-L1 in cell culture was measured using PD-1 expressing Jurkat NFAT luciferase T cells and CHO-hPD-L1 cells. Ex vivo restoration of HBV specific T cell function in subjects with chronic HBV infection was analyzed using fluorospot assay. *In vivo* PK/PD/efficacy were assessed in a humanized-PD-L1 MC38 subcutaneous tumor mouse model. Tolerability in mice and safety and tolerability in rats and cynomolgus monkeys were evaluated after oral administration.
Results: ALG-093940 showed comparable T-cell activation potency to INCB086550. Furthermore, treatment of CHO-hPD-L1 cells with ALG-093940 resulted in internalization and reduction of PD-L1 protein levels. In ex vivo human PBMC assays, ALG-093940 demonstrated PD-L1 target engagement, T cell activation and immune cell mediated tumor cell killing. Importantly, ALG-093940 demonstrated the ability to restore ex vivo T cell functionality in PBMC from HBV infected subjects. *In vivo* ALG-093940 exhibited dose-dependent PD-L1 target engagement. Tumor growth inhibition and tumor size correlated with tumor-infiltration of $CD8^+$ T-cells. In addition, ALG-093940 was well tolerated when orally administered daily in mice for 40 days, in rats for 14 days and in cynomolgus monkeys for 3 days.
Conclusion: ALG-093940, an orally available small molecule, is a potent PD-1/PD-L1 inhibitor targeting PD-L1 dimerization, internalization and degradation. ALG-093940 demonstrated excellent efficacy and safety, warranting further evaluation as a potential clinical candidate for the treatment of CHB and liver cancer.

THU-621

Verification and validation data of the CE-IVD marked AltoStar® HDV RT-PCR Kit 1.5 for monitoring HDV RNA viral load in plasma and serum samples

Karin Rottengatter[1], Philip Rosenstock, Angeles Jimenez[1]. [1]*Altona Diagnostics GmbH, Hamburg, Germany*
Email: karin.rottengatter@altona-diagnostics.com

Background and aims: Next to precise HDV RNA detection and quantification, automation covering extraction of the nucleic acid for amplification of the specific HDV target is pivotal for diagnosis and monitoring of response to newly approved treatment in HDV infectious disease. Limit of Detection, Linearity and precision are basic information required for diagnostic laboratories. Here we show parts of the comprehensive verification data of the CE-IVD marked AltoStar® HDV-RT PCR Kit 1.5 used within the AltoStar® Molecular Diagnostic Workflow.
Method: Human EDTA plasma and serum samples were used next to the WHO 1st International HDV RNA Standard (PEI code 7657/12) and external proficiency panel samples (INSTAND, QCMD). Testing the analytical specifications followed the respective requirements of the Regulation (EU) 2017/746 (IVDR) and CLSI Standards.
Results: All results are based on the AltoStar® HDV RT-PCR Kit 1.5 in combination with the AltoStar® Internal Control 1.5 and the AltoStar® Automation System AM16 on the CFX96™ Deep Well Dx System (Bio-Rad). The Limit of Detection was determined with 1.12 IU/ml [95% CI 0.72 to 2.20 IU/ml] for genotype 1 (WHO Standard) and confirmed for the other seven genotypes. The Linear Range was defined based on patient sample material with 2.00E+01 IU/ml to 1.00E+06 IU/ml, and based on additional IVT testing extended to 1.00E+08 IU/ml. Trueness to the WHO Standard ($\leq \pm 0.10$ $\log_{10}$ IU/ml), repeatability, with-in laboratory precision and inter-laboratory precision were analysed (all CV% ≤5%). Proficiency panel data confirmed correct qualitative and quantitative testing.
Conclusion: Accurate measurement of molecular targets, such as HDV RNA is essential for correct disease diagnosis, monitoring, and treatment decision-making. Standardization by automation minimizes variability across different laboratories, enhancing the comparability of results and ensuring consistency in patient care.

THU-622-YI

A novel human liver chimeric mouse model to study Hepatitis B virus DNA integration

Melina Schäfer[1], Tassilo Volz[1,2], Annika Volmari[1,2], Kristoffer Riecken[3], Boris Fehse[2,3], Maura Dandri[1,2], Lena Allweiss[1,2]. [1]*University Medical Center Hamburg-Eppendorf, I. Department of Medicine, Hamburg, Germany;* [2]*German Center for Infection Research (DZIF) Hamburg-Lübeck-Borstel-Riems site, Hamburg, Germany;* [3]*University Medical Center Hamburg-Eppendorf, Department of Stem Cell Transplantation, Research Department Cell and Gene Therapy, Hamburg, Germany*
Email: me.schaefer@uke.de

Background and aims: Hepatitis B virus (HBV) integrates parts of its DNA into the host genome early upon infection. Although not required for viral replication, integrations are observed in all phases of acute and chronic hepatitis B. They contribute to hepatocellular carcinoma (HCC) development through multiple, not fully defined mechanisms, including viral protein expression, genomic instability and disruption of cancer-associated genes. We aimed to establish a mouse model to generate primary human hepatocytes (PHH) *in vivo* harboring HBV DNA integrations and to investigate how these affect host and viral parameters.
Method: The model uses human liver chimeric urokinase-type plasminogen activator/severe combined immunodeficiency/beige/interleukin 2 receptor gamma −/− (USG) mice and introduces a prototypic HBV DNA integration via lentiviral gene transfer in PHH. This integration comprises the viral surface proteins (HBs) and regulatory X protein open reading frames under endogenous promotors and a downstream enhanced green fluorescent protein (eGFP) sequence. Integrations and integration-derived viral RNA and proteins were characterized by histology, qPCR, Western blot and RNA or DNA in situ hybridization (ISH).
Results: PHH were transduced *ex vivo* (average efficiency 25%) and transplanted into naïve USG mice, leading to the repopulation of mouse livers with clusters of integration-carrying and integration-free PHH. The presence of integrations did not hinder PHH proliferation, as repopulation levels were comparable between integration-carrying and control mice. Consistently, the *in vivo* distribution of eGFP-positive cells resembled initial transduction rates, with an average *in vivo* integration level of 21% (range 5–39%; n = 10). Intrahepatic viral RNAs and DNA were detected by qPCR and HBsAg was secreted into the mouse serum. eGFP and HBsAg could be visualized via histological staining and distinct HBs forms were detected by Western blot. Integrated DNA and expressed RNAs were also visualized at the single-cell level by DNA- and RNA-ISH.
Conclusion: We created a unique model to generate PHH harboring HBV DNA integrations and to study their role in HBV persistence and early carcinogenic events in primary cells *in vivo*. Additional applications include the evaluation of treatments targeting integrations or establishing hepatitis D virus mono-infections.

THU-623-YI

Arrayed human and porcine ISG screens identify hepatitis E virus host restriction factors

Sarah Schlienkamp[1,2], Luca Nörthemann[1,2], André Gömer[1,2], Eleftherios Michailidis[3,4], Yannick Brüggemann[1,2], Daniel Todt[2,5,6], Florian Vondran[7], Axel Hamprecht[8], Finn Grey[9], Charles Rice[4], Volker Kinast[8], Eike Steinmann[1,2,10]. [1]*Department for Molecular and Medical Virology, Ruhr University Bochum, Bochum, Germany;* [2]*Hepatitis E Virus Research Hub (HepE-Hub), Bochum, Germany;* [3]*Laboratory of Biochemical Pharmacology, Department of Pediatrics, School of Medicine, Emory University, Atlanta, United States;* [4]*Laboratory of Virology and Infectious Disease, The Rockefeller University, New York, United States;* [5]*Department of Translational and Computational Infection Research, Ruhr University Bochum, Bochum, Germany;* [6]*European Virus Bioinformatics Centre (EVBC), Jena, Germany;* [7]*Department of General, Visceral, Pediatric and Transplant Surgery, University Hospital RWTH Aachen, Aachen, Germany;* [8]*Department of Medical Microbiology and Virology, Carl von Ossietzky University Oldenburg, Oldenburg, Germany;* [9]*The Roslin Institute, University of Edinburgh, Edinburgh, United Kingdom;* [10]*German Centre for Infection Research (DZIF), External Partner Site, Bochum, Bochum, Germany*
Email: sarah.schlienkamp@rub.de

Background and aims: For hepatitis E virus (HEV) genotype 3, an emerging zoonotic pathogen, the primary reservoirs are pigs and deer. HEV can cause fulminant hepatitis and lead to liver cirrhosis and liver failure in humans, but it is apathogenic in pigs. Based on this divergent progression of HEV infection, this study was designed to evaluate the role of the innate immune response during HEV infection in human and porcine hepatocytes. Further, we aimed to identify human and porcine ISGs with antiviral properties against HEV to ultimately define species-specific host restriction factors of HEV.
Method: Utilizing primary human and porcine hepatocytes (PHH and PPH, respectively), we performed HEV infection experiments and modulated the innate immune response by application of JAK-inhibitors and IFNs. We further made use of arrayed human and porcine ISG libraries which comprise ~400 ISGs each. To characterize individual ISGs with potential restrictive effect on HEV, we performed infection experiments, subgenomic replicon systems, immunofluorescence microscopy analysis and IFN-beta reporter assays.
Results: JAK-inhibitor treatment of PHH and PPH revealed a 50-fold and 400-fold increase of progeny virus production upon HEV infection, suggesting that the canonical IFN-response is critical to

control HEV propagation. By taking advantage of the arrayed ISG libraries, we identified ISG products with promising anti-HEV activity including uncharted factors such as EAAT3. Validation in hepatoma cell lines and further experiments suggest that EAAT3 restricts the entry process of HEV.
Conclusion: The innate immune response is essential for controlling HEV infection in primary human and porcine hepatocytes. By screening for human and porcine ISGs as potential HEV restriction factors, we characterized antiviral strategies of different host species and thereby provide an initial step towards a deeper understanding of how species-specificity in innate immune responses potentially determine HEV pathogenesis.

THU-624-YI
Characterization of isogenic hepatitis B virus variants transcriptomically links the basal core promoter mutation to a subset of hepatitis B-associated hepatocellular carcinoma
Leon Louis Seifert[1], Georgios Dangas[2], Yingpu Yu[1], Chenhui Zou[1], Hong Hur[1], Catherine Freije[1], Xupeng Hong[1], Mengyin Zhang[1], Corrine Quirk[1,3], Yichen Zhou[1,3], Kosuke Ogata[4], Manoj Kandpal[1], Charles Rice[1], William Schneider[1], Eleftherios Michailidis[2], Ype De Jong[1,3]. *[1]The Rockefeller University, New York, United States; [2]Emory University, Laboratory of Biochemical Pharmacology, Department of Pediatrics, Atlanta, United States; [3]Division of Gastroenterology and Hepatology, Weill Cornell Medicine, New York, United States; [4]Department of Molecular and Cellular BioAnalysis, Kyoto University, Kyoto, Japan*
Email: lseifert@rockefeller.edu

Background and aims: Hepatitis B virus (HBV) is generally considered non-cytopathic virus. Basal core promoter (BCP) and precore (PC) mutant variants are clinically associated with worse disease outcomes in chronic HBV. Infection studies on these variants in human hepatocyte chimeric mice have been limited by the lack of isogenic viral stocks. In this study, we sought to characterize how the PC and BCP mutations affected viral parameters and human hepatocyte responses in human hepatocyte chimeric mice.
Method: We developed an efficient method for generating infectious HBV stocks from genetically engineered HBV sequences, and performed HBV infection experiments in immunodeficient human hepatocyte chimeras with WT, PC, and BCP mutant variants of three isolates from genotypes HBV-A, -C, and -D. Viral parameters were measured longitudinally, and liver samples were collected at peak viremia for RNAseq.
Results: Following infection, the PC and BCP variants remained genetically stable and no reversion was observed. Across genotypes, the BCP mutant reduced serum HBeAg levels by ~90% compared to WT, whereas serum HBeAg was undetectable in PC mutant infections. While no differences in viremia kinetics were observed between WT and PC mutant infection across isolates, the BCP mutant accelerated viral kinetics in HBV-D and HBV-A. The single mutant variants exhibited no significant difference in HBV-C infection; however, an engineered double-mutant (PC + BCP mutations combined) accelerated viremia compared to HBV-C WT. Relative to uninfected mice, WT HBV infection showed significantly different transcriptomic profiles, with additional differences between HBV genotypes. KEGG pathway analysis revealed an enrichment of cancer-associated pathways in HBV-D BCP-infected mice. Notably, gene expression in these HBV-D BCP infected livers showed significant overlap with a distinct subset of HBV-associated HCCs from the TCGA dataset, previously linked to impaired survival.
Conclusion: In immunodeficient human hepatocyte chimeric mice, the BCP mutation induces isolate-dependent changes in viral kinetics and host transcriptional responses that are distinct from isogenic WT and PC mutant virus. In HBV-D, BCP mutant infection is associated with cancer-related gene expression that partly overlaps with poor-prognosis of HBV-HCCs. These data support an active role for the HBV BCP mutation in liver disease progression.

THU-625
Clustered regularly interspaced short palindromic repeats associated protein 9 guide RNA circular templates reduce hepatitis B virus replication via covalently closed circular DNA degradation
Deok Hwa Seo[1], Yeochan Yun[2], Min Gu Kim[3], Songmee Bae[4], Yong Kwang Park[4], Hyeon-Yeol Cho[2], Pil Soo Sung[5]. *[1]Department of Medical Sciences, Graduate School of The Catholic University of Korea, Seoul, Korea, Rep. of South; [2]Department of Bio and Fermentation Convergence Technology, Kookmin University, Seoul, Republic of Korea, Seoul, Korea, Rep. of South; [3]Department of Medical Sciences, Graduate School of The Catholic University of Korea, Republic of Korea, Seoul, Korea, Rep. of South; [4]Division of Chronic Viral Diseases, Center for Emerging Virus Research, National Institute of Health, Cheongju, Republic of Korea, Cheongju, Korea, Rep. of South; [5]Department of Medical Sciences, Graduate School of The Catholic University of Korea, Republic of Korea, Division of Gastroenterology and Hepatology, Department of Internal Medicine, College of Medicine, Seoul St. Mary's Hospital, The Catholic University of Korea, Seoul, Republic of Korea, Seoul, Korea, Rep. of South*
Email: smin0904@naver.com

Background and aims: Chronic hepatitis B virus (HBV) infection persists because covalently closed circular DNA (cccDNA) serves as a stable nuclear template for viral transcription. Nucleos(t)ide analogues suppress replication but do not eliminate cccDNA. We aimed to develop an RNA nanoparticle platform generated from circular templates encoding CRISPR associated protein 9 (Cas9) and guide RNA (gRNA) to promote cccDNA degradation and suppress HBV replication.
Method: Circular DNA templates encoding Cas9 and HBV-targeting gRNA were transcribed by rolling circle transcription (RCT) to form RNA nanoparticles, then conjugated with poly-L-lysine and N-acetylgalactosamine (GalNAc) for hepatocyte targeting. Antiviral activity was tested in HepAD38 replication and HepG2-NTCP infection models (n = 3 each). Intracellular cccDNA was quantified by quantitative polymerase chain reaction and secreted hepatitis B surface antigen (HBsAg) by enzyme-linked immunosorbent assay. Particle size and zeta potential were assessed by dynamic light scattering.
Results: Unmodified nanoparticles averaged ~60 nm, increasing to ~80 nm after poly-L-lysine and ~100 nm after GalNAc conjugation, with a zeta potential shift from negative to neutral or partially positive values. Cas9-gRNA circular template nanoparticles reduced intracellular cccDNA by 24% ($p = 0.018$) and HBsAg secretion by 41% ($p = 0.006$) versus controls, consistently across both models.
Conclusion: Cas9-gRNA circular templates generate functional RNA nanoparticles that reduce HBV cccDNA and suppress viral antigen production in vitro. This modular strategy supports further development of direct cccDNA-targeting therapeutics for chronic hepatitis B.

THU-626
The homeobox family suppresses hepatitis B virus via a key non-Immunosuppressive pathway during the active phases of chronic hepatitis B
Lin Yujie[1], Qiu Qian[1], Jing Liu[2], Shaokun Pan[3], Jinyu Wang[1], Youhua Xie[2], Jiming Zhang[1], Zhongliang Shen[1]. *[1]Department of Infectious Diseases, Huashan Hospital, Fudan University, Shanghai Shi, China; [2]Shanghai Medical College, Fudan University, Shanghai Shi, China; [3]Shanghai Institute of Infectious Diseases and Biosecurity, Fudan University, Shanghai Shi, China*
Email: shenzhongliangnjnu@163.com

Background and aims: Hepatitis B e antigen (HBeAg)-positive chronic hepatitis (EPH) and HBeAg-negative chronic hepatitis (ENH) phase are two critical periods in the natural history of chronic hepatitis B (CHB). Previous studies have suggested that immune-mediated liver injury is the key mechanism driving the decline in viral load, focusing primarily on the "external" attack by the immune system on infected cells. However, it remains unclear

whether hepatocytes themselves possess a shared and critical set of antiviral genes or regulatory networks during these two phases, capable of efficiently suppressing HBV gene expression and replication. We previously reported that the homeobox gene MSX1 is significantly upregulated in hepatocytes during the EPH phase. By activating the expression of DNAJA4, a member of the heat shock protein 40 family, MSX1 triggers the proteasome degradation pathway to degrade the HBV X protein, thereby inhibiting HBV covalently closed circular DNA transcription. This finding suggests that the homeobox family may be involved in intracellular antiviral responses during CHB active phases.

Method: We constructed an overexpression plasmid library representing 16 subfamilies of the homeobox family and compared their antiviral functions in bont *in vitro* and *in vivo models*. Subsequently, we analyzed gene expression in liver biopsy tissues across four natural history phases of CHB using transcriptomics and single-cell sequencing technologies. Molecular mechanisms underlying homeobox-mediated activation of DNAJA4 expression and DNAJA4-mediated degradation of HBx were explored through such as bioinformatics, dual-luciferase reporter assays, and protein-protein interaction experiments.

Results: All selected homeobox subfamily members significantly suppressed HBV gene expression and replication, with BARX1, NKX1-1, and SHOX exhibiting particularly strong antiviral activity. Homeobox proteins transcriptionally activate DNAJA4 expression, promoting the degradation of HBx via a ubiquitin-independent proteasome pathway. Different members of homeobox proteins are expressed in a complementary manner during the EPH and ENH phases, while DNAJA4 is consistently and significantly upregulated in both phases. This indicates that the regulatory network of homeobox proteins converges at the level of DNAJA4.

Conclusion: The suppression of HBV mediated by the homeobox family deepens our understanding of the pathological basis of CHB and may offer potential targets for novel therapeutic strategies.

Hepatocellular carcinoma is a viral reservoir during hepatitis C treatment with direct-acting antivirals

Mario Jorge Silva[1,2], Fatima Oliveira Martins[2], Ana Patricia Negrinho[2], Antonio Figueiredo[3], Carina Santos[3], Maria Helena Gloria[4], Pedro Lages Martins[1,2], Elizabeth Padua[5], Pedro Carreiro-Martins[2], Jorge Canena[1,2,6,7], Mario Oliveira[3], Hugo Pinto Marques[2,8], Filipe Calinas[1], Silvia Vilares Conde[2]. *[1]Unidade Local de Saúde de São José – Serviço de Gastrenterologia, Lisboa, Portugal; [2]NOVA Medical School, Lisboa, Portugal; [3]Unidade Local de Saúde de São José – Serviço de Anatomia Patológica, Lisboa, Portugal; [4]Unidade Local de Saúde de São José – Unidade de Transplantes, Lisboa, Portugal; [5]Instituto Nacional de Saúde Dr. Ricardo Jorge, Lisboa, Portugal; [6]Hospital CUF Tejo - Centro Universitário de Gastrenterologia, Lisboa, Portugal; [7]Unidade Local de Saúde Amadora-Sintra – Serviço de Gastrenterologia, Lisboa, Portugal; [8]Unidade Local de Saúde de São José – Centro Hepato-Bilio-Pancreático e de Transplantação, Lisboa, Portugal*
Email: mariojorgesilva01@gmail.com

Background and aims: The presence of hepatocellular carcinoma (HCC) has been associated with reduced efficacy of hepatitis C treatment with direct-acting antivirals (DAA), but the underlying biological mechanisms remain unclear. We aimed to investigate whether HCC acts as a viral reservoir during treatment of hepatitis C with DAA.

Method: We analyzed patients with liver cirrhosis and viable HCC who underwent liver transplantation during ongoing DAA therapy at a national referral center between 2015 and 2024. Hepatitis C virus (HCV) was quantified in explanted livers, in both tumoral (HCC) tissue and adjacent non-tumoral liver tissue. Viral quantification was performed by measuring immunofluorescence (IF) intensity for the HCV nonstructural 3 (NS3) protein, assessed by widefield microscopy and quantified with Fiji® software. Molecular quantification of HCV RNA was tried but not feasible (presumably due to viral RNA degradation). Statistical analyses were performed using STATA v12.1®. The study was approved by the institutional Ethics Committees.

Results: Fifteen patients were included; 87% were male. Liver transplantation was performed between day 14 and day 115 of DAA therapy. Eight patients received sofosbuvir/ledipasvir±ribavirin, six received sofosbuvir + daclatasvir±ribavirin and one received sofosbuvir + ribavirin. During the first 50 days of treatment (n = 8), HCV presence was significantly higher in tumoral (HCC) tissue than in non-tumoral liver tissue (median IF in tumoral tissue 3.01 [0.22–55.77] vs 0.39 [0.18–2.81] in non-tumoral tissue, p = 0.01). After 50 days of therapy (n = 7), HCV levels were similarly low in both tumoral and non-tumoral tissues (median IF in tumoral tissue 0.22 [0.03–2.4] vs. 0.39 [0.27–1.72] in non-tumoral tissue, p = 0.31). None of those patients developed post-transplant HCV recurrence. In both univariate and multivariable analyses - including HCV genotype and baseline pre-treatment viral load, loco-regional HCC therapies, liver function, antiviral regimen, and treatment duration - a significant negative correlation (p = 0.04) was observed between DAA treatment duration and HCV IF intensity, exclusively in HCC tissue.

Conclusion: During treatment of hepatitis C with DAA in cirrhotic patients with viable HCC, HCV persisted longer within HCC tissue than in non-tumoral liver tissue. These findings support the role of HCC as a viral reservoir during treatment of hepatitis C with DAA.

THU-628

The miR-4461-FGA regulatory axis characterises hepatitis B virus infection and HBV-related hepatocarcinogenesis

Aiko Sakai[1], Masaya Sugiyama[1]. *[1]Department of Viral Pathogenesis and Controls, National Institute of Global Health and Medicine, Japan Institute for Health Security, Tokyo, Japan*
Email: sugiyama.m@jihs.go.jp

Background and aims: Hepatitis B virus (HBV) infection leads to heterogeneous clinical outcomes, including hepatocellular carcinoma (HCC), through mechanisms not fully explained by chronic inflammation. MicroRNAs (miRNAs) are key regulators of gene expression, yet HBV-specific miRNA alterations and their functional consequences remain unclear. This study aimed to identify HBV-associated miRNAs at the single-cell level and to clarify their downstream targets and clinical relevance.

Method: Human liver single-cell RNA sequencing (scRNA-seq) was analysed to identify miRNAs altered in HBV-infected hepatocytes. miR-4461 expression was examined in HBV-transfected HuH7 and HepG2 cells and in HBV-infected primary human hepatocytes. Target genes were predicted using multiple databases and validated by 3′ UTR luciferase reporter assays. Plasma miR-4461 and fibrinogen alpha chain (FGA) levels were measured in patients with HBV infection, hepatitis C virus (HCV) infection, and HBV-derived HCC, including paired samples before and after tumour resection.

Results: scRNA-seq analysis of human liver revealed significant downregulation of miR-4461 specifically in HBV-infected hepatocytes. Consistently, miR-4461 expression was reduced in HuH7 and HepG2 cells following HBV transfection and in primary hepatocytes infected with HBV. In silico analysis demonstrated that miR-4461 did not directly bind to HBV RNA, suggesting an indirect mechanism. Among genes commonly predicted across multiple miRNA target databases, FGA was identified as a candidate target. Overexpression of miR-4461 resulted in reduced FGA protein levels, and luciferase reporter assays using the FGA 3′UTR confirmed direct repression by miR-4461. Clinically, plasma miR-4461 levels were significantly lower, while FGA concentrations were higher, in HBV patients compared with HCV patients ($P < 0.05$). These inverse changes were more pronounced in patients with HBV-derived HCC. Importantly, paired analysis before and after surgical resection of HCC demonstrated an increase in miR-4461 levels accompanied by a decrease in FGA levels after tumour removal ($P < 0.05$).

Conclusion: miR-4461 is selectively downregulated in HBV-infected hepatocytes and HBV-derived HCC and directly suppresses FGA expression via its 3′UTR. The consistent inverse relationship between miR-4461 and FGA across single-cell data, experimental models, and patient plasma supports a role for the miR-4461–FGA axis in HBV-specific hepatocarcinogenesis and highlights its potential as a biomarker.

AZD6750, a CD8α-guided IL-2 molecule, enhances hepatitis B virus-specific CD8+ T-cell activation and function

Phillip Swanson II[1], Michael Powell[1], Marcelino Padilla[1], Galit Alter[1].
[1]*AstraZeneca, Gaithersburg, United States*
Email: phillip.swanson@astrazeneca.com

Background and aims: Chronic hepatitis B infection was estimated to affect ~254 million people and caused ~1.1 million deaths in 2022. Current treatment options rarely achieve functional cure, defined as sustained hepatitis B surface antigen loss with hepatitis B virus (HBV) DNA suppression post-treatment, underscoring the need for novel treatment strategies. Antiviral CD8+ T cells are critical for clearing infected hepatocytes and reducing the viral reservoir. Preclinical studies show that restoring CD8+ T-cell function can improve antiviral control. AZD6750, a CD8-guided IL-2 mutein fusion protein, is engineered to preferentially expand and activate CD8+ T cells. We evaluated whether AZD6750 selectively augments HBV-specific CD8+ T cells and enhances antiviral function.
Method: Peripheral blood mononuclear cells from 12 patients with chronic hepatitis B were cultured with AZD6750 to assess immunogenicity and antiviral activity. Pharmacodynamic effects on peripheral immune subsets were quantified by flow cytometry after exposure to AZD6750. The effects of AZD6750 on the phenotype and function of HBV-specific CD8+ T cells were evaluated by intracellular cytokine staining following HBV peptide stimulation. Antigen-specific activity was determined using *in vitro* cytolytic assays against HBV peptide-pulsed target cells.
Results: AZD6750 expanded CD8+ T cells at a 42-fold lower dose than recombinant IL-2 and showed preferential activity, achieving CD8+ T-cell expansion at doses 287-fold and 9-fold lower than those required for CD4+ T cells and NK cells, respectively. Within the expanded CD8+ T-cell pool, AZD6750 drove a dose-dependent increase in the frequency and number of IFNg and TNFa-producing HBV-specific CD8+ T cells, accompanied by elevated activation/proliferation markers (CD69, Ki-67) and cytotoxic mediators (Granzyme B, perforin). AZD6750 also induced a dose-dependent increase in antigen-specific cytolytic activity.
Conclusion: AZD6750 preferentially expands and activates CD8+ T cells, including HBV-specific subsets, from patients with chronic hepatitis B and enhances antigen-specific cytolysis of target cells. These findings support further investigation of AZD6750 as a potential immunotherapy aimed at advancing toward functional cure for chronic hepatitis B.

Email: penfieldwu@gmail.com

Background and aims: This study investigated the impact of single-nucleotide variants (SNVs) in the HBV Pre-S/S region on tumor development, related mechanisms, and evaluated the role of antiviral therapy in chronic hepatitis B (CHB) patients with these SNVs who were in the "gray zone" (ALT <80 U/L or HBV DNA <2000 IU/ml) according to Asian-Pacific guideline.
Method: A retrospective analysis was conducted in 104 CHB patients in the gray zone. Hepatocellular carcinoma (HCC)-associated SNVs, including six in genotype B and twenty-one in genotype C, were analyzed in the baseline samples.
Results: HCC occurred in 15 patients (14.4%) during the median follow-up period of 10.4 years. Genotype B HBV-infected HCC patients had more T53C, A273G, and A529G SNVs and genotype C HBV-infected HCC patients had more T53C, G633A, and A3120G SNVs than HCC-free groups. Antiviral therapy reduced the risk of HCC in patients with HCC-associated SNVs in the gray zone both genotype B or C. Ectopic expression of replication-competent HBV plasmids in Huh7 cells expressing HCC-associated SNVs resulted in greater impairment of mitochondrial dynamics, increased production of reactive oxygen species (ROS), decreased mitochondrial membrane potential, lower ATP production, higher basal calcium levels, and reduced calcium buffering capacity compared to controls or wild-type HBV-expressing cells.
Conclusion: CHB patients in the gray zone remain at risk for HCC owing to both wild-type and HCC-associated HBV SNVs, especially the latter, inducing mitochondrial and metabolic dysfunctions. Antiviral therapy reduces the risk of HCC development in these patients.
P.S. Dr. Wei Teng and Prof. Ting-Tsung Chang share the co-first authors; Dr. Jenny Yuh-Jin Liang and Prof. Jaw-Ching Wu share the co-corresponding authors.

Email: barbara.testoni@inserm.fr

Background and aims: ALG-001075, an HBV capsid assembly modulator inducing the formation of empty capsids (CAM-E), was shown to have secondary antiviral effects against HBV cccDNA formation and HBeAg secretion in vitro. Moreover, pevifoscorvir sodium (pevy), a prodrug of ALG-001075, has demonstrated potent reductions of HBV DNA, RNA, HBsAg, HBcrAg and HBeAg in subjects with CHB. Here, we provide experimental evidence from cell-based experiments that ALG-001075 also potently and durably inhibits HBsAg secretion and intracellular HBV RNA levels.
Method: Differentiated HepaRG cells were treated from day 6 post-infection with 1 µM ALG-001075 or lamivudine (3TC) for 1 month, then ALG-001075 was either continued for an additional month (arm 1) or stopped (arm 2) and cells monitored off-treatment for 4 weeks. Harvested cells and supernatants were analyzed for HBeAg and HBsAg secretion by ELISA, intracellular HBV markers (total HBV DNA and RNA, 3.5Kb RNA) by qPCR, cell viability and hepatocyte differentiation markers.

Results: ALG-001075 treatment resulted in potent inhibition of RNA and HBeAg secretion, as well as 38% inhibition of secreted HBsAg after 4 weeks of treatment, which was absent in 3TC treated cells. During the additional 4 weeks of treatment in arm 1, both HBeAg and HBsAg secretion continued to decrease and reached 90% and 80% inhibition, respectively, compared to untreated or 3TC-treated conditions. Similarly, intracellular HBV RNA detected with primers amplifying 3.5Kb RNAs or all HBV RNA species were more profoundly suppressed after the additional 4 weeks of ALG-001075 treatment. In arm 2, HBeAg inhibition was maintained off-ALG-001075 treatment and HBsAg levels continued to decline reaching 80% reduction with respect to untreated and 3TC-treatment. Consistently, no rebound in intracellular HBV RNAs was detected and only a partial rebound of intracellular total HBV DNA was found in the ALG-001075 treated cells, contrary to full rebound to baseline levels seen with 3TC. The ALG-001075 antiviral effect was not associated with cytotoxicity or reduced gene expression of bona fide hepatocyte differentiation markers.
Conclusion: Long term ALG-001075 treatment resulted in profound suppression of HBeAg, HBsAg and intracellular HBV RNAs which was durable after treatment withdrawal in HBV-infected HepaRG cells, suggesting a potential reduction in cccDNA level and/or transcriptional activity in these experimental conditions.

THU-635
Mitochondrial-ER remodeling differentiates HCC-adjacent and HCC-free HBV-infected liver tissues

Kousho Wakae[1], Haruyo Aoyagi[1], Ryuta Ueda[1], Akihito Tsubota[2], Akira Matsukura[3], Teruyuki Usuba[4], Hiroko Iijima[5], Yuriko Sakamaki[6], Shizuko Ichinose[7], Kento Fukano[8], Masaya Sugiyama[9], Kazuyoshi Hosomichi[10], Koichi Watashi[1], Masamichi Muramatsu[11], Masanori Isogawa[1], Takaji Wakita[8], Hideki Aizaki[1]. *[1]National Institute of Infectious Diseases, Japan Institute of Health Security, Tokyo, Japan; [2]The Jikei University School of Medicine, Tokyo, Japan; [3]Otakanomori Hospital, Chiba, Japan; [4]The Jikei University Katsushika Medical Center, Tokyo, Japan; [5]Hyogo Medical University, Hyogo, Japan; [6]Institute of Science Tokyo, Tokyo, Japan; [7]Nippon Medical School Hospital, Tokyo, Japan; [8]Japan Institute for Health Security, Tokyo, Japan; [9]National Center for Global Health and Medicine, Japan Institute for Health Security, Tokyo, Japan; [10]Tokyo University of Pharmacy and Life Sciences, Tokyo, Japan; [11]Foundation for Biomedical Research and Innovation, Hyogo, Japan*
Email: wakae.k@jihs.go.jp

Background and aims: Hepatitis B virus (HBV)-associated hepatocarcinogenesis is driven by multiple factors, including metabolic alterations and inflammation. However, it remains unclear when these cancer hallmarks emerge during tumor initiation and how they relate to subcellular structural changes. In this study, we compared HBV-infected liver tissues adjacent to hepatocellular carcinoma (HCC), with HBV-infected liver tissues from patients without HCC, to highlight early morpho-metabolic changes preceding HCC formation.
Method: HBV-infected liver tissues adjacent to HCC and those without HCC, were analyzed by Transmission electron microscopy (TEM), to quantify mitochondrial morphology, ER structure, ER-mitochondrial contacts, and glycogen content. Transcriptomic analyses were concurrently performed to compare gene expression profiles between the two tissue types.
Results: HCC-adjacent tissues were characterized by increased ER-mitochondrial proximity and reduced glycogen content compared with HCC-free tissues. These ultrastructural changes were accompanied by upregulation of genes associated with oxidative phosphorylation (OXPHOS), suggesting a metabolic shift toward enhanced glucose utilization. In addition, the adjacent tissues exhibited reduced mitochondrial elongation, indicative of increased oxidative stress. Consistently, genes related to oxidative stress and inflammatory signaling were concurrently upregulated.
Conclusion: These findings provide evidence of mitochondria and ER remodeling in the HCC-adjacent HBV-infected liver, accompanying increased glucose metabolism, oxidative stress, and inflammation. How these changes link to each other and contribute to HCC initiation, along with HBV infection, will be discussed.

THU-636
Construction and application of a mouse model for hepatitis E virus infection

Tianxu Liu[1], Xinyue Yang[1], Lin Wang[1]. *[1]Peking University Health Science Center, Beijing, China*
Email: lin_wang@pku.edu.cn

Background and aims: Hepatitis E virus (HEV) causes approximately 19.47 million symptomatic cases annually and is an emerging cause of chronic hepatitis. Although HEV is zoonotic, no definite evidence demonstrates that laboratory mice are susceptible to all known HEV genotypes. The factors define the HEV's host species range remain unclear. Given numerous genetic variants and toolkits available for mice that permit deep mechanistic studies, we aimed to develop inbred mouse models of HEV infection.
Method: AG129 and C57BL/6J mice were infected with HEV for experimental analyses. Key infection parameters assessed included HEV RNA detection (quantitative RT-PCR and in situ hybridization via RNAscope), liver function tests, histopathological examination, and liver transcriptomic profiling. Single-cell RNA sequencing was employed alongside transcriptomics analysis to delineate the infection dynamics and investigate virus-host interactions.
Results: We show that an emerging human-pathogenic HEV genotype discovered in rats can breach species barrier and robustly infect AG129 mice (double IFNα/β and IFNγ receptor knockout mice). By single-cell sequencing and RNAscope, we demonstrate viral tropism to macrophages and hepatocytes of the liver, providing previously unknown single-cell atlas of intrahepatic HEV infection. We subsequently adapted this HEV isolate by serial passaging in AG129 mice. The resulting mouse-adapted strain at passage 13 showed ability to infect immunocompetent C57BL/6J mice. Thus, we developed two mouse models using immunocompromised and immunocompetent mice, both support efficient HEV replication, and antiviral and vaccine testing. This study reveals that $CD4^+$ T cell exhaustion is a pivotal driver of chronic infection.
Conclusion: We developed two mouse models using AG129 and wild-type C57BL/6J mice, both support efficient HEV replication. This work also establishes the first immunocompetent mouse model for HEV infection. These mouse models offer a robust platform for studying HEV immunopathogenesis, evaluating antivirals and vaccines, and investigating cross-species transmission mechanisms.

THU-637
Aacquisition of four amino acid substitutions promotes robust replication of hepatitis C virus genotype 1b in cell culture

Tomoko Date[1], Noriyuki Watanabe[2], Kano Sakamoto[1], Masaya Sugiyama[1], Kousho Wakae[2], Haruyo Aoyagi[2], Hideki Aizaki[2], Takaji Wakita[2]. *[1]National Institute for Global Health and Medicine, Japan Institute for Health Security, Chiba, Japan; [2]National Institute of Infectious Diseases, Japan Institute for Health Security, Tokyo, Japan*
Email: date.t@jihs.go.jp

Background and aims: The JFH-1 cell culture system has greatly advanced hepatitis C virus (HCV) research, enabling the development of direct-acting antivirals (DAAs) with cure rates >95% and detailed dissection of the HCV life cycle (entry, replication, assembly, and release). In this study, we focused on genotype 1b (GT1b), a major globally prevalent HCV subtype. Using next-generation sequencing (NGS), we analyzed GT1b isolates from patient samples and identified three major phylogenetic clusters (Q1, Q2, and R). Our aim was to establish representative replication-competent infectious clones for each cluster to facilitate virological and therapeutic studies.

Method: Subgenomic replicons and full-length GT1b cDNA clones were constructed based on sequences from each cluster. Replicon RNAs were transfected into Huh7 cells, and replication efficiency was evaluated by colony formation. Full-length genomes carrying adaptive mutations were introduced into Huh7 cells and maintained in long-term culture. HCV replication was monitored by measuring core protein levels in culture supernatants. Viral genomes were sequenced at time points corresponding to peak replication.
Results: Colony formation assays showed that the EG substitution in NS3 (E1204G) and the SI substitution in NS5A (S2206I) enhanced GT1b replication. A full-length Q1 clone containing both mutations (EGSI) achieved peak replication during long-term culture after >130 days. Sequence analysis at peak replication identified two additional amino acid substitutions in E2. For both Q2 and R strains, introducing EGSI together with these E2 substitutions further increased viral production in long-term culture.
Conclusion: Cooperative mutations in nonstructural (NS3 and NS5A) and structural (E2) regions markedly enhance GT1b replication in vitro. These adaptations enabled the generation of replication-competent infectious clones representing major GT1b lineages, providing valuable tools for HCV biology and antiviral development.

THU-638
A male-enriched NFIC–p300 axis drives sex-biased HBV cccDNA activation

Lu Zhang[1], Hongzhi Guo[2], Xinai Chen[1], Xiaoming Cheng[1], Yuchen Xia[1]. [1]*Wuhan University, Wuhan, China;* [2]*Fudan University, Shanghai, China*
Email: 00032118@whu.edu.cn

Background and aims: Sex differences are a prominent yet incompletely understood feature of hepatitis B virus (HBV) infection, with males exhibiting higher viral loads and increased risk of disease progression. This study aimed to elucidate the molecular and epigenetic mechanisms underlying sex-biased HBV replication.
Method: We integrated mouse models carrying HBV covalently closed circular DNA (cccDNA), human hepatocyte systems, and multi-omics analyses. Chromatin accessibility, transcription factor binding, and histone modifications on the viral minichromosome were examined using ATAC-seq, CUT&Tag, chromatin immunoprecipitation, and in vitro reconstituted minichromosome assays. Functional relevance was assessed through genetic perturbation and antisense oligonucleotide–mediated knockdown in vitro and in vivo.
Results: We identified nuclear factor I C (NFIC) as a male-enriched transcription factor that directly binds HBV cccDNA and recruits the histone acetyltransferase p300. This NFIC–p300 epigenetic axis enhances histone acetylation, increases viral chromatin accessibility, and drives male-biased HBV transcription. Depletion of NFIC eliminated sex differences in viral transcription without affecting cccDNA abundance, and antisense targeting of NFIC robustly suppressed viral transcription in vivo without detectable toxicity.
Conclusion: These findings define a sex-dependent epigenetic mechanism governing HBV transcription and identify NFIC as a promising host-directed therapeutic target for HBV infection.

THU-639
Cross-species core protein chimerism enables HBV cccDNA formation in murine hepatocytes

Kaitao Zhao[1], Xueyun Luo[1], Chen Li[1], Xiaoyun Li[1], Xiaoming Cheng[1], Yuchen Xia[1]. [1]*Wuhan University, Wuhan, China*
Email: 00032118@whu.edu.cn

Background and aims: Murine hepatocytes are not permissive to hepatitis B virus (HBV) infection, even with ectopic expression of the viral receptor, human NTCP (hNTCP). We previously reported that a major restriction lies in the inefficient disassembly of cytoplasmic HBV nucleocapsids. This study aimed to overcome this barrier by constructing HBV chimeras incorporating HBc proteins from other mammalian species.
Method: HBV sequences from various mammals were analyzed evolutionarily. Twelve HBc proteins, derived from 18 mammalian HBV isolates, were co-transfected with an HBc-null HBV replication plasmid into the murine hepatoma cell line Hepa1-6-hNTCP. Core-associated HBV DNA and Hirt-extracted DNA were analyzed by Southern blot. In vivo cccDNA formation was assessed using a hydrodynamic injection mouse model. DNase I sensitivity assays were performed to evaluate nucleocapsid disassembly. HBc protein and capsid localization were examined via immunofluorescence and nuclear/cytoplasmic fractionation. HBV chimeras harboring different HBc variants were also generated to assess infectivity in murine hepatocytes.
Results: Eighteen mammalian HBV sequences were analyzed, and 12 HBc variants were screened for their ability to support cccDNA formation in murine hepatic cells. Three HBc proteins enabled robust cccDNA formation both *in vitro* and *in vivo*. Notably, the core-associated HBV DNA from these variants was fully sensitive to DNase I digestion, indicating highly efficient nucleocapsid disassembly.
Conclusion: These findings reinforce that nucleocapsid disassembly is a key restriction step in HBV infection in mice. Engineering HBV to express specific non-human HBc proteins represents a promising strategy to establish HBV infection in murine models.

THU-640
The impact of nucleos(t)ide analogues anti-hepatitis B virus therapy on PD-1 expression levels in peripheral blood T cells of patients

Iiu Yang[1], Jia Li[1], Chenrui Liu[1], Meng Zhang[1], Yaping Li[1], Shuangsuo Dang[1]. [1]*The Second Affiliated Hospital of Xi'an Jiaotong University, Xi'an, China*
Email: dang212@126.com

Background and aims: Currently, nucleotide analogues (NAs) represent the predominant class of antiviral agents employed in clinical practice. However, the immunological response outcomes exhibit significant heterogeneity among individuals despite comparable virological suppression efficacy. Based on this, this study took the expression level of PD-1 on peripheral blood T cells of CHB patients as the main observation index to observe the effect of NA antiviral therapy on the expression level of PD-1 on peripheral blood T cells of CHB patients.
Method: A cross - sectional study was conducted on patients who visited the Department of Infection and the Health Examination Department of the Second Affiliated Hospital of Xi'an Jiaotong University from September 2022 to December 2024. Including three groups, the untreated group, the NAs treatment group (patients who had received NAs treatment for more than 1 year) and the healthy control group. The proportions of $CD3^+PD1^+T$, $CD4^+PD1^+T$, and $CD8^+PD1^+T$ cells were collected.
Results: 1. The levels of $CD3^+PD1^+T$, $CD4^+PD1^+T$, and $CD8^+PD1^+T$ cells in the untreated group were significantly higher than those in the healthy control group ($P < 0.001$). 2. The levels of $CD3^+PD1^+T$, $CD4^+PD1^+T$, and $CD8^+PD1^+T$ cells in the NAs treatment group were lower than those in the untreated group ($P = 0.01/0.01/0.04$). 3. The results indicated that there was no significant statistical difference in the proportion of $CD8^+PD1^+$ T cells among the different antiviral groups, while there were statistical differences in the proportions of $CD3^+PD1^+$ T and $CD4^+PD1^+$ T cells. Further pairwise comparisons revealed that the proportion of $CD3^+PD1^+T$ cells in the ETV group was significantly higher than those in the TAF group and the TMF group ($P = 0.031/0.032$). The proportion of $CD4^+PD1^+$ T cells in the ETV group was significantly higher than those in the TAF group and the TMF group ($P = 0.038/0.040$). Although the proportion of $CD4^+PD1^+$ T cells in the ETV group was higher than that in the TDF group, the difference was not statistically significant. There were no statistical differences among the remaining groups ($P > 0.05$).
Conclusion: 1. The high expression of PD-1 on T cells in CHB patients is related to the chronicity of HBV infection.

2. Antiviral treatment with NAs can down-regulate the expression level of PD-1 on T cells in CHB patients. 3. Nucleotide analogues have a more obvious down-regulating effect on the expression level of PD-1 on T cells in CHB patients than nucleoside analogues.

THU-641

SERPINE1 activates PIKfyve-dependent lysosomal autophagy to restrict HBV replication and restore antiviral CD8⁺ T cell immunity

Yina Yu[1], Yunqing Qiu[1], Yan Lou[1]. [1]*The First Affiliated Hospital of Zhejiang University, Hangzhou, China*
Email: yanlou@zju.edu.cn

Background and aims: Functional cure of chronic hepatitis B (CHB) remains limited by persistent viral antigen expression and virus-induced immune tolerance. Current therapies rarely achieve HBsAg clearance or restore antiviral immunity. This study aimed to define the role of the host factor SERPINE1 in HBV infection and to determine whether it coordinates viral clearance and immune restoration by regulating lysosomal function and autophagy flux.
Method: SERPINE1 was genetically manipulated in HBV-replicating cell lines (HepG2.2.15, HepAD38) and a natural infection model (HepG2-NTCP) to assess its effects on HBV replication, antigen expression, and viral particle production. In vivo validation was performed using AAV-HBV and hydrodynamic injection mouse models. Protein interaction networks and downstream pathways were identified by co-immunoprecipitation, mass spectrometry, and quantitative proteomics. Lysosomal function and autophagy flux were evaluated using biochemical and imaging-based assays. Photoaffinity labeling, surface plasmon resonance, and cellular thermal shift assays were used to verify the interaction between SERPINE1 and the natural compound betulinic acid.
Results: SERPINE1 markedly suppressed HBV replication and reduced HBsAg levels in vitro and in vivo. Mechanistically, SERPINE1 directly interacted with the lysosomal lipid kinase PIKfyve, enhancing PtdIns(3,5)P_2 production, lysosomal acidification, autophagosome–lysosome fusion, and overall autophagy flux. Enhanced autophagy promoted degradation of viral components and limited diversion of defective ribosomal products to the proteasome, thereby reducing hepatocyte MHC-I antigen presentation and alleviating $CD8^+$ T cell exhaustion. Betulinic acid was identified as a direct SERPINE1 agonist that phenocopied these antiviral and immunomodulatory effects.
Conclusion: SERPINE1 activates the PIKfyve–lysosome–autophagy axis to couple HBV clearance with restoration of antiviral $CD8^+$ T cell function. This mechanism identifies SERPINE1 as a host target capable of breaking the cycle of viral persistence and immune tolerance in CHB, and highlights betulinic acid as a candidate molecule for therapies integrating antiviral and immune-reconstitutive strategies.

NIK activates IRF1-dependent interferon signaling to suppress hepatitis B virus in hepatocytes

Ziying Liu[1], Xiaoyong Zhang[2]. [1]*Department of Infectious Diseases, Nanfang Hospital, Southern Medical University, Guangzhou, 510515, China, State Key Laboratory of Multi-organ Injury Prevention and Treatment, Key Laboratory of Infectious Diseases Research in South China (Southern Medical University), Ministry of Education, Guangdong Provincial Key Laboratory for Prevention and Control of Major Liver Diseases, Guangdong Provincial Clinical Research Center for Viral Hepatitis, Guangdong Institute of Hepatology, Guangdong Provincial Research Center for Liver Fibrosis Engineering and Technology., Department of Infectious Diseases, The Second Affiliated Hospital, Guangzhou Medical University, Guangzhou, China, Guangzhou, China;* [2]*Department of Infectious Diseases, Nanfang Hospital, Southern Medical University, Guangzhou, 510515, China, State Key Laboratory of Multi-organ Injury Prevention and Treatment, Key Laboratory of Infectious Diseases Research in South China (Southern Medical University), Ministry of Education, Guangdong Provincial Key Laboratory for Prevention and Control of Major Liver Diseases, Guangdong Provincial Clinical Research Center for Viral Hepatitis; Guangdong Institute of Hepatology, Guangdong Provincial Research Center for Liver Fibrosis Engineering and Technology, Guangzhou, China*
Email: liuziying2636@foxmail.com

Background and aims: Hepatitis B virus (HBV) persistence relies on stably established covalently closed circular DNA (cccDNA). While NF-κB-inducing kinase (NIK) mediates non-canonical NF-κB signaling is critical in antiviral defense, its role in HBV control is undefined.
Method: Hepatocyte-specific NIK knockout ($NIK^{\Delta hep}$) and wild-type mice received hydrodynamic pAAV-HBV1.2 injection. NIK was modulated (knockdown/overexpression/mutants) in HBV-transfected/infected hepatoma cells. Signaling components (IKKα, NF-κB2, IRFs, STAT1) were depleted via CRISPR/Cas9. Mechanistic studies included RNA-seq, co-IP, plasmon resonance imaging and molecular docking. Murine NIK mRNA was delivered via lipid nanoparticles (LNPs) in HBV-persistent mice.
Results: We demonstrate that NIK suppresses HBV replication by directly binding and phosphorylating interferon regulatory factor 1 (IRF1), promoting its nuclear translocation and enhancing type I/III interferon production in hepatocytes. This kinase-dependent mechanism operates independently of the IRF3 or NFKB2 mediated non-canonical NF-κB pathway. Using hepatocyte-specific delivery of NIK mRNA via LNPs, we achieved rapid clearance of HBV antigens and DNA in mouse models without inducing hepatic inflammation. Clinically, CHB livers transcriptome showed elevated NIK expression correlating positively with IRF1, STAT1, and ISGs ($p < 0.001$) expression.
Conclusion: NIK is a potent hepatocyte-intrinsic HBV restriction factor acting via kinase-dependent IRF1 phosphorylation and IFN/ISG induction, independent of non-canonical NF-κB pathway. LNP-NIK mRNA represents a promising therapeutic strategy for functional HBV cure.

Background and aims: Achieving a 'functional cure' in chronic hepatitis B (CHB), defined as sustained hepatitis B surface antigen (HBsAg) seroclearance, is an achievable treatment goal, but with only a small minority of patients reaching this endpoint. Immune tolerance and T-cell mediated immune dysfunction are key factors contributing to the persistent presence of HBsAg. Plasma exosomes in T cells may play a role, but the mechanisms governing their functional manipulation are not well understood. This study evaluated the changes in the plasma exosomal miRNA profile during HBsAg seroclearance and explored their role in T cell dysfunction.
Method: miRNA sequencing (miRNA seq) was conducted on exosomes derived from treatment-naïve HBsAg-positive hepatitis B e antigen (HBeAg)-negative ($HBsAg^+$, $HBeAg^-$) CHB patients ($n = 10$) and patients achieving HBsAg seroclearance ($n = 10$) to identify key miRNAs. Target genes of let-7a-5p were validated via online prediction tools (Targetscan, mirDIP, miRWalk), dual-luciferase reporter assays, and western blot. Naïve $CD4^+$ T cells were treated with exosomes or transfected with let-7a-5p mimics/inhibitors to assess effects on Th17 cell, evaluated by flow cytometry and ELISA.
Results: Flow cytometry analysis revealed peripheral blood mononuclear cells from patients achieving HBsAg seroclearance exhibited a significantly lower proportion of Th17 cells compared to $HBsAg^+$·$HBeAg^-$ CHB patients ($1.64 \pm 0.73\%$ vs. $2.41 \pm 1.02\%$, $p < 0.01$).

miRNA seq identified 33 downregulated and 30 upregulated exosomal miRNAs. Among these, let-7a-5p was significantly increased in patients achieving HBsAg seroclearance ($p < 0.05$). IL6R, predicted as a target gene of let-7a-5p by online tools and validated through dual-luciferase reporter assay, was found to be involved in Th17 cell differentiation. In-vitro experiments showed that overexpression of let-7a-5p could downregulate IL6R expression, reduced the proportion of Th17 cells (2.05 ± 0.4% vs. 4.67 ± 0.5%, $p < 0.01$), and decrease IL17 levels (204.7 ± 27.1 pg/mL vs. 268.3 ± 22.8 pg/mL, $p < 0.05$), whereas inhibition of let-7a-5p reversed these effects.

Conclusion: We investigated the role of plasma exosomes in HBsAg seroclearance and demonstrated that exosomal let-7a-5p from HBeAg-negative CHB patients regulates Th17 cell differentiation by targeting IL6R. These findings may contribute to the development of novel immunotherapeutic strategies and provide new scientific insights to achieving functional cure.

Viral hepatitis B and D – Clinical aspects

Investigation of intrahepatic cccDNA activity in HBsAg-negative HBV-infected individuals and its association with hepatocellular carcinoma risk

Yanfei Feng[1], Jianning Jiang[1,2]. [1]*The first affiliated hospital of Guangxi Medical University, Nanning, China;* [2]*Key Laboratory of Early Prevention and Treatment for Regional High Frequency Tumor (Guangxi Medical University), Ministry of Education, Nanning, China*
Email: gxjjianning@163.com

Background and aims: Hepatitis B surface antigen (HBsAg)-negative chronic hepatitis B (CHB) patients are often considered to have reduced viral activity but remain at risk for hepatocellular carcinoma (HCC) and viral reactivation. This study aimed to investigate the presence, transcriptional activity of hepatitis B virus (HBV) covalently closed circular DNA (cccDNA) in the liver, and its association with HCC development in HBsAg-negative individuals.

Method: 138 patients were enrolled. Study cohort: 92 HBsAg-negative, HBcAb-positive patients (41 HCC, 25 post-therapy "functional cure", 26 spontaneous resolution). Control cohort: 46 HBsAg-positive patients (<100 IU/mL; 22 HCC, 24 treated but still positive). Intrahepatic cccDNA and total HBV DNA (tDNA) were quantified by digital PCR (log10 copies/10^9 cells); cccDNA/tDNA ratio was calculated. Serum pgRNA was undetectable in all.

Results:

- Higher cccDNA activity in peritumoral tissue: Among 63 HCC patients, cccDNA levels were significantly higher in peritumoral tissue than in tumor tissue (2.25 ± 67 vs 0.73 ± 1.53 log10 copies/10^9 cells, P = 0.000), with a higher cccDNA/tDNA ratio.
- HBsAg-negative HCC patients show intermediate viral load: In peritumoral tissue, HBsAg-negative patients (n = 41) had lower cccDNA and tDNA than HBsAg-positive patients (n = 22), but higher levels than the spontaneous resolution group (n = 26), with no difference in cccDNA/tDNA ratio between serogroups.
- Persistent virus in "functionally cured" patients: The functionally cured subgroup (n = 25) had lower tDNA than non-seroconverted patients (n = 24), but its cccDNA, tDNA, and cccDNA/tDNA ratio were all significantly higher than in the spontaneous resolution group.
- Comparable viral status in HBsAg-negative subgroups: No significant differences in cccDNA, tDNA, or cccDNA/tDNA ratio were found between HBsAg-negative HCC patients and the functionally cured group.

Conclusion: Transcriptionally active cccDNA persists in the livers of HBsAg-negative individuals at a level significantly higher than in spontaneous resolution, underpinning their long-term HCC risk and potential for viral reactivation. "Functional cure" does not equate to complete virological eradication, as a low-level viral reservoir persists in the liver. This study highlights the need for monitoring intrahepatic cccDNA in high-risk, HBsAg-negative, HBcAb-positive individuals and suggests that current functional cure criteria may require refinement by incorporating intrahepatic virological parameters for more precise assessment.

Background and aims: qHBsAg is increasingly recognised as a tool for clinical management of CHB. An international expert panel conducted a Delphi consensus exercise to develop statements on qHBsAg use; updated EASL guidelines on HBV management were published whilst this was ongoing. We compared the final qHBsAg consensus statements with 2025 EASL recommendations on qHBsAg use.

Method: Futuring Liver Care (FLC), convened by GSK, is an international panel including hepatologists, gastroenterologists, infectious disease specialists, public health specialists and patient advocates. The Delphi consensus included 42 participants from FLC and their networks, representing CHB care stakeholders across North America, Asia-Pacific and Europe. Initial statement development was supported by systematic and scoping literature reviews. The Delphi process included 3 voting rounds and a finalization meeting. Voting used a 7-point Likert scale (strongly agree to strongly disagree) with the opportunity to provide free-text comments, and to propose new statements in Round 1. Consensus was defined as ≥75% agree/strongly agree in 2 rounds with ≥80% panel response. Final

statements were compared with relevant sections of the 2025 EASL HBV management guidelines.
Results: The Delphi panel had a high response rate (≥90% across 3 rounds), confirming 37 statements on: (A) CHB natural history (3 statements); (B) disease outcomes (5); (C) management of individuals not on therapy (3); (D) treatment goals (5); (E) factors associated with HBsAg loss (5); (F) monitoring during treatment and prediction of HBsAg loss (6); (G) thresholds to guide decisions (4), and (H) research gaps and challenges (6). Closest alignment with EASL guidelines was seen in topics A, C, D and F; overall, 25/37 statements were aligned with EASL 2025 guidelines, with 11 providing more detailed guidance. The 12/37 additional statements covered topics outside of EASL scope, such as qHBsAg and novel finite therapies and qHBsAg-specific research priorities. Key statements covered the value and durability of spontaneous HBsAg loss vs that achieved with therapy, and qHBsAg thresholds predictive of HBsAg loss during finite therapy.
Conclusion: These global consensus statements complement the EASL 2025 guidelines and strongly support routine qHBsAg testing in CHB care. Clinicians, liver associations and policymakers should consider integrating qHBsAg testing to inform current and future CHB management.

Hepatitis B core–related antigen predicts immune-active transition in HBeAg-negative indeterminate chronic hepatitis B
Hsing-Yu Yeh[1], Hsin Kuan-Hui[1], Chun-Jen Liu[1], Chun-Ming Hong[1], Tung-Hung Su[1], Hung-Chih Yang[1], Chen-Hua Liu[1], Pei-Jer Chen[1], Tai-Chung Tseng[1], Jia-Horng Kao[1]. *[1]National Taiwan University Hospital, Zhongzheng District, Taiwan*
Email: tctsenghbv@gmail.com

Background and aims: Chronic HBV (CHB) infection with ongoing hepatic inflammation increases the risk of cirrhosis and hepatocellular carcinoma (HCC). Among HBeAg-negative individuals, those in the indeterminate phase exhibit a heterogeneous clinical course, with a subset eventually progressing to immune-active hepatitis.
This study aimed to investigate whether hepatitis B core-related antigen (HBcrAg), a surrogate marker of intrahepatic cccDNA activity, can predict transition from the indeterminate phase to the immune-active phase in HBeAg-negative patients.
Method: We analyzed 1,090 HBeAg-negative grey zone patients from the ERADICATE-B cohort (n = 2,666), which excluded inactive CHB patients (HBV DNA <2000 IU/mL +ALT < 1× ULN by AASLD definition) and those with ALT >2× ULN. Baseline measurements included HBV-related seromarkers (HBcrAg, HBV DNA, HBsAg) and liver function. The risk of immune-active transition (ALT> 2× ULN + HBV DNA >2000 IU/mL), HBV-associated hepatitis (ALT> 100 U/L + HBV DNA >2000 IU/mL), HBsAg loss, death and liver-related death were assessed using Kaplan-Meier survival analysis and Cox proportional hazards models. Sensitivity analyses excluded patients who developed immune-active transition within the first year of follow-up.
Results: During 11,674.6 person-years of follow-up, 619 patients progressed to the immune-active phase, yielding an incidence rate of 5.3 per 100 person-years (95% CI, 4.9–5.7). Higher baseline HBcrAg levels were associated with an increased risk of immune-active transition and demonstrated superior predictive performance compared with HBV DNA (P = 0.03). Compared with patients with HBcrAg <10 KU/mL, those with levels of 10–99 KU/mL and ≥100 KU/mL had significantly higher risks of immune-active transition, a finding that remained consistent in sensitivity analyses. Higher HBcrAg levels were also associated with increased risks of HBV-associated hepatitis, all-cause mortality, and liver-related mortality, as well as a lower probability of HBsAg loss. In multivariable analysis adjusting for age, baseline ALT, HBV DNA, and HBsAg levels, HBcrAg remained an independent predictor of immune-active transition.
Conclusion: Among HBeAg-negative indeterminate patients, baseline HBcrAg levels are independent predictors of immune-active transition and other adverse outcomes. HBcrAg may serve as a useful biomarker to identify patients who may benefit from closer monitoring or preemptive antiviral therapy.

TOP-567
AASLD–EASL zone ALT associated with higher risk of HCC and liver-related mortality inchronic hepatitis B patients
Tai-Chung Tseng[1], Shih-Jer Hsu[1], Mei-Hung Pan[2], Chun-Jen Liu[1], Chien-Jen Chen[2], Tung-Hung Su[1], Hung-Chih Yang[1], Chen-Hua Liu[1], Pei-Jer Chen[1], Hwai-I Yang[2], Jia-Horng Kao[1]. *[1]National Taiwan University Hospital, Taipei, Taiwan; [2]Academia Sinica, Taipei, Taiwan*
Email: tctsenghbv@gmail.com

Background and aims: The optimal alanine aminotransferase (ALT) threshold for defining normal values in chronic hepatitis B (CHB) remains controversial. This study aimed to determine if CHB patients with ALT levels within the EASL-defined normal range, but exceeding the stricter AASLD-defined normal thresholds (the AASLD–EASL zone), are at increased risk for hepatocellular carcinoma (HCC) and liver-related death.
Method: We analyzed 5,102 CHB patients with EASL-defined normal ALT levels from the ERADICATE-B and REVEAL-HBV cohorts. Over a median follow-up of 24.4 years, we compared adverse liver outcomes between patients with AASLD-defined normal ALT and those with levels falling in the AASLD–EASL zone.
Results: During follow-up, 368 patients developed HCC and 292 experienced liver-related death. A total of 386 patients were identified with baseline ALT levels in the AASLD–EASL zone. Multivariable analysis demonstrated that the AASLD–EASL zone was an independent predictor of HCC (adjusted hazard ratio [HR] 1.81, 95% CI: 1.31–2.50) and liver-related death (adjusted HR: 1.49, 95% CI: 1.04–2.15). Longitudinal analysis revealed a stepwise increase in risk for patients with intermittent or persistent ALT elevation within this zone. Notably, among patients in the indeterminate phase, the AASLD–EASL zone was associated with significant risk differences: adjusted HR of 2.22 (95% CI:1.50–3.29) for HCC and adjusted HR of 1.65 (95% CI: 1.05–2.60, Fig 2D) for liver-related death.
Conclusion: ALT levels that are considered normal by EASL standards but exceed AASLD thresholds are associated with a significantly higher long-term risk of liver-related mortality and HCC. This association is most pronounced in patients in the indeterminate phase of CHB; thus, antiviral treatment should be considered in these patients with AASLD–EASL zone ALT.

HBV preS1 haplotypes mediate the protective effect of NTCP S267F variant against liver cirrhosis in chronic hepatitis B
Hsiang-Hsuan Chuang[1,2], Ding-Lian Wang[2,3], Chih-Jen Huang[2], Mei-Hung Pan[2], Po-Hsien Hsu[2,3], Chien-Jen Chen[2], Hwai-I Yang[2]. *[1]School of Medicine, Chung Shan Medical University, Taichung, Taiwan; [2]Genomics Research Center, Academia Sinica, Taipei, Taiwan; [3]Graduate Institute of Life Science, National Defense Medical University, Taipei, Taiwan*
Email: stan92100755@gmail.com

Background and aims: Chronic hepatitis B (CHB) accounts for over 1 million deaths worldwide each year, primarily due to liver cirrhosis (LC) and hepatocellular carcinoma (HCC). Hepatitis B virus (HBV) entry requires binding of its large surface antigen (LHBs) preS1 domain to the hepatocyte receptor sodium taurocholate cotransporting polypeptide (NTCP). The East Asian-predominant NTCP p. Ser267Phe (S267F; c.800G>A, rs2296651) variant has been consistently linked to reduced LC and HCC risks, but the mechanism remains unclear. We investigated whether the S267F variant drives HBV preS1 evolution and if such host-virus interactions contribute to disease progression.
Method: HBV genomes from 377 CHB participants in the community-based REVEAL-HBV cohort were deep-sequenced to examine associations between S267F and HBV preS1 alleles and haplotypes.

Repeat measurements characterized longitudinal haplotype dynamics. Cox proportional hazards models and causal mediation analysis were used to estimate hazard ratios with 95% confidence intervals for LC and evaluate whether preS1 haplotypes mediated the S267F-LC association, respectively.
Results: PreS1 alleles at nucleotide positions 2881A, 2902G, and 2956A were enriched among NTCP S267F carriers (GA/AA) versus wild-type individuals (GG; Bonferroni-adjusted $p < 0.001$ for all positions). We defined a 3-locus haplotype (nt2881/2902/2956, CTG reference, others non-CTG) corresponding to distinct amino acid variant at preS1 residues 10/17/35, linking the observed genetic selection to specific viral protein variants. Among HBV genotype C patients at baseline (n = 224), the primary serum non-CTG haplotype was more frequent in GA/AA than GG carriers (42.9% vs. 7.1%; $p < 0.001$), and the divergence increased over a median follow-up of 11.5 years (52.9% vs. 5.8%; $p < 0.001$, n = 69), consistent with sustained host-associated selection on HBV genomes. Baseline non-CTG carriage was associated with lower LC risk than CTG haplotype (adj-HR 0.20; 95% CI 0.06–0.25; $p = 0.008$). Causal mediation analysis further indicated that reduced CTG carriage partially mediated the S267F protection against LC (indirect effect [IE] adj-HR 0.61; 95% CI 0.48–0.75; $p < 0.001$).
Conclusion: In CHB patients with HBV genotype C, NTCP S267F was associated with longitudinal selection of a non-CTG HBV preS1 haplotype at nt2881/2902/2956 that mediated protection against cirrhosis. These findings provide human evidence linking host genetic variation, viral adaptation, and disease progression in chronic hepatitis B.

Email: cyurdaydin@ku.edu.tr

Background and aims: Turkey is considered an endemic country for hepatitis D virus (HDV), and liver transplantation (LT) remains an important rescue treatment. Guidelines recommend indefinite hepatitis B immune globulin (HBIg) and nucleos(t)ide analog (NA) treatment to prevent hepatitis D virus (HDV) recurrence after LT. We aimed to present LT outcomes for HDV in Turkey from 7 liver transplantation centres (2010 to 2025).
Method: HDV recurrence was defined as becoming HBsAg and HDV-RNA positive after LT. Patients had received livers from HBsAg negative, anti HBc negative donors except for one case who received a HBsAg (+) after talking to patient who accepted the risk. Except one centre (Ege University) at which HBIg was given only for one year all other centres offered HBIg + NA treatment of indefinite duration.
Results: During the 15 year period a total of 5955 LTs were performed (1054 cadaveric and 4901 living related). HBV and HBV/HDV associated liver disease were the etiology in 1845 (31%) and 315 (5,3%) of 5955 LTs, respectively. Post-transplantation HDV recurrence (Post-txR) occurred in 18 patients (5.7%); (median age: 49 [18–66], 16 men, 2 women). LT indication was decompensated liver disease (DLD) in 10 and hepatocellular cancer (HCC) in 8. Post-txR occurred after a median of 27.5 months (1–54 months). HBIg was administered for median 10.5 months (0–36 months). Except one patient (HBsAg+ donor), post-txR occurred after HBIg discontinuation in all cases. Of 18 patients with post-txR, 10 patients enjoyed a mild disease course despite lack of antiviral treatment. Eight patients died during median 92.5 months follow up (4–158 months). Causes: liver-related (n = 2, including one with severe HDV recurrence with ALT >5000U/mL, >100 million and 1 million IU/nmL of HDVRNA and HBVDNA, respectively), biliary stenosis-linked sepsis (n = 2), B-cell lymphoma (n = 1), COVID-19 (n = 1), earthquake (n = 1), unknown (n = 1). Notably, Koç University had zero HDV recurrence among 11 HDV-related LTs (all living donor, 2018–2025) using their risk-stratified HBIg/NA protocol.
Conclusion: HBsAg recurrence is rare after LT for HDV but can occur with HBIg/NA non-compliance, potentially leading to HDV recurrence. HDV recurrence appears to run a mild clinical course in line with early reports from Italy and France (1, 2), though severe recurrence with graft failure may also occur. Latent HDV infection of the liver allograft may be rescued by HBV superinfection up to 4 years after LT as suggested previously (3).

Email: fegarcia@ugr.es

Background and aims: Hepatitis delta virus (HDV) is classified into eight major genotypes, with HDV-1 being the most prevalent worldwide. Relevant discrepancies persist, especially regarding HDV-1 subgenotype classification. This lack of consensus complicates epidemiological interpretation, inter-study comparability, and potential clinical correlations. The aim of this study was to compare these classification systems and evaluate their impact on subgenotype assignment in clinical HDV sequences.
Method: A comparative phylogenetic analysis was performed using 162 near full-length HDV genome sequences from positive clinical samples, using references from Le Gal et al (subgenotypes 1a–1d), and Karimzadeh et al. (subgenotypes 1a–1e). Phylogenetic trees were constructed using MEGA software version 6, based on the T92+G model and MAFFT v. 7, with reference sequences of HDV genotypes and sub-genotypes, with the Neighbor-Joining method and branch support was assessed by 1,000 bootstrap replicates.
Results: Results from both classification systems clustered consistently at the genotype level, showing full concordance regardless of reference sequences used. HDV genotype 1 was predominant (n = 142, 87.7%), followed by GT5 (n = 18, 11,1%), and GT3 (n = 1) and GT7 (n = 1). Genotype 5 subgenotypes were 5a (n = 6), and 5b (n = 12). Within HDV-1, the two classifications show markedly different

subtype distributions: 97.2% of sequences showed discordant subgenotype assignment depending on the classification system used. Using Le Gal, subtype 1d was overwhelmingly predominant (84.5%), whereas 1a, 1b, and 1c were infrequent (3.5%, 5.6%, and 6.3%, respectively) and 1e was not detected. In contrast, Karimzadeh identified 1e (66.9%) and 1c (23.2%) as the dominant subtypes, with 1a and 1b occurring at similar low frequencies (4.9% and 4.2%), and 1d being rare (0.7%).

Conclusion: Our findings highlight substantial discrepancies in subtype assignment between the two approaches. While HDV genotyping is robust and fully concordant across classification systems, HDV-1 subgenotype assignment remains highly dependent on the reference sequences used. Establishing a harmonized phylogenetic nomenclature is essential to improve epidemiological interpretation, ensure comparability across HDV studies, and support future clinical and translational research.

Email: philippa.matthews@crick.ac.uk

Background and aims: The World Health Organization (WHO) has set a goal to eliminate viral hepatitis as a public health threat by 2030. Achieving this target requires robust data on hepatitis B virus (HBV) to support public health interventions. Data from high-prevalence regions in Africa are limited. This study aimed to characterise HBV epidemiology, associated comorbidities, and treatment eligibility among individuals living with HBV in rural KwaZulu-Natal (KZN), South Africa.

Method: The EVOLVE-HBV study sampled 2200 individuals from a population-based health survey conducted in rural KZN in 2018–2020 (ethics ref. 00004495/2022 and 23221/001). Stored samples were tested for Hepatitis B surface antigen (HBsAg). Sampling was stratified by age, sex and HIV status and sampling weights were applied to estimate the population prevalence of HBV infection. In 2025 participants who tested positive for HBsAg were invited for clinical evaluation. This included repeat HBV testing, measurement of alanine aminotransaminase (ALT) using WHO-defined upper limits of normal (ULN), assessment for metabolic dysfunction-associated steatotic liver disease (MASLD) and liver stiffness measurement using FibroScan® and cardiometabolic risk factors. Treatment eligibility was determined according to 2024 WHO guidelines.

Results: Among the 2200 individuals tested, 58.6% were female and mean age was 37.6 years (SD 8.3). Weighted prevalence of HBV infection was 10.5% (95% CI 9.1–12.2). Of the 240 individuals who had tested HBsAg-positive at baseline, we were able to contact 101 (42.1%) and have reassessed 43 individuals with confirmed chronic HBV infection. Among these, 23/43 (53.5%) were living with HIV and receiving antiretroviral treatment. Liver stiffness measurements were available for 42/43; 18 (43.9%) had fibrosis (>7 kPa) and one had cirrhosis (>12 kPa). *ALT* was >ULN in 19/40 (47.5%), and 18/42 (42.9%) met the criteria for MASLD. Among 20 individuals with HBV mono-infection, 11 (55%) met WHO treatment criteria.

Conclusion: HBV is common in rural KZN. All HIV/HBV co-infected individuals were on HBV-active therapy, however, among individuals living with HBV mono-infection, almost half met WHO treatment criteria to start HBV treatment but were not yet on treatment. This suggests that where HBV is not comorbid with HIV, follow-up, and linkage to care is challenging in this setting. Improved HBV prevention, diagnosis, risk assessment, and integration of MASLD services into existing HIV and chronic disease programs are needed.

Email: maria.anolli@unimi.it

Background and aims: In patients with compensated cirrhosis, gastroesophageal varices (EV) are associated with a higher risk of hepatic decompensation. Non-invasive tests (NITs) are increasingly used in clinical practice for assessing the risk of EV, but specific studies in chronic hepatitis Delta (CHD) are missing.
Method: Untreated CHD patients with compensated cirrhosis with available liver stiffness measurement (LSM) and esophagogastroduodenoscopy (EGD) enrolled in the SAVE-D and D-SHIELD studies were included. In a subgroup of patients, spleen stiffness measurement (SSM) was available. Baveno VI and AASLD criteria for avoiding screening endoscopy (LSM <20 kPa + platelets [PLT] count >150 × 10^9/L); and the Baveno VII SSM ≤40 kPa cut-off to rule-out high-risk varices (HRV) were applied. NIT performance was assessed by Sensibility (Sn), Specificity (Sp), Positive Predictive Value (PPV), Negative Predictive Value (NPV), and accuracy. The diagnostic performance of LSM was evaluated using Receiver Operating Characteristic (ROC) curve analysis. All tests were performed prior to Bulevirtide start.
Results: 347 patients were included: median age was 54 years, 56% males, 156 (45%) with EV on EGD, 93 (27%) with HRV. Median LSM was 16.7 (11.8–25.2) kPa, PLT 95 (65–147) 10^9/L, albumin 4.9 (3–7–4.3) g/dL, ALT 78 (50–146) U/L, spleen length 14 (12–17) cm. 65 (19%) patients fulfilled the LSM and PLT "avoid endoscopy" criteria, resulting in 4 (9%) missed HRV (Sn 95.7%, NPV 93.8%). Median SSM was 47.2 kPa (30.4–67.2) kPa, and in patients with SSM ≤40 kPa the rate of missed HRV was 7% (Sn 89.5%, NPV 92.9%). ROC analysis retrieved an optimal LSM cut-off for HRV of 18.7 kPa: AUROC 0.620 (95% CI 0.550–0.690), 60.2% Sn and a false positive rate (1 - Sp) of 0.319, corresponding to a Sp of approximately 68.1%. The corresponding PPV was 40.8%. Based on these data, we identified two cutoffs to respectively discriminate the absence or presence of HRV: <10.3 kPa, where HRV risk is low (Sn 88% and NPV 75%), and >24.9 kPa, where HRV risk increases (Sp 80%, PPV 40%).
Conclusion: In untreated CHD patients with cirrhosis, the Baveno VI/VII criteria failed to identify a significant proportion of patients with HRV who are at high risk of variceal bleeding.

Email: maria.anolli@unimi.it

Background and aims: Chronic hepatitis Delta represents the most aggressive form of viral hepatitis, with higher rates of cirrhosis development and hepatocellular carcinoma (HCC) incidence. While cardiometabolic risk factors influence outcomes in other chronic liver diseases, their prevalence and relevance in CHD remain poorly characterized.

Method: CHD patients included in the retrospective multicenter real-world European SAVE-D study and in the prospective multicenter Italian D-SHIELD study were included. The prevalence of cardiometabolic risk factors (arterial hypertension, type 2 diabetes, overweight/obesity) were evaluated at BLV start.

Results: 828 patients treated with BLV 2 mg/day subcutaneous monotherapy up to 144 weeks were included in this analysis: age 52 (IQR 42–60) years, 57% men, 698 (84%) with cirrhosis, median BMI was 24.8 (22.7–27.4). 39 (5%) patients had type 2 diabetes (T2DM), and 126 (15%) patients had arterial hypertension (AHTN), 85 (10%) patients had obesity (defined as BMI ≥30), of whom 13 (15%) grade II obesity (BMI 35–39) and 2 (2%) grade III obesity (BMI≥40). Controlled Attenuation Parameter (CAP) on Fibroscan® was available in 484 (59%) patients: median CAP values were 209 (181–238) dB/m. 50 (5%) patients showed hepatic steatosis (by CAP >275 dB/m): median BMI in these patients was 28.4, 6 (12%) patients had T2DM, 11 (22%) AHTN. Overall, median alanine aminotransferase (ALT) levels were 78 (50–127) U/L in patients without and with T2DM, respectively (p = 0.57). Median gamma glutamyl transferase (gGT) were 56 (35–94) and 68 (30–125) U/L in patients without and with T2DM, respectively (p = 0.19). When analyzing the impact of cardiometabolic risk factors (AHTN, T2DM), BMI and CAP values on responses rates to BLV, only CAP values predicted the achievement of a biochemical response at on-treatment week 48 (OR 1.01 95% CI 1.00–1.02, p = 0.02). Conversely, none of the baseline features predicted the achievement of a virological response, combined response, and of HDV RNA undetectability at week 48 of BLV monotherapy.

Conclusion: Prevalence of cardiometabolic risk factors in European CHD patients (MetHDV) is lower than reported for other types of viral hepatitis and did not significantly impact response rates in the first year of BLV monotherapy.

SAT-561

Long-term risk and predictors for hepatocellular carcinoma and other liver-related outcomes in a large African-born cohort with chronic hepatitis B, living in Sweden

Katarina Århem[1], Habiba Kamal[1], Karin Lindahl[1], Frida Jakobsson[2], Ann-Sofi Duberg[3], Soo Aleman[1]. *[1]Department of infectious diseases, Karolinska University Hospital, Department of medicine Huddinge, Karolinska Institutet, Stockholm, Sweden; [2]Department of Infectious Diseases, Sunderby Hospital, Department of Clinical Microbiology, Umeå University, Umeå, Sweden; [3]Department of Infectious Diseases, Faculty of Medicine and Health, Örebro University, Örebro, Sweden*
Email: katarina.johansson-arhem@regionstockholm.se

Background and aims: Sub Saharan African (SSA) origin has been suggested as a potential risk factor for hepatocellular carcinoma (HCC) in persons with chronic hepatitis B (CHB) but large longitudinal studies on Africans with CHB are scarce both in and outside of Africa and the natural course of CHB in this population remains poorly characterized. We assessed the risk of HCC and other liver-related events (LRE) among African-born patients with CHB living in Sweden.
Method: This retrospective cohort study included 1,167 African-born patients with CHB attending Karolinska University Hospital, Stockholm, and Sunderby Hospital, Northern Sweden. We retrieved demographic, clinical, and laboratory data from our national quality register InfCare Hepatit and medical records. Incidence rates (IRs) and cumulative risks of HCC and composite LRE (new-onset cirrhosis, hepatic decompensation, HCC, liver transplantation, or liver-related death) were assessed using Kaplan–Meier analysis. Risk factors for LRE and HCC were evaluated using Cox regression.
Results: The cohort consisted of 60% men with a median age of 33.3 years; most patients originated from East (51%) and West Africa (31%). 6.9% and 4.5% were seropositive for HIV and HDV, respectively. Median follow-up time was 6.5 years. Twelve patients developed HCC (IR 0.11/ 100 person-years [PY]), with 5- and 10-year cumulative risks of 0.29% and 0.64%, respectively. Eleven cases occurred in men, mean age at diagnosis was 47.6 years, and four patients were < 40 years. Cirrhosis was present at HCC diagnosis in 83%, and 50% had baseline HBV-DNA levels > 6 $\log_{10}$ IU/mL. Among patients with baseline cirrhosis, the HCC IR was 1.40/ 100 PY, with a 5-year cumulative risk of 9.49%. Thirty-six patients experienced one or more LREs (IR 0.41/100 PY), with 5- and 10-year cumulative risks of 2.00% and 2.98%. Age, HBeAg positivity, HBV-DNA > 2,000 IU/mL, and baseline cirrhosis were associated with both HCC alone and composite LRE. In multivariable analysis, HBeAg positivity and baseline cirrhosis independently predicted LRE, whereas HCC cases were too few for a robust multivariable analysis.
Conclusion: African-born patients with CHB in Sweden had a low overall risk of HCC, although cases occurred at a relatively young age. HCC rarely developed in the absence of cirrhosis, and most patients with HCC or LRE had established risk factors, including cirrhosis and high viral load at baseline.

Email: fleur.ballet@uantwerpen.be

Background and aims: Flares frequently occur after nucleos(t)ide analogue (NUC) cessation, necessitating close follow-up. Identifying end-of-treatment (EOT) predictors could improve safety. We assessed patient characteristics and EOT biomarkers to predict severe biochemical flares (SBFs; ALT >10×ULN).
Method: Individual patient-level data from five prospective NUC stop studies within the PROSTOP consortium were pooled. All patients were HBeAg negative, long-term virologically suppressed, and none had advanced liver fibrosis. Multivariate Fine-Gray models for SBFs were fitted with retreatment as competing risk and stratification by study. Age, sex, ethnicity, EOT HBsAg and NUC type were evaluated in the full cohort. HBV genotype (gt) and EOT hepatitis B core related antigen (HBcrAg), hepatitis B core IgG antibodies (anti-HBc) and HBV RNA were evaluated in available subcohorts, adjusting for identified predictors. Predictive performance was assessed by using the time-dependent area under the ROC curve (AUC) at 48 weeks.
Results: Among 402 patients, 83 experienced an SBF, corresponding to a cumulative incidence of 18.7% within 48 weeks. During follow-up, 113 (28.1%) patients were retreated, one (0.2%) underwent liver transplantation, and no liver-related deaths occurred. In the full cohort, tenofovir showed a borderline non-significant association with SBF risk (SHR = 1.65, p = 0.0504), with earlier flares compared with entecavir. Male sex was associated with increased SBF-risk (SHR = 2.38, p = 0.002). Overall, log HBsAg levels were not associated with SBF occurrence (p > 0.05), however no patients with HBsAg <10 IU/mL developed a SBF. Ethnicity was not associated with SBF risk. Gt A (SHR = 0.06, p = 0.007) and higher anti-HBc levels (SHR = 0.33, p < 0.001) were protective, while detectable HBcrAg (SHR = 2.67, p = 0.002) and HBV RNA (SHR = 2.2, p = 0.02) increased SBF risk. Prediction based on age, sex, ethnicity, HBsAg and NUC type yielded an AUC of 0.62. Models incorporating gt, HBcrAg, and anti-HBc achieved an AUC of 0.77, increasing to 0.83 with addition of sex, NUC type and HBV RNA.
Conclusion: In this pooled analysis of five prospective NUC cessation studies, genotype A and EOT anti-HBc were the strongest protective factors against post-cessation SBFs, whereas EOT HBcrAg and HBV RNA were the most important risk factors. A biomarker-based model substantially improved prediction of SBFs, and may enable safer, individualized NUC cessation strategies.

SAT-563-YI

Longitudinal HBsAg trajectories might predict virological outcomes in patients with chronic hepatitis B infection

Sara Battistella[1,2], Andreu Roca[3], Anna Pocurull Aparicio[1,2], Zoe Mariño[1,2], Sergio Rodriguez-Tajes[1,2], Xavier Forns[1,2], Sabela Lens[1,2]. *[1]Liver Unit, Hospital Clinic, IDIBAPS, Barcelona, Spain, Barcelona, Spain; [2]Centro de Investigación Biomédica en Red de*

Enfermedades Hepáticas y Digestivas (CIBEREHD), Madrid, Spain; [3]Medical Statistics Core Facility, Hospital Clinic Barcelona, IDIBAPS, Barcelona, Spain, Barcelona, Spain
Email: sarabattistella93@gmail.com

Background and aims: Quantitative HBsAg (qHBsAg) has emerged as a valuable biomarker to predict HBsAg seroclearance, support finite nucleos(t)ide analogue (NUCs) therapy decisions, and predict response to emerging HBV antiviral agents. Yet, real-life evidence on long-term qHBsAg trajectories remains scarce. This study aimed to characterize long-term qHBsAg dynamics in a real-life cohort and to identify predictors of clinically relevant virological endpoints.
Method: A total of 294 patients with chronic HBV infection (80% non-Asian), both treated and untreated, HBeAg positive or negative, with at least two qHBsAg measurements over a minimum follow-up of three years, were followed for a median of 7.5 (5.5–10.5) years. Longitudinal qHBsAg kinetics were analysed to identify predictors of functional cure, eligibility for NUCs discontinuation, and inclusion in future antiviral trials.
Results: At baseline, 61 (20.7%) were HBeAg positive and 49.3% received antiviral treatment during follow-up. Overall, a downward trend in qHBsAg levels was observed: the proportion of patients with qHBsAg < 100 IU/mL increased from 11.6% to 31.6%, those with < 1000 IU/mL from 40.1% to 59.2%, and those with < 3000 IU/mL from 59.2% to 77.9% at the last visit. Sixty-four patients (21.8%) showed an annual decline in HBsAg ≥ 0.5 log, corresponding to a ~70% reduction. Among treated Caucasian patients with baseline qHBsAg > 1000 IU/mL (n = 70), 21 (30%) reached the recommended threshold of < 1000 IU/mL to stop NUCs treatment. Among patients with baseline qHBsAg > 3000 IU/mL (n = 120), 57 (47.5%) decreased below 3000 IU/mL at the last visit, potentially meeting the inclusion criteria for novel antiviral trials. NUCs exposure and > 0.5 log HBsAg decline were independently associated with this outcome, with HBsAg reduction emerging as the most powerful predictor (OR = 14.197).
Functional cure occurred in 8.8% of patients; an annual qHBsAg decline ≥0.5 log was the strongest independent predictor of HBsAg loss, irrespective of antiviral treatment, baseline viral load, or HBeAg status.
Conclusion: In a real-word, predominantly non-Asian cohort, long-term qHBsAg trajectories demonstrated that both baseline qHBsAg levels and the magnitude of longitudinal decline strongly influence key virological outcomes. Dynamic HBsAg monitoring may help predict functional cure and inform tailored decisions for NUCs finite therapy and enrolment in novel treatment strategies.

Email: jbb4@me.com

Background and aims: In settings with access to direct acting antivirals for HCV, HBV is the leading cause of chronic viral hepatitis among people with HIV (PWH). Adherence to HBV management guidelines in this population remains poorly characterized. Our aim was to evaluate adherence to current HBV management guidelines among PWH in Spain (SP) and Germany (GE).
Method: Cross-sectional study conducted in 42 centers (SP 21; GE 21) between June 2024 and March 2025. PWH with chronic HBV (≥2 HBsAg-positive tests ≥6 mo. apart) were included. Adherence to the 2024 European AIDS Clinical Society Guidelines was assessed: HBV-active therapy (TAF, TDF, or entecavir); laboratory monitoring (ALT/AST and HBV DNA within 12 mo.); anti-HDV testing; HDV-RNA testing in anti-HDV–positive individuals; and hepatocellular carcinoma (HCC) surveillance, defined as liver ultrasound every 6 mo. in patients with cirrhosis or ≥1 risk factor (age >45 yr, Asian/African origin, active HDV, or PAGE-B ≥10 in Caucasians). Family history was not assessed; patients with prior HCC were excluded from the HCC surveillance analysis.
Results: A total of 1,235 PWH with chronic HBV were included (SP 771; GE 464). Median age 56 yr; 85% male; 36% non-European origin. Sex between men accounted for 48% of HIV acquisition. HIV RNA was undetectable in 88%, median CD4 623 cells/μL. Cirrhosis 10%; HCC 1%. Adequate HBV-active therapy was prescribed in 88% (SP 89%; GE 86%). ALT/AST testing within 12 mo. was documented in 94% (SP 95%; GE 92%) and HBV DNA testing in 71% (SP 68%; GE 76%). Anti-HDV testing was performed in 82% (SP 83%; GE 81%); among anti-HDV–positive individuals, HDV-RNA testing was documented in 66% (SP 62%; GE 89%). HCC surveillance was performed in patients with cirrhosis in 67% overall (77/115 [SP 66/92, 72%; GE 11/23, 48%]), in non-cirrhotic patients with ≥1 risk factor in 24% overall (228/969 [SP 88/571, 15%; GE 140/398, 35%]), and in all patients meeting HCC surveillance criteria in 28% overall (305/1,084 [SP 154/663, 23%; GE 151/421, 36%]).
Conclusion: Most PWH with chronic HBV received appropriate HBV-active therapy; however, gaps in guideline adherence were identified. HCC surveillance showed the lowest adherence, with fewer than one-third of eligible individuals adequately screened. Improving HCC

surveillance and strengthening HBV DNA monitoring and HDV diagnostic pathways are essential components of strategies aimed at optimizing liver-related outcomes in this population.

Email: kalishabheemraj@gmail.com

Background and aims: Hepatitis B virus (HBV) is highly prevalent in Africa, affecting approximately 65 million people, yet key virological characteristics of endemic genotypes A, D, and E remain incompletely defined. We evaluated patterns and regional differences in hepatitis B e antigen (HBeAg) positivity and HBV DNA concentrations among treatment naive individuals living with HBV in Africa.
Method: We performed a cross sectional analysis of treatment naive individuals attending 14 clinics across North, Southern, East, and West Africa between 2014 and 2025 within HEPSANET. Liver disease was classified as normal, significant fibrosis, compensated cirrhosis, or decompensated cirrhosis. HBV DNA (log10 IU/mL) was modelled using a generalized additive model (GAM) with a cubic spline (k = 4), stratified by HBeAg status. Predictors of HBeAg positivity were assessed using a binomial logistic GAM with a penalized cubic spline for age (k = 9). Models were adjusted for sex, region, and liver disease status. We also estimated the proportion of women of reproductive age (15 to 49 years) at high risk of vertical transmission (HBV DNA >200,000 IU/mL or HBeAg positive).
Results: Of 13,359 individuals in the cohort, 4,293 were negative for HIV, HCV, and HDV and had both HBV DNA and HBeAg measured. Median age was 32 years (IQR 27 to 41), and 60% were male. HBeAg was positive in 423 (10%). HBeAg positivity was higher in Southern versus West Africa (adjusted odds ratio [aOR] 2.06, 95% CI 1.48 to 2.87), in decompensated liver disease versus normal liver (aOR 6.38, 95% CI 4.26 to 9.55), and in males (aOR 1.48, 95% CI 1.13 to 1.80). Overall HBV DNA was 2.92 log10 IU/mL (IQR 2.08 to 3.85). In adjusted models, HBV DNA was higher in East versus West Africa (difference 0.20 log10 IU/mL, 0.10 to 0.30), in males (0.19 log10 IU/mL, 0.10 to 0.28), and in HBeAg positive individuals (3.05 log10 IU/mL, 2.90 to 3.20). Among 1,497 women of reproductive age, 174 (12%) met criteria for high risk of vertical transmission; women in Southern Africa had higher odds of high risk status than women in West Africa (aOR 1.96, 95% CI 1.16 to 3.33).
Conclusion: HBV replication markers and viral expression vary substantially across African regions, with potential implications for vertical transmission risk and treatment eligibility. These findings support the need for region specific data to guide HBV elimination planning and implementation.

SAT-570

Good response to short-term peginterferon α in chronic hepatitis B patients with HBsAg <100 IU/mL: a 276-patient cohort study

Weihua Cao[1,2], Yao Xie[1,2,3], Minghui Li[1,2,3]. *[1]Department of Hepatology Division 2, Beijing Ditan Hospital, Capital Medical University, Beijing, China; [2]HBV Infection, Clinical Cure and Immunology Joint Laboratory for Clinical Medicine, Capital Medical University, Beijing, China; [3]Department of Hepatology Division 2, Peking University Ditan Teaching Hospital, Beijing, China*
Email: weihuacaohappy@163.com

Background and aims: Patients with chronic hepatitis B (CHB) and low baseline hepatitis B surface antigen (HBsAg) levels are considered optimal candidates for interferon-based therapy. This study aimed to evaluate the clinical cure rates following short-term Peginterferon α (PEG-IFN α) treatment in this specific population.
Method: In this retrospective study, 276 CHB patients with baseline HBsAg <100 IU/mL received PEG-IFN α therapy for 48 weeks. Clinical cure was defined as HBsAg loss with or without seroconversion to anti-HBs. Clinical characteristics and treatment outcomes were analyzed, with subgroups compared based on HBeAg status and baseline HBsAg levels (0–20, 20–50, and 50–100 IU/mL).
Results: A total of CHB patients with HBsAg <100 IU/mL were enrolled. Following 48 weeks of PEG-IFN α therapy, the overall clinical cure rates were 30.80% (85/276) at week 24 and 33.70% (93/276) at week 48. HBeAg-negative patients (n = 222) achieved significantly higher cure rates than HBeAg-positive patients (n = 32) at both week 24 (35.59% vs. 15.63%, *P* = 0.025) and week 48 (44.59% vs. 25.00%, P = 0.036). A clear gradient was observed based on baseline HBsAg levels: patients with HBsAg <20 IU/mL achieved the highest cure rates (34.97% at week 24, 43.72% at week 48), followed by those with HBsAg 20–50 IU/mL (28.21% and 33.33%), and those with HBsAg 50–100 IU/mL (16.67% and 22.22%) (*P* = 0.014 for trend).
Conclusion: Short-term PEG-IFN α therapy induces high clinical cure rates in CHB patients with HBsAg <100 IU/mL, particularly in those who are HBeAg-negative or have baseline HBsAg levels below 20 IU/mL. Baseline HBsAg level is a strong predictor of treatment success.

SAT-571

Low pre-treatment concentrations of HBV cccDNA transcriptional activity markers – HBcrAg and pre-genomic RNA - can predict response to therapy with pegylated interferon, but not to bulevirtide monotherapy in chronic hepatitis D patients

Ivana Carey[1], Mark Anderson[2], James Lok[1], Tiffany Fortney[2], Zillah Cargil[1], Gavin Cloherty[2], Geoffrey Dusheiko[1], Kosh Agarwal[1].
[1]Institute of Liver Studies, King's College Hospital NHS Foundation Trust, London, United Kingdom; [2]Department of Infectious Diseases, Abbott Laboratories, Chicago, United States
Email: ivana.carey@nhs.net

Background and aims: Hepatitis delta (HDV) is a satellite virus that requires the envelope proteins of HBV (HBs) for cell entry. Bulevirtide blocks virion engagement with NTCP receptors and achieves undetectable HDV RNA (sustained, off-treatment) in approximately 20% of patients. Meanwhile, pegylated interferon (IFN) exerts pleotropic antiviral effects, including on cccDNA episomes. In this study, we compared peripheral biomarkers of HBV infection (HBsAg, HBcrAg, pgRNA) during IFN vs. BLV therapy and assessed their temporal relationship to serum HDV RNA.
Method: We analysed 51 patients with HBV/HDV co-infection (median age 42 yrs, 31 males, 55% compensated cirrhosis). 33 patients were treated with IFN for 48 weeks (+24 weeks follow-up) and 18 patients were treated with BLV monotherapy for at least 72 weeks. The following biomarkers were measured at start-of-treatment, week 24, 48 & 72: HBcrAg [CLEIA Fujirebio, $\log_{10}$ U/ml, LLOQ 3.0 $\log_{10}$ U/ml], pgRNA [RealTime RUO, Abbott Diagnostics, LLOQ = 0.49 $\log_{10}$ U/ml]), HBsAg quant [Abbott ARCHITECT, LLOQ 0.05 IU/ml], and HDV RNA [RealTime RUO, Abbott Diagnostics, LLOQ 5 IU/ml]. Treatment response was defined as undetectable HDV RNA

on therapy (BLV cohort) or 24 weeks after end-of-treatment (IFN cohort).
Results: 19 (58%) IFN patients achieved HDV RNA loss vs. 7 (39%) patients on 72 weeks of BLV therapy. Lower pre-treatment HDV RNA (<100 000 IU/ml), HBsAg (<5 000 IU/ml), pgRNA (<1.75 $\log_{10}$ U/mL), & HBcrAg (<3.5 $\log_{10}$ U/mL) were predictive of response in IFN patients, but only HDV RNA <50 000 IU/ml was predictive of BLV-induced HDV RNA loss. Irrespective of treatment modality, a higher proportion of responders had HBcrAg or pgRNA < LLOQ at start-of-treatment, as compared with non-responders (HBcrAg 23% vs 0%; pgRNA 16% vs 6%). Responders also demonstrated steeper on-treatment declines in HBcrAg (−1.25 vs −1.05 $\log_{10}$ U/ml/year, $p < 0.05$) and pgRNA (−1.14 vs −0.86 $\log_{10}$ U/ml/year, $p < 0.05$). The percentage of patients with HBcrAg or pgRNA < LLOQ increased during therapy, but only amongst responders (week 72: HBcrAg 83%; pgRNA: 76%). HBsAg declines were exclusively encountered in the IFN-treatment cohort (−973 IU/ml/year), of whom 4 patients (12%) achieved HBsAg seroclearance.
Conclusion: Baseline levels of HBV cccDNA transcription were predictive of response to IFN, but not BLV, and this may reflect their distinct mechanisms of action. Changes in HBcrAg and pgRNA were more pronounced in responders irrespective of therapy type.

SAT-572
Durability of functional cure in chronic hepatitis B: a systematic review and meta-analysis
Yuxing Chen[1], Yonglu Su[1], Qiao Tang[1], Yuanhai Zhou[1], Tianquan Huang[1], YunLing Xue[1], Xiaoqing Liu[1], Hu Li[1], Zhi-wei Chen[1], Li Zhang[1], Peng Hu[1]. *[1]Department of Infectious Diseases, Institute for Viral Hepatitis, The Key Laboratory of Molecular Biology for Infectious Diseases, Chinese Ministry of Education, The Second Affiliated Hospital of Chongqing Medical University, 76# Linjiang Road, Yuzhong District, Chongqing 400010, China, Chongqing, China*
Email: hp_cq@163.com

Background and aims: The latest international consensus defines functional cure in chronic hepatitis B (CHB) as sustained HBsAg loss and undetectable serum HBV DNA, with or without hepatitis B surface antibody (anti-HBs) seroconversion, confirmed 24 weeks after treatment cessation. However, long-term data validating the durability of this newly standardized definition remain limited. This meta-analysis aims to evaluate the durability of functional cure in CHB patients using current criteria.
Method: We conducted a systematic literature search across PubMed, Embase, Web of Science, and the Cochrane Library from January 2000 to August 2025. The extracted data were analyzed using either a random-effects model or a fixed-effects model. Potential sources of heterogeneity were explored through subgroup analysis.
Results: A total of nineteen studies involving 16,875 CHB patients were included. The pooled sustained response rate, defined as persistent HBsAg loss and undetectable HBV DNA during post-treatment follow-up regardless of 24-week confirmation, was 84.9% (95% CI: 81.1–88.3%). Among patients meeting the formal functional cure definition—HBsAg loss and undetectable HBV DNA confirmed 24 weeks after treatment cessation—the durability rate was 92.6% (95% CI: 91.3–93.9%). Nucleos(t)ide analogue (NA) monotherapy was associated with a higher sustained response rate compared to interferon-based therapy. Although the sustained functional cure rate was numerically higher with NA, the difference was not statistically significant. Longer consolidation therapy (≥12 weeks) was associated with a higher sustained response rate; however, data were insufficient to assess its impact on durable functional cure. Additionally, anti-HBs seroconversion was significantly associated with more durable outcomes for both sustained response and functional cure.
Conclusion: Patients with functional cure confirmed 24 weeks after treatment cessation exhibit substantially greater long-term durability than those who achieve HBsAg loss and undetectable HBV DNA only at end of treatment. Moreover, anti-HBs seroconversion further enhances the durability of this response.

SAT-573
Seroprevalence and clinical characteristics of hepatitis d virus infection in korean patients with chronic hepatitis B and HBV-related hepatocellular carcinoma
Min Kyung Park[1], Yun-Sook Lim[1], Gwang Hyeon Choi[1], Eun Ju Cho[2], Su Jong Yu[2], Yun-Tae Kim[3], Eun Sun Jang[1], Jin-Wook Kim[1], Sook-Hyang Jeong[1]. *[1]Seoul National University Bundang Hospital, Seongnam, Korea, Rep. of South; [2]Seoul National University College of Medicine, Seoul, Korea, Rep. of South; [3]Seoul Clinical Laboratories, Yongin, Korea, Rep. of South*
Email: jsh@snubh.org

Background and aims: Hepatitis delta virus (HDV) coinfection worsens clinical outcomes in patients with chronic hepatitis B (CHB). With the emergence of HDV-targeted therapeutics, accurate data on HDV prevalence and its clinical impact are essential. This study aimed to assess the seroprevalence, clinical significance, and molecular characteristics of HDV in Korean patients with CHB, liver cirrhosis (LC), and hepatocellular carcinoma (HCC).
Method: This multicenter, retrospective study enrolled 527 patients with chronic HBV infection, stratified into CHB (n = 100), LC (n = 100), and HCC (n = 327). Serum samples were collected from two tertiary centers, Seoul National University Hospital and Seoul National University Bundang Hospital, between 2006 and 2024. Anti-HDV antibodies were detected using commercial kits, and HDV RNA was analyzed for full-length genomic sequencing.
Results: The median age was 58.0 years (interquartile range, 51.0–64.0), and 71.2% were male. The overall anti-HDV seroprevalence was 2.7% (14/527). Prevalence varied slightly across disease groups: 2.0% in CHB, 4.0% in LC, and 2.4% in HCC ($p = 0.732$). Male sex was associated with anti-HDV positivity (odds ratio 5.37; 95% confidence interval [CI], 1.06–98.02; $p = 0.107$). Notably, in patients with HCC, anti-HDV prevalence was significantly higher in advanced stages (BCLC C–D) compared to early-to-intermediate stages (BCLC 0–B) (5.3% vs. 0.9%; $p = 0.023$). Although anti-HDV positivity was associated with an elevated hazard ratio for mortality in HCC patients (adjusted HR 1.92; 95% CI, 0.60–6.16), statistical significance was not reached ($p = 0.271$). HDV RNA was detected in one of the 14 anti-HDV positive patients (7.1%). Using this RNA-positive sample, we successfully identified the full-length HDV genome for the first time in Korea.
Conclusion: Anti-HDV seroprevalence in Korean HBV patients is approximately 2.7%. HDV coinfection is associated with male sex and advanced tumor stage in HCC. These findings highlight the need for early screening, particularly in patients with advanced liver disease, and provide the first molecular characterization of a Korean HDV strain.

SAT-574
Antiviral therapy based on the EASL guideline 2025 reduces the risk of hepatocellular carcinoma: a multinational study
Ho Soo Chun[1], Minjong Lee[1], Hye Ah Lee[2], Tae Hun Kim[1], Terry Cheuk-Fung Yip[3], Yan Liang[3], Shang-Chin Huang[4], Tai-Chung Tseng[4], Grace Lai-Hung Wong[3], Seung Up Kim[5]. *[1]Department of Internal Medicine, Ewha Womans University College of Medicine, Seoul, Korea, Rep. of South; [2]Clinical Trial Center, Ewha Womans University Seoul Hospital, Seoul, Korea, Rep. of South; [3]Medical Data Analytics Center, State Key Laboratory of Digestive Disease, Li Ka Shing Institute of Health Sciences, The Chinese University of Hong Kong, Hong Kong SAR, China; [4]Division of Gastroenterology and Hepatology, Department of Internal Medicine, National Taiwan University Hospital, Taipei, Taiwan; [5]Department of Internal Medicine, Institute of Gastroenterology, Yonsei University College of Medicine, Seoul, Korea, Rep. of South*
Email: minjonglee2@naver.com

Background and aims: The EASL 2025 guideline introduced a simplified algorithm for managing chronic hepatitis B (CHB), recommending earlier initiation of antiviral therapy (AVT) based on viral load and fibrosis stage. We evaluated whether AVT initiation according to the EASL 2025 guideline is associated with a reduced risk of hepatocellular carcinoma (HCC).
Method: This multinational cohort study included 24,788 treatment-naïve CHB patients from 7 centers in South Korea, Hong Kong, and Taiwan (2007–2022). Predicted HCC risk assuming AVT initiation was estimated using PAGE-B (for groups including patients with cirrhosis) or PAGED-B scores (for groups including patients without cirrhosis). Patients were categorized according to the EASL 2025 guideline as follows: Groups 1 and 2 included patients with advanced fibrosis or cirrhosis without (Group 1) or with (Group 2) detectable HBV DNA; Group 3, HBV DNA ≥ 2,000 IU/ml with significant fibrosis or alanine aminotransferase (ALT) > upper limit of normal (ULN); Group 4, HBV DNA ≥ 2,000 IU/ml without significant fibrosis or ALT > ULN; and Group 5, HBV DNA < 2,000 IU/ml with ALT ≤ ULN. For each group, observed 5-year HCC incidence in untreated patients was compared with the predicted incidence derived from the models, assuming AVT initiation. An additional AVT-treated cohort (n = 8,414) was propensity score–matched to the untreated cohort to compare HCC risk between treated and untreated patients in Groups 2 and 3.
Results: When fibrosis was assessed by transient elastography, observed HCC risk in Group 1 was comparable to that predicted by PAGE-B. In contrast, observed HCC risk in untreated patients was significantly higher than predicted by PAGE-B in Group 2 (standardized incidence ratio [SIR] = 2.539, 95% confidence interval [CI] = 2.278–2.818) and by PAGED-B in Group 3 (SIR = 3.116, 95% CI = 1.755–5.045) (all $p < 0.001$). In Groups 4 and 5, observed and predicted HCC risks were comparable (all $p > 0.05$). These findings were consistent when fibrosis was assessed using fibrosis-4 or aspartate aminotransferase-to-platelet ratio index. In propensity score–matched analyses incorporating an additional cohort of patients treated with AVT, AVT initiation was associated with a significantly lower risk of HCC compared with no treatment in both Group 2 and Group 3 ($p = 0.035$ and $p = 0.007$, respectively).
Conclusion: AVT initiation based on viral load and fibrosis stage according to the EASL 2025 guideline is associated with a reduced HCC risk.

SAT-575

Epidemiology of hepatitis delta virus in Belgium: interim results of a prospective cross-sectional cohort study

Marie Coessens[1,2], Florence Lemaitre[3], Inge Roukaerts[3], Jérémie Wawrzyniak[4], Matthias Steverlynck[5], Mounzer Reda[6], Marie De Vos[7], Marijke Reynders[8], Hans Orlent[9], Hilde Vanpoucke[10], Charlotte De Vloo[11], Margot De Spiegeleer[12], Jos Van Acker[12], Laura Coremans[13], Thiberiu Banica[14], Elizaveta Padalko[14], Xavier Verhelst[15], Hélène Tatiana Besse-Hammer[16], Luc Lasser[17], Anaïs Scohy[18], Giulia Zorzi[18], Yves Horsmans[19], Nicolas Yin[20], Christophe Moreno[21], Sofie Goes[22], Annelien Van Dalem[22], Silke François[23], Pablo Beckers[24], Marie-Pierre Hayette[24], Jean Delwaide[25], Sarah Vandamme[26], Hafid Dahma[20], Sigi Van den Wijngaert[20], Thomas Sersté[27], Katrien Hoet[28], Bruno Van Herendael[28], Peggy Bruynseels[28], Natasja Van Gasse[28], Stefan Bourgeois[29], Wim Verlinden[2,30,31], Marina Mukovnikova[32], Alexandra Vodolazkaia[32], Steven Van Gucht[3], Thomas Vanwolleghem[1,31]. *[1]Viral Hepatitis Research Group, Laboratory of Experimental Medicine and Pediatrics (LEMP), University of Antwerp, Antwerp, Belgium; [2]Department of Gastroenterology and Hepatology, Vitaz, Sint-Niklaas, Belgium; [3]Infectious Diseases in Humans, Viral Diseases, National Reference Centre for Hepatitis Viruses, Sciensano, Brussels, Belgium; [4]Department of Clinical Biology, Centre Hospitalier de Mouscron, Mouscron, Belgium; [5]Department of Gastroenterology and Hepatology, Centre Hospitalier de Mouscron, Mouscron, Belgium; [6]Department of Clinical Biology, Hôpital Jolimont, Haine St. Paul, Belgium; [7]Department of Gastroenterology and Hepatology, Hôpital Jolimont, Haine St. Paul, Belgium; [8]Department of Laboratory Medicine, AZ Sint-Jan, Bruges, Belgium; [9]Department of Gastroenterology and Hepatology, AZ Sint-Jan, Bruges, Belgium; [10]Department of Laboratory Medicine, AZ Delta, Roeselare, Belgium; [11]Department of Gastroenterology and Hepatology, AZ Delta, Roeselare, Belgium; [12]Laboratory of Microbiology, AZ Sint-Lucas Ghent, Ghent, Belgium; [13]Department of Gastroenterology and Hepatology, AZ Sint-Lucas Ghent, Ghent, Belgium; [14]Laboratory of Medical Microbiology, Ghent University Hospital, Ghent, Belgium; [15]Department of Gastroenterology and Hepatology, Ghent University Hospital, Ghent, Belgium; [16]Clinical Research Department, Brugmann University Hospital, Brussels, Belgium; [17]Department of Gastro-Enterology, Brugmann University Hospital, Brussels, Belgium; [18]Department of Microbiology, Cliniques universitaires Saint-Luc, Brussels, Belgium; [19]Department of Gastroenterology and Hepatology, Cliniques universitaires Saint-Luc, Brussels, Belgium; [20]Department of Microbiology, Laboratoire Hospitalier Universitaire de Bruxelles - Universitair Laboratorium Brussel (LHUB-ULB), Brussels, Belgium; [21]Department of Gastroenterology and Hepatology, CUB-Erasme Hospital, Université Libre de Bruxelles, Brussels, Belgium; [22]Department of Clinical Biology, University Hospital Brussels, Brussels, Belgium; [23]Department of Gastroenterology and Hepatology, University Hospital Brussels, Brussels, Belgium; [24]Department of Microbiology, CHU Sart-Tilman, Université de Liège, Liège, Belgium; [25]Department of Gastroenterology and Hepatology, CHU Sart-Tilman, Université de Liège, Liège, Belgium; [26]Department of Clinical Biology, University Hospital Antwerp, Antwerp, Belgium; [27]Department of Hepato-Gastroenterology, CHU Saint-Pierre, Brussels, Belgium; [28]Department of Clinical Biology, Ziekenhuis aan de Stroom, Antwerp, Belgium; [29]Department of Gastroenterology and Hepatology, Ziekenhuis aan de Stroom, Antwerp, Belgium; [30]Laboratory of Experimental Medicine and Pediatrics (LEMP), University of Antwerp, Antwerp, Belgium; [31]Department of Gastroenterology and Hepatology, University Hospital Antwerp, Antwerp, Belgium; [32]Medical Microbiological Laboratory, Sciensano, Brussels, Belgium*

Background and aims: With new treatment options for chronic hepatitis delta virus (HDV) infection emerging, it is crucial to optimize screening and linkage to care. This prospective, cross-sectional study aims to systematically assess the HDV seroprevalence, viremia, and circulating genotypes (gt) in hepatitis B surface antigen (HBsAg) positive patients in Belgium. Also, the sensitivity of HDV antibody (HDVAb) testing in immunocompromised (IC) patients and patients suspected of having an acute HBV-HDV co-infection, will be evaluated.
Method: From 15 large Belgian hospitals, all consecutive samples testing positive for HBsAg during the study period (2024/11/25–2025/10/27), were sent to Sciensano (National Reference Center for Viral Hepatitis). Double HDV reflex testing was performed (HDVAb total: ELISA assay DiaSorin; HDV PCR: Realstar® kit Altona Diagnostics; in house HDV genotyping). Irrespective of the HDVAb result, HDV RNA screening was performed for all IC patients and those suspected of having an acute co-infection. Advanced fibrosis was defined based on elastography (HBV > 8 kPa; HDV > 10.4 kPa), histology and clinical cirrhosis criteria.
Results: HDV seroprevalence is 6.14% (n = 129/2101; 5.19%–7.25%). Of 129 HDVAb+ patients, 49 tested HDV RNA+. Of all IC patients (n = 91) and those with presumed acute co-infection (n = 18), 1 co-infected HBV-HIV+ patient tested HDV RNA+ (5.46 IU/mL) despite negative HDVAb. Therefore, HDV viremia in the entire cohort is 2.38% (n = 50/2100; 1.81%–3.13%), with predominant gt 1 (n = 34) and gt 5 (n = 8). HDVAb+ patients were more often female (51.2% vs 48.8%, $p = 0.022$) and were more likely to be HCV seropositive (7.0% vs 1.9%, $p = 0.010$). HDV RNA+ patients had higher FIB-4 (1.67 vs 1.13, $p < 0.001$), GGT (gamma-glutamyl transferase, 47 vs 23 U/L, $p < 0.001$), bilirubin (0.63 vs 0.50 mg/dL, $p = 0.010$), and INR values (international normalized ratio, 1.10 vs 1.00, $p < 0.001$). In a subset of 304 HBsAg+ patients [262 HDVAb-, 26 HDVAb+/RNA-, and 16 HDVAb+/RNA+ patients (2 newly

diagnosed)] from 5 hospitals, HDVAb+ patients more often had a history of injecting drug use (10.5% vs 0%, p = 0.034) and HDV viremia was strongly associated with advanced fibrosis (adjusted OR 22.2, CI 5.00–98.24, p < 0.001), independently of BMI and alcohol consumption.
Conclusion: Active HDV co-infection presents with more advanced liver disease and is expected in around one in every 40 HBsAg+ patients in Belgium. Wider implementation of HDV reflex-testing in Belgium is needed.

SAT-576

Hepatitis B virus genotype distribution and viral load patterns in African immigrants to Canada

Welde Aregawi[1], Haris Imsirovic[1], Alexa Keeshan[1], Curtis Cooper[1].
[1]Ottawa Hospital Research Institute, School of Epidemiology and Public Health, University of Ottawa, Division of Infectious Diseases, The Ottawa Hospital, Ottawa, Canada
Email: weldedr77@gmail.com

Background and aims: Hepatitis B virus (HBV) genotypes have distinct geographic and demographic distributions with important clinical implications. In Canada, immigration-driven HBV epidemiology provides globally diverse genotype and sociodemographic patterns reflecting regions of origin including Africa.
To characterize HBV genotype distribution and examine associations between genotype, sociodemographic factors, and HBV DNA levels in African immigrants to Canada.
Method: We conducted a retrospective cohort study of patients with HBV genotype results (2001–2025) in The Ottawa Hospital Viral Hepatitis Program. Genotype data were linked to sociodemographic characteristics. Associations between genotype and viral load were examined among treatment-naïve patients.
Results: Among 778 patients (median age 42.5 years; 52% male), 94% were born outside Canada, representing 78 countries and predominantly Asian (51%) and Black (35%) populations. Six genotypes were identified: A (19.8%), B (25.6%), C (21.0%), D (17.4%), E (15.9%), and F (0.4%). Distribution reflected global migration patterns: A in East Africa and the Caribbean, E in West Africa, B/C in East-Southeast Asia, and D across Middle East and North Africa (MENA), South Asia, and Europe/Central Asia. Genotype-race patterns were concordant (A/E predominantly Black; B/C >95% Asian; D heterogeneous). Age at presentation differed by genotype and race (p < 0.0001), with African-associated genotypes (A/D/E) and Black and Arab/MENA patients presenting younger than those with B/C. HBV viral load differed by genotype (A-E, p < 0.0001), with lower median log10 HBV DNA in A, D and E (2.9–3.0 IU/mL) than in B and C (3.6 and 3.3 IU/mL). In multivariable models, genotype (particularly B/C), male sex and younger age were associated with higher baseline HBV DNA. Genotype was associated with antiviral initiation (p < 0.0001), lowest in A/E (26–28%) and highest in B/C (42–50%).
Conclusion: In this globally diverse, immigration-driven cohort, African-associated genotypes (A, D, E) and Black patients presented at younger ages, providing an opportunity to apply international recommendations for earlier HCC surveillance in high-risk African-origin populations. Among other factors, lower HBV DNA levels may inaccurately dissuade antiviral initiation in this at risk population.

SAT-577

HLA genetic markers identify HDV patients at risk of persistent viremia and advanced fibrosis

Maria Francesca Cortese[1,2], Adriana Palom[2,3], Francesc Rudilla[4,5], Ariadna Rando-Segura[2,3], David Tabernero[1,2], Juan Carlos Ruiz-Cobo[2,3], Judit Vico Romero[2,3], Mar Riveiro Barciela[2,3,6], Maria José Herrero[4,5], Maria Buti[2,3,6].

Email: mariafcortese@gmail.com

Background and aims: Hepatitis delta virus (HDV) infection shows highly variable outcomes, from spontaneous viral control to rapid fibrosis progression. Identifying host factors that predict disease course is critical for early risk stratification and personalized management. Human leukocyte antigen (HLA) molecules orchestrate antiviral immunity, yet their clinical impact in HDV infection remains unclear. Here, we investigated HLA genetic markers associated with virological control and fibrosis progression.
Method: Blood samples from 75 anti-HDV–positive patients underwent high-resolution genotyping of classical HLA class I (A, B, C), class II (DPB1, DQB1, DRB1), and non-classical (HLA-G, HLA-E) genes. Patients were stratified by HDV RNA status (controllers: undetectable HDV-RNA in ≥2 consecutive samples, n = 38; viremic: persistently detectable HDV-RNA, n = 37) and fibrosis stage (METAVIR F0–F2, n = 38; F3–F4, n = 37). Associations were assessed using univariate and multivariable Firth's penalized logistic regression models. One hundred fifty healthy donors served as controls.
Results: HLA-A*11:01 was significantly enriched among viremic patients (27% vs 2.6% of controllers; OR = 12.9, 95% CI 1.8–569.4; p = 0.002) and was strongly linked to persistent viremia in multivariate analysis (p = 0.02). Advanced fibrosis was associated with HLA-A*11:01 and HLA-DPB1*17:01 (>21% of patients), while HLA-DPB1*01:01 predominated in mild fibrosis (34.2%). While all alleles were associated with fibrosis stage in univariate analyses (p < 0.05), only HLA-DPB1*17:01 remained independently associated with advanced fibrosis in multivariate analysis (p = 0.03). In addition, the presence of HLA-A*11:01 emerged as a factor independently associated with both the presence of detectable HDV-RNA and advanced fibrosis (8/25 patients; p = 0.03).
Conclusion: Specific HLA alleles may help to identify HDV patients at high risk of persistent viremia and progressive fibrosis. Incorporating HLA genotyping could enable earlier risk stratification and guide personalized monitoring and therapeutic decisions, offering a precision medicine approach in HDV management.

A systematic literature review of quantitative HBsAg distribution, HBsAg/HBeAg loss and clinical outcomes in HIV/HBV co-infected population

Myriam Drysdale[1], Grace Dolman[2], Pankdeep Chhabra[3], Deepali Mittal[3], Pooja Malhotra[3], Marjan Hezareh[1]. *[1]GSK, London, United Kingdom; [2]GSK, Stevenage, United Kingdom; [3]Bridge Medical Consulting Ltd, London, United Kingdom*
Email: myriam.g.drysdale@gsk.com

Background and aims: About 1% (~2.7 million) of patients (pts) with chronic hepatitis B virus (HBV) infection are coinfected with human immunodeficiency virus (HIV), and 8–10% with HIV have chronic HBV. Coinfection accelerates HBV-related liver disease. HBV-active antiretroviral therapy (ART) suppresses viral replication but rarely achieves hepatitis B surface antigen (HBsAg) loss. This systematic literature review (SLR) assessed epidemiology, treatment patterns, quantitative HBsAg (qHBsAg) and clinical outcomes in HIV/HBV coinfection.
Method: We searched Embase and MEDLINE (01/01/2015–24/06/2025) for HIV/HBV coinfection studies (SLRs, narrative reviews, observational studies and clinical trials [for HBsAg data]; excluding preclinical and paediatric studies [< 18 years], case reports and small

case series [< 10 pts]), supplemented by global reports. Data extracted included baseline (BL, i.e. prior to initiation of HBV-active ART) and on-treatment qHBsAg, HBV DNA, hepatitis B e-antigen (HBeAg), treatment regimens and liver outcomes.
Results: 90 articles were included. In treated pts, ~11–21% had qHBsAg ≤ 1000 IU/mL and 79–90% had qHBsAg > 1000 IU/mL at BL; qHBsAg ranged between 631–15849 IU/mL at BL and tended to decline on HBV-active ART (251–794 IU/mL at 3 years). At any ART timepoint, pts with detectable HBV DNA after 24 months had significantly higher qHBsAg kinetics than those with undetectable HBV DNA, indicating qHBsAg levels reflect ongoing HBV replication. qHBsAg was also higher in HBeAg-positive than HBeAg-negative pts (7943 vs 6310 IU/mL at 3 years of treatment), with HBeAg seroclearance mainly occurring within 5 years of therapy at a median rate of 1.7–12.1 per 100 pt-years. HBsAg loss on therapy was infrequent and typically happened soon after initiation of anti HBV-active ART when it occurred. Factors associated with HBsAg loss included lower qHBsAg levels at BL and greater HBsAg declines, as well as alanine transaminase elevation, tenofovir alafenamide/tenofovir disoproxil fumarate-based regimens and longer HBV therapy duration. Limited evidence suggested that HBsAg loss was associated with substantially better liver outcomes (e.g., cirrhosis, odds ratio: 0.21).
Conclusion: HBsAg loss is associated with improved outcomes in HIV/HBV coinfected pts. While qHBsAg declines are observed with current HBV-active ART, HBsAg loss remains uncommon. Larger prospective studies are needed to identify predictors of clearance and evaluate novel strategies.
Funding: GSK (300495).

Predictors of HBsAg loss, including baseline quantitative HBsAg, in adults with chronic hepatitis B: a regional cohort study in China

Yuanyuan Kong[1], Xiaohua Li[2], Mei Yang[3], Ying Shen[4], Sida Wei[4], Xin Li[4], Xin He[5], Lydia Demetriou[6], Menchi Wu[7], Huifen Yang[8], Jidong Jia[9], Myriam Drysdale[10]. *[1]Clinical Epidemiology and EBM Unit, Beijing Friendship Hospital, Capital Medical University, Beijing, China; [2]The Second Hospital of Tianjin Medical University, Clinical Trial Institution, Tianjin, China; [3]3EVYD Technology, RWE Global, Short Hills, United States; [4]Tianjin Happy Life Technology Co. Ltd, Innovative Healthcare Solution, RWE Global, Shanghai, China; [5]GSK, Value Evidence and Outcomes, Shanghai, China; [6]GSK, Clinical Development, London, United Kingdom; [7]GSK, Shanghai, China; [8]The Second Hospital of Tianjin Medical University, Department of Infectious Diseases and Immunology, Tianjin, China; [9]Liver Disease Center, Beijing Friendship Hospital, Capital Medical University, Beijing, China; [10]GSK, London, United Kingdom*
Email: kongyuanyuan2000@163.com

Background and aims: Chronic hepatitis B virus (HBV) infection is a major global public health problem and a leading cause of liver-related morbidity/mortality. The goal of treatment is functional cure (FC: sustained HBV DNA and hepatitis B surface antigen [HBsAg] loss after stopping all treatment). Lower quantitative HBsAg (qHBsAg) levels are associated with improved outcomes, but routine qHBsAg testing is limited and population-level data are sparse. This study characterised demographic, clinical and virological predictors–including baseline (BL) qHBsAg–of HBsAg loss among patients (pts) with chronic HBV infection in China.
Method: This retrospective cohort study used Tianjin regional electronic health records from 82 hospitals (2016–2023). Eligible pts were adults with chronic HBV infection, ≥ 1 qHBsAg measurement (first test = index date), no coinfection and no major adverse liver outcomes (compensated/decompensated cirrhosis, hepatocellular carcinoma or liver transplant) before index. Demographic and clinical variables were recorded in the 12 months before index. A multivariate Cox proportional hazards model evaluated predictors of time to HBsAg loss.
Results: 28,659 pts were included (mean [standard deviation] age 41.7 [12.9] years; 55.9% male; median duration of follow-up 4.6 years). BL qHBsAg distribution was: ≤ 100 IU/mL 13.7%, > 100–≤ 1000 IU/mL 20.6%, > 1000–≤ 3000 IU/mL 19.9%, and > 3000 IU/mL 45.8%. Of 5369 pts (18.7%) treated with nucleos(t)ide analogues (NAs), 3039 (56.6%) had BL qHBsAg ≤ 3000 IU/mL and 1653 (30.8%) had ≤ 1000 IU/mL. HBsAg loss occurred in 2.9% (454/15,529) of all pts with BL qHBsAg ≤ 3000 IU/mL, 3.4% (102/3039) of NA-treated pts with BL qHBsAg ≤ 3000 IU/mL and 4.8% (79/1653) of NA-treated pts with qHBsAg ≤ 1000 IU/mL. Cox regression showed lower BL qHBsAg was strongly associated with HBsAg loss: hazard ratios (95% confidence interval) vs > 3000 IU/mL were 7.03 (5.66–8.73) for ≤ 100 IU/mL, 1.57 (1.23–2.01) for > 100–≤ 1000 IU/mL, and 1.03 (0.79–1.35) for > 1000–≤ 3000 IU/mL. Older age was associated with reduced likelihood of HBsAg loss, while higher alanine aminotransferase (> 5 × vs 1× upper limit of normal), BL hepatitis B e antigen positivity, type 2 diabetes and non-alcoholic liver disease were associated with increased likelihood of HBsAg loss.
Conclusion: These data reflect a strong association between low BL qHBsAg and HBsAg loss and highlight the need for routine qHBsAg testing to identify pts most likely to achieve FC with emerging therapies.
Funding: GSK (219254).

SAT-580

Prolonged HDV RNA positivity and significant risk of HDV RNA re-ocurrence in hepatitis delta patients who underwent liver transplantation

Esmee Fath el Bab[1], Ainura Khammetova[1], Jolanda Kreeft-Voermans[1], Caroline den Hoed[1], Harry L.A. Janssen[1,2], Maikel P. Peppelenbosch[1], Annemiek Van der Eijk[1], Milan J. Sonneveld[1]. *[1]Erasmus MC, University Medical Center, Rotterdam, Netherlands; [2]Toronto Center for Liver Disease, Toronto General Hospital, University of Toronto, Toronto, Canada*
Email: e.fathelbab@erasmusmc.nl

Background and aims: Liver transplantation (LT) is an important treatment option for hepatitis delta patients with liver failure or HCC. The risk of HDV recurrence after LT remains ill-defined. We studied early HDV RNA kinetics and risk of re-occurrence of HDV RNA in patients who underwent LT.
Method: We analyzed all HDV RNA positive patients who underwent LT between 2005–2025 in the largest liver transplantation center of the Netherlands. All patients were treated with HBIG and nucleos(t)ide analogues (NA) after LT. HDV RNA, HBsAg and anti-HBs levels were assessed in stored samples obtained post-transplant. Recurrence was defined as re-occurrence of HDV RNA after the first sample reported as target not detected (TND, <50 IU/mL).
Results: A total of 11 patients were included, with a mean age of 44.3 (±10) years at LT, of whom 10 (90.9%) were male. Median follow-up time was 8.0 years (IQR 0.3–15.0). Indication for LT was decompensated cirrhosis (n = 7, 63.6%), HCC (n = 3, 27.3%) or ALF (n = 1, 9.1%). One patient received an anti-HBc positive graft. Pre-LT, median HDV RNA was 6.10 log IU/mL (IQR 5.84–6.88). At day 7 from LT, n = 9 (81.8%) remained HDV RNA positive (median HDV RNA at day 7 was 2.87 log IU/mL; median decline from baseline 3.62 log IU/mL), despite all achieving anti-HBs titers >100 mIU/mL. The median duration to HDV RNA and HBsAg negativity was 26.5 (7.0–63.0) and 6.0 days (1.0–28.0) respectively. Pre-LT HDV RNA was not associated with time-to-negative HDV RNA. There was also no association between anti-HBs levels and HDV RNA decline or clearance. After HDV RNA negativity, n = 4 (40%) experienced HDV RNA recurrence, all of whom had anti-HBs >100 and negative HBsAg at the time of HDV RNA recurrence. Re-emergence of HDV RNA was transient in 3 patients, but 1 patient was still positive for HDV RNA at the most recent assessment.
Conclusion: In patients who underwent LT for hepatitis delta, we observed prolonged HDV RNA positivity and frequent re-occurrence of HDV RNA despite negative HBsAg and high anti-HBs levels. These

findings underscore the importance of close HDV RNA monitoring after LT, and suggest a potential need for additional HDV specific therapies to reduce the risk of graft infection.

SAT-581

Scaling up ProLINK nationwide in Spain, early results of an implementation strategy for hepatitis C and hepatitis B and delta virus search and linkage to care

Email: albertovb97@hotmail.es

Background and aims: Chronic viral hepatitis remains a major cause of liver-related morbidity. In HCV and HBV infection, a substantial proportion of previously diagnosed individuals remain untreated or lost to follow-up, representing a persistent gap in the care cascade and a barrier to elimination. Re-linking these patients during routine healthcare encounters allows reassessment of virological status and initiation of appropriate management. In hepatitis B, re-linkage also enables identification of hepatitis delta virus infection through reflex or dual-reflex diagnostic strategies. We aimed to assess the early results of a nationwide implementation of an automated laboratory-driven strategy to improve search and linkage to care.

Method: ProLINK integrates automated rules into the laboratory information system to identify patients with prior positive anti-HCV or HBSAg results whenever a serum sample is available for any clinical request. Laboratory databases and electronic medical records are reviewed to identify patients lost to follow-up. For hepatitis C, if no sustained virological response is documented, HCV-RNA testing is performed using the available sample. For hepatitis B, if no serological follow-up has been recorded within the previous 12 months, HBsAg is retested and, if positive, reflex testing for HDV is performed.

Results: In the hepatitis C programme, 5,269 anti-HCV positive individuals were identified. Among them, 656 (12.5%) required RNA testing due to incomplete follow-up, 608 could be tested, and 190 (31.3%) had active viremia. To date, 134 viremic patients have been contacted; 90 initiated antiviral treatment, 19 declined therapy, and 28 remain under reassessment. In the hepatitis B/delta programme, 116 HBsAg positive individuals without recent follow-up were identified. Testing was not feasible in five cases, 93 patients remained HBsAg positive, and 78 (84%) had incomplete follow-up. Hepatitis delta antibodies were detected in six patients, all of whom were RNA negative.

Conclusion: A nationwide, automated, laboratory-integrated opportunistic strategy enables systematic identification and re-linkage of patients with chronic hepatitis C and hepatitis B who remain outside the care cascade. Importantly, hepatitis B re-linkage facilitates detection of hepatitis delta infection through reflex testing. This approach represents a scalable, virology-driven tool to strengthen hepatitis elimination efforts.

SAT-585

Hepatitis delta in Spain: prevalence and clinical, demographic and virological characterization from a nationwide prospective cohort

Ana Alberola Romano[1], Lucía Pérez-Rodríguez[1], Adolfo de Salazar[1], Raquel Carracedo[2], Teresa Cabezas Fernandez[3], Carolina Freyre[4], Berta Becerril Carral[5], Isabel Viciana[6], Inmaculada López[7], Natalia Montiel[8], Samuel Bernal[9], Jaime Borrego[10], Encarnación Ramirez Arellano[11], Carmen Liébana[12], Francisco Franco Álvarez De La Luna[13], María Carmen Lozano Domínguez[14], Mercedes Pérez-Ruiz[15], Antonio Sampedro[16], Ana Belén Pérez[17], Sonia Algarate Cajo[18], Pablo Fraile Ribot[19], Aldara Vallejo[20], María José Pena[21], Maria Aroca[22], Ana Rodríguez-Fernández[23], José Joaquín Blas Señalada[24], César Gómez[25], Alejandro González Praetorius[26], Santiago Muñoz[27], Ruth Saez[28], Sonsoles Garcinuño Pérez[29], Pilar Tajada[30], Susana García-De Cruz[31], Marta Sandoval Torrientes[32], Belen Lorenzo[33], María Reyes Vidal-Acuña[34], Luz Moldes[35], Noelia Calvo[36], María José Gude[37], Patricia Ordóñez[38], Sandra Cortizo Vidal[39], Miriam Blasco[40], Ana Arribi[41], Iker Falces[42], Juan Carlos Galán[43], María Asunción Iborra[44], Jorge Galán[45], Maria Jesus Del Amor Espin[46], Eva Cascales[47], María Luz Núñez[48], Ana Miqueleiz Zapatero[49], A. Background and aims: Hepatitis delta virus (HDV) infection represents the most severe form of chronic viral hepatitis, leading to rapid fibrosis progression, early hepatic decompensation and increased mortality. Despite its clinical relevance, contemporary epidemiological data on HDV in Europe remain limited. In Spain, systematic information on the prevalence and clinical, demographic and virological characteristics of patients with hepatitis delta is scarce. Defining the burden and profile of HDV infection is essential to inform screening strategies and optimize patient management.
Method: We conducted a nationwide, multicenter, observational study including a retrospective evaluation of HDV prevalence among HBsAg-positive individuals (2022–2024) and a prospective cohort launched in 2024. Anti-HDV–positive individuals were enrolled prospectively across Spain. Demographic data, risk factors, clinical variables related to liver disease severity, and virological parameters (HDV-RNA status, viral load, genotype, HBV markers and HIV/HCV co-infection) were systematically collected in a centralized database.
Results: Between 2022 and 2024, 65,763 HBsAg-positive individuals were evaluated in 80 centers from 16 Autonomous Communities. Anti-HDV prevalence remained stable over time (5.6% in 2022, 4.9% in 2023 and 5.3% in 2024). The proportion individuals with confirmed chronic HDV infection were 40.1% in 2022, 31.6% in 2023 and 31.0% in 2024. By December 2025, 534 anti-HDV–positive individuals were prospectively enrolled. Median age was 54 years (IQR 42–61), 58% were male and 49% were born in Spain. HDV genotype 1 predominated (88%). Active HDV infection was detected in 43%, with a mean viral load of log 4.16 IU/mL. Co-infections were frequent (18% HIV, 20% HCV) and were associated with higher rates of active HDV replication (55% and 56%, respectively; $p < 0.05$). Advanced liver disease was common: 26% had FIB-4 >2.67, mean liver stiffness was 10.5 kPa, 41% had METAVIR F3–F4 fibrosis, and 23% had a history of hepatic decompensation.
Conclusion: This nationwide prospective cohort provides robust contemporary data on hepatitis delta in Spain, revealing a high prevalence of advanced liver disease and active viral replication. These findings highlight the substantial clinical burden of HDV infection and reinforce the need for systematic surveillance and optimized clinical management strategies.

SAT-586

Enhanced HBcAg immunoassay enables detection of clinically relevant low-level HBV viremia for treatment eligibility

Rene Geissler[1], Megha Patel[1], Anika Koehler[2], Joerg Herzogenrath[2], Eduardo Almaraz[1], Justin Blumenthal[1], Amit Kumar[1], Todd Solbrig[1], Cyrille Diédhiou[3], Moustapha Mbow[3], Noel Manga[4], Souleymane Mboup[3], Ambroise Ahouidi[3], Michael Berg[1], Gavin Cloherty[1]. *[1]Abbott, Abbott Park, United States; [2]Abbott, Wiesbaden, Germany; [3]IRESSEF, Dakar, Senegal; [4]Hôpital Universitaire de la Paix, Ziguinchor, Senegal*
Email: rene.geissler@abbott.com

Background and aims: Accurate staging of chronic hepatitis B is essential for guiding treatment decisions and predicting clinical outcomes. Current treatment guidelines rely on HBV DNA quantification, with therapeutic thresholds set at ≥2,000 IU/mL or ≥20,000 IU/mL depending on liver enzyme levels, HBeAg status, and evidence of fibrosis or cirrhosis. Despite these guidelines, access to molecular diagnostics for HBV DNA measurement remains limited in many low- and middle-income countries (LMICs) where most infections (~80%) occur, creating barriers to timely and effective care. Importantly, non-phosphorylated HBcAg, located in HBV DNA-containing particles, has emerged as surrogate biomarker for HBV DNA. However, more sensitive HBcAg immunoassays could offer additional clinical utility by enabling HBV detection at clinically relevant thresholds.
Method: We modified a first-generation (v1) HBcAg-specific assay by incorporating a new formulation and monoclonal antibodies. Additionally, this updated assay format was implemented on a digital platform (v2), improving clinical sensitivity on average 225-fold.
Results: The enhanced version (v2) achieved a limit of quantification of 30 fg/mL, corresponding to approximately 1,000 HBV DNA IU/mL. Comparative analysis of v1 and modified v2 assays demonstrated a reduction in the detection threshold from 4.9×10^5 to 1,000 HBV DNA IU/mL, which aligns with treatment eligibility criteria. Longitudinal blood draws from acute HBV patients and single timepoint specimens from treatment-naïve blood donors showed significantly improved detection and quantification using the v2 HBcAg assay.
Conclusion: The HBcAg v2 assay enables increased detection of low viral titers consistent with treatment guidelines and corresponds directly to HBV DNA levels. Its ability to specifically detect low-abundance HBcAg enhances disease staging and may support therapeutic management, particularly in resource limiting settings, where affordable and deployable diagnostic tools are urgently needed.

Background and aims: Hepatitis B surface antigen (HBsAg) circulates as three isoforms (small [S], medium [M], large [L]), reflecting distinct steps of viral life cycle and morphogenesis. In HBV/HDV co-infection, we investigated the relationship between total HBsAg and its isoforms with markers of viral activity and liver injury according to different clinical phenotypes.
Method: This analysis included 366 patients with HBV/HDV co-infection, all HDV-RNA positive, mostly males (62.6%) and Italians (59.0%) with a median (IQR) age of 56 (46–62) years, from the HDV Describe study. Serum total, S-, M-, and L-HBsAg levels were quantified by ELISAs (Beacle Inc.) and were correlated with HDV-RNA (Robogene v2), HBcrAg (Fujirebio), ALT, and liver stiffness measurement (LSM) (Fibroscan, Echosens). Patients were classified into distinct clinical phenotypes according to liver cirrhosis status, with non-cirrhotic patients further stratified into high-viremic chronic hepatitis D (CHD; HDV-RNA ≥3 Log IU/mL), and low-viremic CHD (HDV-RNA <3 Log IU/mL).
Results: Median (IQR) HDV-RNA was 5.1 (3.4–6.0) Log IU/mL and total HBsAg was 3331 (675–9055) ng/mL, while median (IQR) levels of S-, M-, L-HBsAg were 2686 (483–7234), 538 (92–1467) and 0.75 (0.10–4.50) ng/mL, respectively. Total, S-, M-, L-HBsAg correlated positively with HDV-RNA (r_s = 0.47, 0.47, 0.47, and 0.42, respectively; all $p < 0.001$) and HBcrAg (r_s = 0.57, 0.56, 0.57, and 0.44, respectively; all $p < 0.001$). Total, S-, M-, and L-HBsAg levels were significantly higher in patients with ALT >40 U/L compared to those with ALT ≤40 U/L (all $p < 0.001$), whereas only L-HBsAg showed a modest correlation with LSM (r_s = 0.16; p = 0.007). Total, S-, M-, L-HBsAg levels varied according to patients' clinical phenotype, with the highest levels observed in high-viremic CHD, followed by cirrhosis and low-viremic CHD. In multivariate analysis, higher S-HBsAg levels were significantly associated with high-viremic CHD (OR = 1.58, 95% CI 1.16–2.15; p = 0.003), higher M-HBsAg with liver cirrhosis (OR = 1.78, 95% CI 1.04–3.03; p = 0.035), while lower L-HBsAg levels were associated with low-viremic CHD (OR = 0.38, 95% CI 0.25–0.58; $p < 0.001$).
Conclusion: Both total HBsAg levels and HBsAg isoforms correlated with the extent of HDV replication and cytolytic activity. Notably, HBsAg isoforms showed distinct associations across clinical phenotypes, suggesting a differential regulation of HBV envelope proteins in HDV-driven liver disease.

SAT-588

Beyond virological control: persistent psychological burden and the patient quest for functional cure in chronic hepatitis B

Robin Habermann[1], Alexandra Rickert[1], Sven Pischke[1], Peine Sven[2], Ansgar W. Lohse[1], Julian Schulze zur Wiesch[1], Felix Piecha[1].
[1]Department of Internal Medicine, University Medical Center Hamburg-Eppendorf, Hamburg, Germany; [2]Institute of Transfusion Medicine, University Medical Center Hamburg-Eppendorf, Hamburg, Germany
Email: robin.habermann@icloud.com

Background and aims: Chronic hepatitis B (CHB) infection remains a major global public health concern with significant risk for patients of developing chronic liver disease (CLD). While antiviral therapies effectively suppress viral replication, their impact on patient-reported health-related quality of life (HRQoL) remains poorly characterized in European populations. With the emergence of finite treatment strategies and novel cure-directed approaches, understanding patient perspectives on disease and treatment goals has become increasingly important. This study aimed to characterise the HRQoL in a northern German cohort of CHB patients, identify factors influencing patient-reported outcomes, and explore the patients' perspective on the disease.
Method: A total of 219 participants were enrolled in this study, 161 CHB patients (57 on antiviral therapy, 104 untreated) and 58 healthy controls. HRQoL was assessed using the Short Form-36 Health Survey (SF-36), with an additional questionnaire assessing the patients' illness perception. Linear regression analysis identified independent predictors of the Physical Component Summary (PCS) and Mental Component Summary (MCS) scores of the SF-36.
Results: Antiviral treatment was not associated with improved PCS or MCS scores in CHB patients. However, both treated and untreated CHB patients demonstrated significantly impaired mental wellbeing (MCS 42.5 and 42.2, respectively) compared with healthy controls (50.2; $p < 0.05$). Stratification by the region of origin revealed lower MCS scores for patients of Turkish and Middle Eastern origin. The presence of comorbidities ($p = 0.002$) and higher liver stiffness ($p = 0.043$) were independent predictors for a reduced PCS. Notably, the desire for a functional cure was highly prevalent in both groups (86.6% of treated and 78.8% of untreated patients), reflecting high treatment aspirations extending beyond virological suppression.
Conclusion: This analysis reveals a critical disconnect: despite preserved physical function and viral suppression, CHB patients experience persistent psychological burden unresolved by current antiviral therapies. The overwhelming patient preference for a functional cure underscores an unmet psychological and therapeutic need. These findings advocate for a paradigm shift toward holistic, cure-directed management strategies that address both clinical outcomes and psychosocial determinants of health.

Email: hahn.anna@mh-hannover.de

Background and aims: Non-invasive tests (NIT), including vibration-controlled transient elastography (VCTE), have been evaluated as an alternative to liver biopsy for the staging of liver disease in patients with chronic hepatitis D (CHD). Previous studies have shown superior diagnostic performance of VCTE compared to other NIT; however, analyses in large patient cohorts are lacking.
Method: Individual patient data from the two largest published studies were pooled to evaluate the diagnostic performance of VCTE, aspartate aminotransferase-to-platelet ratio (AAR), AST to platelet ratio index (APRI), and fibrosis-4 index (FIB4) for the detection of advanced fibrosis and cirrhosis in patients with CHD. This multi-center retrospective study included 506 patients with paired liver biopsy and VCTE performed within ± 6 months. The cohort was randomly stratified by METAVIR stage and ALT levels into derivation and validation cohort (70:30). Diagnostic accuracy was assessed using AUC, and optimal VCTE cutoffs were determined using Youden index.
Results: In the derivation cohort, the distribution of histologic fibrosis stages was 30% (107/359) for F0/F1, 29% (103/359) for F2, 19% (67/359) for F3, and 23% (82/359) for F4. Median VCTE values were significantly higher in patients with METAVIR F4 (17.4 kPa [IQR 11.9–28.2 kPa] compared with those with F0/F1 (7.2 kPa [IQR 5.8–10 kPa], $p < 0.0001$), F2 (8.9 kPa [IQR 7.6–11.1 kPa, $p < 0.0001$], and F3 (10.4 kPa [IQR 8.6–14 kPa], $p < 0.0001$). VCTE was superior to other NIT for the detection of cirrhosis (AUCs: 0.83 [VCTE], 0.59 [AAR], 0.70 [APRI], 0.76 [FIB4]). The optimal VCTE cutoff for diagnosing cirrhosis was > 15.2 kPa (sensitivity (Se) 61%, specificity (Sp) 90.3%, positive predictive value (PPV) 65%, negative predictive value (NPV) 88.7%), with 83.6% of patients correctly classified. Using a cutoff of 10.2 kPa for advanced fibrosis (≥ F3), sensitivity, specificity, PPV, NPV, and accuracy were 70%, 70%, 63%, 77%, and 70%, respectively. For ≥ F2, the optimal cutoff was > 8.5 kPa (Se 73.4%, Sp 65.4%, PPV 83.3%, NPV 51.1%), resulting in 71% correctly classified patients. In the validation cohort (n = 147), 76%, 65%, and 71% of patients were correctly classified when applying the cutoffs for ≥ F4, ≥ F3, and ≥ F2 derived from the derivation cohort.
Conclusion: VCTE is a valuable diagnostic method for staging liver disease in patients with CHD. However, liver biopsies will continue to play a role in patients with discrepant clinical and NIT results.

SAT-590

Reflex anti-HDV testing among HBsAg-positive patients: diagnostic yield and screening impact in a retrospective cohort study

Tor Sadeh[1], Orit Rozenberg[2], Fadi Abu Baker[3], Tarek Saadi[4], Rawi Hazzan[5]. *[1]Bruce Rappaport Faculty of Medicine, Technion-Israel Institute of Technology Haifa, Israel, Haifa, Israel; [2]Emek Medical Center Laboratories, Clalit Health Services, Afula, Israel; [3]Department of Gastroenterology and Hepatology, Hillel Yaffe Medical Center, Hadera 38100, Israel, Bruce Rappaport Faculty of Medicine, Technion-Israel Institute of Technology Haifa, Israel, Hadera, Israel; [4]Bruce Rappaport Faculty of Medicine, Technion-Israel Institute of Technology Haifa, Israel, Liver Unit, Rambam health care campus, Haifa, Israel, Haifa, Israel; [5]Clalit Health Services, Northern Region, Israel, Azrieli Faculty of Medicine, Bar-Ilan University, Safed, Israel, nazareth, Israel*
Email: rawihazzan1@gmail.com

Background and aims: Hepatitis D virus causes one of the most severe forms of chronic viral hepatitis. Although European guidelines recommend universal screening of all HBsAg-positive individuals, this practice is not yet widely implemented, and many remain unscreened. The objective of our study was evaluate the yield of reflex HDV testing and characterize HBV carriers who tested positive or negative for HDV in northern Israel.
Method: A retrospective cohort study was conducted using data from Clalit Health Services in northern Israel between May 2014 and May 2024. Hepatitis B surface antigen–positive patients were categorized into two groups: those screened for hepatitis D antibody via reflex testing (2019–2024) and those tested based on clinical discretion (2014–2019). Demographic, clinical, and laboratory characteristics were extracted for analysis.

Results: Among 1,336 HBsAg-positive individuals, HDV screening rates increased from 57.5% to 93.1% following reflex implementation. HDV seropositivity rose from 3.17% to 6.48% (P = 0.02). Ethiopian-born individuals had significantly higher positivity compared to other patients (10.4% vs. 3.9% respectively; P = 0.0221). The average time from HBV diagnosis to HDV testing decreased from 38.1 ± 31 months (median 37.5) in the pre-reflex period to 1.3 ± 6.1 months (median 0) in the reflex period.
Conclusion: Reflex anti-HDV antibody testing improves screening coverage and detects more seropositive cases. These findings support its integration into national screening policies to promote early diagnosis and ensure all at-risk individuals are tested for HDV.

SAT-591

Correlation of bile acid dynamics with bulevirtide response and disease severity in patients with hepatitis D

Marlene Hintersteininger[1,2], Michael Schwarz[3], Philipp Schwabl[1,2], Lukas Hartl[1,2], Lorenz Balcar[1,2], Benedikt Hofer[1,2,4], Georg Kramer[1,2], Christian Sebesta[1,2], Paul Thöne[1,2], Patrik Attalla[1], Michael Gschwantler[5], Michael Trauner[1], Mattias Mandorfer[1,2], Thomas Reiberger[1,2,4], Mathias Jachs[1,2]. *[1]Division of Gastroenterology and Hepatology, Department of Medicine III, Medical University of Vienna, Vienna, Austria; [2]Vienna Hepatic Hemodynamic Lab, Division of Gastroenterology and Hepatology, Department of Medicine III, Medical University of Vienna, Vienna, Austria; [3]Division of Gastroenterology and Hepatology, Department of Internal Medicine II, University Hospital of Sankt Pölten, Sankt Pölten, Austria; [4]Christian Doppler Lab for Portal Hypertension and Liver Fibrosis, Medical University of Vienna, Vienna, Austria; [5]Department of Internal Medicine IV, Klinik Ottakring, Vienna, Austria*
Email: marli.hintersteininger@gmail.com

Background and aims: Bulevirtide (BLV) inhibits hepatitis D virus (HDV) entry into hepatocytes by blocking the sodium taurocholate co-transporting polypeptide (NTCP), which is also the major hepatic bile acid (BA) uptake system. This study investigated the association between BA dynamics and antiviral response during BLV therapy.
Method: Patients with chronic HDV infection and longitudinal measurements of serum BA levels before, during, and after BLV treatment were included. Virologic response (VR) was defined as a ≥2 $\log_{10}$ HDV-RNA decline and discriminated versus virologic non-response (VNR). Changes in BA levels (ΔBA) were analysed (i) in relation to HDV-RNA dynamics, (ii) after pegylated interferon-alpha (pegIFN) add-on therapy and (iii) after BLV discontinuation.
Results: 25 patients (48% male; advanced chronic liver disease [ACLD]: 92.0%, 17 patients [68.0%] with VR at W48) were included. Baseline BA levels were significantly higher in ACLD patients with portal hypertension (PH, n = 10) compared to those without (19.2 µmol/L vs. 5.1 µmol/L; p = 0.015). Median on-treatment BA levels did not differ between patients with VR vs. VNR at W24 (25.4 µmol/L vs. 22.7 µmol/L; p = 1.000) and W48 (25.4 µmol/L vs. 20.8 µmol/L; p = 1.000). Relative to baseline, ΔBA from baseline to W48 did neither differ between patients with VR and VNR (p = 0.534) nor correlate with HDV-RNA decline at W48 (ρ = 0.08; p = 0.719). Comparable results were observed at W24, W72, and W96. Addition of pegIFN did not affect median BA levels during combination therapy (before add-on: 29.8 µmol/L vs. during add-on: 23.7 µmol/L; p = 0.500). Six patients discontinued BLV therapy after reaching sustained HDV-RNA suppression; and their BA levels promptly returned to normal levels (median at last on-treatment assessment: 18.9 µmol/L vs. median after discontinuation: 7.6 µmol/L; p = 0.028). Pruritus was reported by 11 patients during BLV therapy. Baseline BA levels were significantly higher in patients experiencing pruritus compared to those without (13.6 µmol/L vs. 6.8 µmol/L; p = 0.047). Importantly, BA levels during treatment were not associated with self-reported treatment compliance nor other adverse events.
Conclusion: Our cohort of predominantly ACLD-HDV patients showed elevated baseline and significant BLV-mediated increases in BA levels. Importantly, ΔBA did neither predict VR nor adverse events on BLV treatment. BA elevations during BLV treatment are fully reversible upon cessation.

SAT-592-YI

Low HBsAg and HBV DNA levels lead to stable state of sustained control among chronic hepatitis B patients: results from the SIGNAL study

Grishma Hirode[1,2], Sanam Tabataba Vakili[1], Leila Amiri[1], Andrew Mendlowitz[1,2,3], Aaron Vanderhoff[1,2], Saima Naim[1], Harry L.A. Janssen[1,4], Scott K. Fung[1], Adam Gehring[1], Jordan J. Feld[1,2]. *[1]Toronto Centre for Liver Disease, Toronto General Hospital, University Health Network, Toronto, Canada; [2]The Viral Hepatitis Care Network Canada (VIRCAN), Toronto, Canada; [3]Institute of Health Policy, Management and Evaluation, University of Toronto, Toronto, Canada; [4]Department of Gastroenterology and Hepatology, Erasmus MC University Medical Center, Rotterdam, Netherlands*
Email: grishma.hirode@gmail.com

Background and aims: Partial cure (sustained HBsAg <100 IU/mL and HBV DNA <LLOQ 24 weeks off-treatment), a novel treatment endpoint for hepatitis B virus (HBV) cure trials, has been proposed as an alternative to functional cure or hepatitis B surface antigen (HBsAg) loss. In this study, we examined whether even a single occurrence of low HBsAg and HBV DNA levels was a marker of a stable state of sustained control.
Method: Cohort study of chronic hepatitis B patients with at least 1 HBsAg measurement ≥0.05 IU/mL between January 2010-December 2022. The "sustained control state" was defined as HBsAg <100 IU/mL and HBV DNA <20 IU/mL; study entry as the first HBsAg measurement, and state entry as the first occurrence of the "sustained control state." We compared characteristics and HBsAg loss rate among patients who entered this state even once during follow-up, regardless of duration in this state, treatment or phase of infection, with those who never entered this state.
Results: Among 8239 patients (mean age 48 ± 14 years, 56% male, 81% Asian, HBsAg 2.6 ± 1.4 $\log_{10}$ IU/mL, HBV DNA 3.2 ± 2.5 $\log_{10}$ IU/mL, 77% HBeAg-negative, ALT 1.4 ± 4.5x ULN, APRI 1.0 ± 16, mean follow-up 316 ± 216 weeks), 1652 (20%) patients entered this state (17% entered this state more than once). At study entry, compared with patients who never entered this state, these patients were older (54 vs 46 years), had lower HBsAg (1.3 vs 3.0 $\log_{10}$ IU/mL) and HBV DNA (1.6 vs 3.6 $\log_{10}$ IU/mL), and were more often male (67 vs 54%) and HBeAg-negative (88 vs 75%) (p < 0.001 for all). At state entry, mean HBsAg was 0.7 ± 1.4 $\log_{10}$ IU/mL, and ALT was 0.8 ± 0.6× ULN. Median duration in this state was 108 (25–249) weeks and the majority who entered this state remained in it until end of follow-up (n = 1493, 90%). At end of follow-up, HBsAg loss was higher among those who entered this state compared with those who did not (30 vs 0.9%, p <0.001), and even among those who entered this state, HBsAg levels were significantly lower at state entry among those who achieved HBsAg loss. Among those who did not remain in this state at end of follow-up (n = 159), 18% experienced ≥1 occurrence of HBV DNA >2000 IU/mL and 8% ALT >5× ULN after entry into the state.
Conclusion: HBeAg-negative patients who achieve HBsAg <100 IU/mL and HBV DNA <20 IU/mL even once, regardless of treatment or phase of infection, have a high probability of remaining in that state for a prolonged period, and a high probability of subsequent HBsAg loss.

SAT-593

Impact of cardiometabolic risk factors control in patients with chronic hepatitis B treated with nucleos(t)ide analogues

Karen Cheuk-Ying Ho[1], Rex Wan-Hin Hui[1], Wai-Kay Seto[1,2], Man-Fung Yuen[1,2], Lung Yi Loey Mak[1,2]. [1]*Department of Medicine, Queen Mary Hospital, The University of Hong Kong, Hong Kong, China;* [2]*State Key Laboratory of Liver Research, The University of Hong Kong, Hong Kong, Hong Kong*
Email: loeymak@gmail.com

Background and aims: The long-term impact of individual cardiometabolic risk factors (CMRFs) in patients with chronic hepatitis B (CHB) treated with nucleos(t)ide analogues (NUCs) remains poorly defined.
Method: We conducted a single-center prospective analysis enrolling patients with CHB who were on NUCs since baseline assessment between Oct 2014 to November 2025. CMRFs were defined as per established criteria, with body mass index (BMI) threshold of 23 kg/m^2. We categorized patients as having poor control of CMRFs if they met any of the following criteria: a BMI of ≥30 kg/m^2, the use of three or more antihypertensive or antidiabetic medications, or the use of more than one lipid-lowering agent. Vibration controlled transient elastography (VCTE) was performed at baseline and at three to five years of follow-up. Advanced fibrosis was defined as >/= 10 kPa. Fibrosis progression was defined as liver stiffness (LS) increase by ≥20%. Liver-related events (LREs) were defined as ascites, hepatic encephalopathy (HE), variceal bleeding, hepatocellular carcinoma, liver-transplant or liver-related mortality.
Results: A total of 723 NUC-treated patients (median age 61.0 [54.5–66.7] years; 69.4% male; 90.5% undetectable HBV DNA, median NUCs duration of 14.1 [11.4–16.5] years, baseline LS 6.8 [4.90–10.90] kPa) were analysed with a follow-up time of 9.74 (7.27–10.20) years. LREs occurred in 112 (15.5%) patients, with annual incidence of 1.59%. All-cause mortality was observed in 86 (11.9%) patients, including 47 (6.50%) liver-related mortality, with annual incidence of 1.22% and 0.67%, respectively. 193 (26.7%) patients developed fibrosis progression, which was significantly associated with having three or more CMRFs (OR 1.648, 95% CI 1.026–2.648). An increase in number of CMRFs beyond three did not correspond to a higher risk of fibrosis progression. Patients with three or more CMRFs with a poor control was significantly associated with higher incidences of developing LREs (HR 2.765, 95% CI 1.639–4.663) and all-cause mortality (HR 2.889, 95% CI 1.608–5.191). These findings were only significant among patients without baseline advanced fibrosis.
Conclusion: The presence of three or more CMRFs increases risk of liver fibrosis progression. Poor control of CMRFs, instead of number of CMRFs, correlates with a higher LREs and all-cause mortality. Maintaining well-controlled CMRFs is crucial for reducing adverse clinical outcomes in CHB patients who are on NUCs.

SAT-594

Human leukocyte antigen DQB1 variants and seroclearance of hepatitis B markers in the REVEAL cohort

Claire Hsu[1], Chih-Jen Huang[2], Mei-Hung Pan[2], Chien-Jen Chen[2], Hwai-I Yang[2]. [1]*Cornell University, Ithaca, United States;* [2]*Genomics Research Center, Academia Sinica, Taipei, Taiwan*
Email: cph67@cornell.edu

Background and aims: Seroclearance of hepatitis B surface antigen (HBsAg), hepatitis B e antigen (HBeAg), and hepatitis B virus deoxyribonucleic acid (HBV DNA) represents key milestones of immune control in the natural history of chronic hepatitis B. Host immunogenetic factors, particularly within the human leukocyte antigen (HLA) region, are thought to influence long-term viral control, yet their roles across different serological endpoints remain incompletely defined. We investigated whether HLA-DQB1 variants were associated with seroclearance of major hepatitis B markers in a large community-based cohort.
Method: The REVEAL-HBV is a community-based cohort comprising 3,653 HBsAg-seropositive participants. Imputed HLA class I and II genotypes at loci A, B, C, DPB1, DQA1, DQB1, and DRB1 were analyzed. Seroclearance of HBsAg, HBeAg, and HBV DNA was evaluated using two complementary approaches: (i) binary outcomes (seroclearance vs. no seroclearance) analyzed by logistic regression and (ii) time-to-seroclearance analysed by Cox proportional hazards models, both under an additive genetic model. All analyses were adjusted for age, sex, alanine aminotransferase, smoking, alcohol consumption, cirrhosis, with multiple-testing correction applied.
Results: Distinct HLA-DQB1 variants were associated with seroclearance of different hepatitis B markers. DQB1*06:09 was associated with higher odds of HBsAg seroclearance (odds ratio [OR] = 2.17, p = 0.011) and a faster seroclearance rate (hazard ratio [HR] = 2.07, p = 0.003). For HBeAg seroclearance, HLA-DQB1*05:03 was associated with reduced odds (OR = 0.20, p = 0.009) and slower seroclearance rates (HR = 0.29, p = 0.016). For HBV DNA seroclearance, HLA-DQB1*06:02 was associated with higher odds (OR = 1.70, p = 0.008) and faster seroclearance rates (HR = 1.50, p = 0.010).
Conclusion: HLA-DQB1 variants were differentially associated with seroclearance of HBsAg, HBeAg, and HBV DNA in chronic hepatitis B, highlighting a role for host immunogenetics in shaping long-term viral control across distinct phases of HBV natural history.

Email: habiba.khodir.kamal@ki.se

Background and aims: Chronic hepatitis D (CHD) is a severe chronic liver disease. Persistent HDV RNA replication and cirrhosis are known predictors of liver-related outcomes. However, the association between quantitative HDV RNA levels with liver disease progression remains insufficiently studied. We aimed to evaluate the prognostic value of baseline HDV RNA levels for liver-related events (LREs) and death in patients with CHD.
Method: We conducted a retrospective longitudinal study of patients with CHD between 2015 and 2025 at a hepatology center in Mongolia. Adults (≥18 years) without prior liver-related events (LREs, i.e. hepatic decompensation, hepatocellular carcinoma (HCC), or liver transplantation/liver-related death) at first HDV RNA test, and

without anti-CHD therapy were eligible. HDV RNA levels were quantified using the Bio-Rad amplification kit (Bio-Rad Laboratories, USA) with a lower limit of quantification of 10 IU/mL. Annual incidence rates (IRs) per 100 person-years (PYs) and predictors of composite LREs were assessed using Cox regression models.

Results: A total of 2,447 patients were included with: median age 40.3 years (IQR 33.5–49.9), 56.1% females, 9.2% diabetes mellitus, median HDV RNA 5.3 (4.1–6.1) $\log_{10}$ IU/mL, median HBV DNA 2.2 (1.1–3.1) $\log_{10}$ IU/mL, HBeAg+ 39.0%, 77.5% elevated ALT, and 20.9% having cirrhosis at baseline. During a median of 7.3 years (range 0.9–12.7); 216 (11.2% of 1,936) patients progressed to cirrhosis, and 287 (11.7%) experienced any LREs or death, at an IR of 1.74% and 3-, 5-, 10-year cumulative risks of 4.0%, 6.9%, and 18.0%, respectively. The corresponding IR of LREs in patients with baseline cirrhosis was 4.63%, with 3-, 5-, and 10-year cumulative risks of 10.6%, 18.7% and 41.2%, respectively. Baseline HDV RNA level was an independent predictor of LREs (adjusted hazard ratio [aHR] 1.15; 95% CI 1.05–1.26), with older age (aHR 1.06; 95% CI 1.04–1.07), elevated GGT (aHR 2.16; 95% CI 1.59–2.94), elevated ALT (aHR 1.74; 95% CI 1.15–2.64), and baseline cirrhosis (aHR 3.70; 95% CI 2.77–4.92). In patients with baseline cirrhosis, HDV RNA level, older age and elevated GGT remained independent predictors, but not ALT.

Conclusion: In this large Asian untreated CHD cohort, baseline quantitative HDV RNA levels were independently associated with the risk of liver-related events. Nonetheless, cirrhosis and biochemical markers showed stronger prognostic impact, underscoring the multifactorial nature of disease progression in CHD.

SAT-596

Serum gamma glutamyl transferase (GGT) levels is superior to alanine aminotransferase (ALT) to predict long-term liver-related complications and mortality in patients with chronic hepatitis D (CHD)

Habiba Kamal[1,2], Ganbolor Jargalsaikhan[3], Sanjaasuren Enkhtaivan[3], Karin Lindahl[1], Bekhbold Dashtseren[3], Oyungerel Lkhagva-Ochir[3], Tuvshinjargal Ulziibadrakh[3], Andreas Bungert[3], Elisabetta Degasperi[2,4], Pietro Lampertico[2,4,5], Heiner Wedemeyer[2,6,7], Naranjargal Dashdorj[3], Soo Aleman[1,2].

Migliavacca" Center for Liver Disease, Department of Pathophysiology and Transplantation, University of Milan, Milan, Italy, Milan, Italy; [6]Department of Gastroenterology, Hepatology, Infectious Diseases and Endocrinology, Hannover Medical School, Hannover, Germany, German Centre for Infection Research (DZIF), Site Hannover-Braunschweig, Hannover, Germany, Excellence Cluster RESIST, Hannover Medical School, Hannover, Germany, Hannover, Germany; [7]Excellence Cluster RESIST, Hannover Medical School, Hannover, Germany, Hannover, Germany
Email: habiba.khodir.kamal@ki.se

Background and aims: Elevated gamma-glutamyl transferase (GGT) has been associated with liver disease progression in chronic hepatitis D (CHD). However, its prognostic value for liver-related events (LREs) and survival, compared with alanine aminotransferase (ALT), remains insufficiently explored. We therefore evaluated the association between elevated GGT and the risk of LREs and mortality in patients with CHD.

Method: We conducted a retrospective cohort study of patients with CHD at a hepatology center in Mongolia. Adults (≥18 years) without prior LREs (defined as cirrhosis, hepatic decompensation, liver transplantation, or death), without previous antiviral treatment for CHD, and with >6 months follow-up were included. Baseline was the date of first HDV RNA test. Upper limits of normal (ULN) were 35 and 31 IU/mL for GGT, and 41 and 31 IU/mL for ALT in males and females, respectively. Incidence rates (IR) per 100 person-years (PYs) were estimated using Poisson models and cumulative incidence was assessed by Kaplan–Meier method. Prognostic performance of GGT and ALT was assessed using time-dependent AUROC at 5 and 10 years and C-index.

Results: Overall, 2,506 patients were included with baseline characteristics of median age 40.3 years, 55.9% females, overweight 59.5%, diabetes 9.1%, alcohol overconsumption 8.4%, elevated ALT 77.5%, elevated GGT 42.4%, median HDV RNA 5.3 (4.1–6.1) $\log_{10}$ IU/mL, and 20.9% had cirrhosis at baseline. During a median follow-up of 7.4 (IQR 5.6–8.7) years, 290 (11.6%) developed LREs (IR 1.71/100 PYs), with 5- and 10-year cumulative risks of 6.8% and 17.7%. A total of 107 (4.3%) underwent liver transplantation or died (IR 0.61/100 PYs), with 5- and 10-year risks of 2.1% and 6.3%. Elevated GGT was independently associated with higher risk of LREs (aHR 2.11) and mortality (aHR 2.30). Elevated ALT was associated with LREs (aHR 1.85) but not with mortality. For GGT, 10-year risk increased from thresholds of 56 IU/mL for LREs and 58.7 IU/mL for mortality (AUROC 0.69 and 0.72; C-index 0.68 and 0.73, respectively). For ALT, 10-year LRE risk increased from 44 IU/mL (AUROC 0.58; C-index 0.57).

Conclusion: GGT demonstrated superior prognostic performance to ALT for predicting long-term liver-related outcomes and mortality in CHD, supporting its use as a simple biomarker for clinical risk stratification.

SAT-597

Risk of hepatitis B virus reactivation in patients with prior or chronic infections undergoing transarterial chemoembolization for hepatocellular carcinoma

Dong Yun Kim[1], Jaehong Jeong[1], Jung Pyo Hong[1], Jae Seung Lee[1], Mi Na Kim[1], Beom Kyung Kim[1], Seung Up Kim[1], Jun Yong Park[1], Sang Hoon Ahn[1], Do Young Kim[1], Hye Won Lee[1]. *[1]Department of Internal Medicine, Yonsei University College of Medicine, Yonsei Liver Center, Severance Hospital, Seoul, Korea, Rep. of South*
Email: lorry-lee@yuhs.ac

Background and aims: Transarterial chemoembolization (TACE) is a cornerstone treatment for hepatocellular carcinoma (HCC), yet the hepatitis B virus (HBV) reactivation risk—particularly among patients who previously had an infection—remains incompletely characterized. We aimed to determine the incidence of HBV reactivation and identify risk factors in patients undergoing TACE for HBV-related HCC.

Method: We retrospectively analyzed patients who underwent TACE for HBV-related HCC at a tertiary hospital during 2007–2025. Patients receiving baseline antiviral therapy were excluded. HBV reactivation was defined according to Asian guidelines. Among patients with definitive HBV serostatus (n = 774), patients were stratified according to HBV serological status into chronic-infection (hepatitis B surface antigen [HBsAg]-positive, n = 727) and resolved-infection (HBsAg-negative/anti-hepatitis B core antibody [HBc]-positive, n = 47) groups. Cumulative incidences and risk factors were assessed using Kaplan–Meier analysis and Cox regression.

Results: During a median follow-up of 16.7 months, HBV reactivation occurred in 60 patients (6.1% overall). Patients with a resolved HBV status had a higher reactivation rate (21.3% vs. 6.9%; $P < 0.001$). A resolved HBV status (adjusted hazard ratio: 3.98, 95% confidence interval: 1.99–7.97; $P < 0.001$) and an elevated alpha-fetoprotein level (1.33 per $\log_{10}$ ng/mL, 1.04–1.69; $P = 0.024$) were independent predictors of reactivation. The median time to reactivation was 12 months.

Conclusion: HBV reactivation occurred in approximately 6% of patients undergoing TACE for HBV-related HCC, with a resolved infection status conferring a >3-fold higher risk, with a reactivation

incidence exceeding 20%. Current guidelines may underestimate the reactivation risk in this population; prophylactic antiviral therapy may be considered rather than monitoring alone for HBsAg-negative/anti-HBc-positive patients undergoing TACE.

SAT-601-YI

Distinct associations of baseline hepatitis B virus deoxyribonucleic acid with liver-related death in hepatitis B e antigen-negative versus hepatitis B e antigen-positive chronic hepatitis B

Hsuan Chia Kuo[1], Tai-Chung Tseng[1,2,3], Chien-Jen Chen[4], Chun-Jen Liu[1,2,5], Tung-Hung Su[1,2], Hung-Chih Yang[1,5,6], WanTing Yang[2], Chen-Hua Liu[1,2], Pei-Jer Chen[1,2,3,5,6], Hwai-I Yang[4,7,8,9,10], Jia-Horng Kao[1,2,3,5]. *[1]Department of Internal Medicine, Division of Gastroenterology and Hepatology, National Taiwan University Hospital, Taipei, Taiwan, Taipei City, Taiwan; [2]Hepatitis research center, National Taiwan university hospital, Taipei, Taiwan, Taipei City, Taiwan; [3]Department of Medical Research, National Taiwan University Hospital, Taipei, Taiwan, Taipei City, Taiwan; [4]Genomics Research Center, Academia Sinica, Taipei, Taiwan, Taipei City, Taiwan; [5]Graduate Institute of Clinical Medicine, National Taiwan University College of Medicine, Taipei, Taiwan, Taipei City, Taiwan; [6]Department of Microbiology, National Taiwan University College of Medicine, Taipei, Taiwan, Taipei City, Taiwan; [7]Institute of Clinical Medicine, National YangMing Chiao Tung University, Taipei, Taiwan, Taipei City, Taiwan; [8]Graduate Institute of Medicine, College of Medicine, Kaohsiung Medical University, Kaohsiung, Taiwan, Kaohsiung City, Taiwan; [9]Biomedical Translation Research Center, Academia Sinica, Taipei, Taiwan, Taipei City, Taiwan; [10]Doctoral Program of Clinical and Experimental Medicine, National Sun Yat-Sen University, Kaohsiung, Taiwan, Kaohsiung City, Taiwan*
Email: tarenkuo5402@gmail.com

Background and aims: Chronic hepatitis B (CHB) remains a leading cause of global liver-related mortality. While serum hepatitis B virus (HBV) deoxyribonucleic acid (DNA) is a well-established prognostic marker, its linear association with outcomes may vary significantly across different phases of infection. We aimed to delineate the distinct associations between baseline HBV DNA levels and the risk of liver-related death (LRD) in hepatitis B e antigen (HBeAg)-negative and HBeAg-positive patients, utilizing long-term follow-up data from two large-scale community and clinical cohorts.
Method: We pooled data from 6,250 treatment-naïve, non-cirrhotic CHB patients from the renowned REVEAL-HBV and ERADICATE-B cohorts. Patients were stratified by baseline HBeAg status. The primary outcome was LRD. We assessed the hazard ratios (HRs) of LRD across baseline HBV DNA categories (log10 IU/mL) using Cox proportional hazards models, adjusting for age and sex.
Results: Over a median follow-up of 26.5 years, 458 incidences of LRD were identified. In the HBeAg-negative cohort (n = 5,189), LRD risk exhibited a strong, dose-dependent increase with baseline HBV DNA levels (p-for-trend < 0.001), plateauing at viral loads greater than or equal to 5 log10 IU/mL. Specifically, patients with HBV DNA greater than or equal to 7 log10 IU/mL had a nearly seven-fold higher risk of LRD compared to those with < 3 log10 IU/mL (adjusted HR: 6.95, 95% confidence interval [CI]: 4.13–11.68). Conversely, among HBeAg-positive patients (n = 1,061), no clear dose-response relationship was observed for viral loads greater than or equal to 4 log10 IU/mL, with LRD risk showing no significant gradient across higher DNA categories. These distinct risk patterns persisted after multivariable adjustment.
Conclusion: Baseline HBV DNA is a robust, dose-dependent predictor of liver-related mortality in HBeAg-negative CHB, whereas its prognostic value is markedly attenuated in the HBeAg-positive phase. These findings highlight the necessity of phase-specific risk stratification and suggest that viral load thresholds for predicting mortality should be interpreted differently based on HBeAg status.

SAT-602

Real-world experience of 25 years of Lamivudine therapy: highlighting favorable long-term outcomes in chronic hepatitis B

Jaejun Lee[1], Hyun Yang[1], Jeong Won Jang[1]. *[1]Catholic university of Korea, Seoul, Korea, Rep. of South*
Email: pwln0516@gmail.com

Background and aims: Lamivudine, the first oral nucleoside analogue for chronic hepatitis B (CHB), transformed antiviral therapy by enabling durable viral suppression and improving long-term outcomes. However, comprehensive evidence on its long-term clinical impact across diverse treatment patterns is limited.
Method: This real-world cohort study analyzed 1,134 CHB patients who initiated lamivudine between 1997 and 2010. Clinical outcomes, including liver transplantation (LT)-free survival, hepatocellular carcinoma (HCC) incidence, and hepatitis B surface antigen (HBsAg) seroclearance, were evaluated according to treatment continuation, cessation, virologic response, and rescue therapy. Propensity score matching and landmark analyses were applied to minimize bias.
Results: Over a maximum follow-up of 28 years (median, 14.8 years), the 10-year LT-free survival rate was 93.7%, and cumulative HCC incidence was 12.6%. HBsAg seroclearance occurred in 4.8% of patients. Treatment discontinuation significantly increased the probability of HBsAg seroclearance without negatively impacting survival or HCC incidence when performed per stopping criteria. Virologic responders demonstrated superior long-term survival (15-year LT-free survival 96.8%) and higher HBsAg seroclearance rates compared with non-responders. Among these responders, treatment discontinuation did not worsen LT-free survival or HCC risk compared with continued therapy, while achieving higher rates of HBsAg seroclearance in patients maintaining sustained virologic response. Lamivudine resistance was associated with a higher HCC risk (HR 1.95, P < 0.001), whereas rescue therapy improved LT-free survival (HR 0.37, P = 0.007) and reduced HCC incidence (HR 0.60, P = 0.038).
Conclusion: Lamivudine therapy provides durable long-term survival and HCC risk reduction, with safe cessation in selected patients and clear benefits of timely rescue therapy. These findings support optimization of CHB management strategies using current potent antiviral agents.

SAT-603

High-sensitivity HBsAg next assay predicts HBsAg seroreversion in chronic hepatitis B patients following functional cure

Fahong Li[1], Xiaoting Zhao[1], Yao Hu[2], Yuqi Liu[1], Yifei Guo[1], Tiantian Hu[1], Hao Wang[1], Lin Yujie[1], Luhan Zheng[1], Lei Wang[3], Ming Guan[2], Jiming Zhang[1]. *[1]Department of Infectious Disease, Huashan Hospital, Shanghai, China; [2]Department of Clinical Laboratory, Shanghai, China; [3]Department of Infectious Diseases and Hepatology, The Second Hospital of Shandong University, ShanDong, China*
Email: minelihong@163.com

Background and aims: Functional cure, defined as sustained HBsAg loss (<0.05 IU/mL) 24 weeks after treatment cessation, represents the optimal therapeutic endpoint for chronic hepatitis B (CHB). Although functional cure is increasingly achievable, HBsAg seroreversion affects at least 10% of patients. Therefore, the identification of reliable biomarkers to predict seroreversion is critical.
Method: This study enrolled patients across two cohorts: an ambispective cohort and a prospective cohort. The ambispective cohort comprised CHB patients who had previously achieved HBsAg loss; participants underwent ultra-sensitive HBsAg Next testing (analytical sensitivity: 0.005 IU/mL, Abbott Laboratories), discontinued antiviral therapy, and were followed for 72 weeks. The prospective cohort recruited HBeAg-negative patients receiving 48-week peginterferon-based therapy. Patients achieving HBsAg loss at the end of treatment (EOT) discontinued therapy, underwent HBsAg Next testing, and entered a 72-week post-EOT follow-up. The primary endpoint was HBsAg seroreversion (HBsAg ≥ 0.05 IU/mL) at week 72 post-EOT.

Results: A total of 104 patients achieving HBsAg loss were evaluated in the ambispective cohort. At the off-treatment baseline, 17 patients (16.3%) were reactive for HBsAg Next. Six patients experienced seroreversion by week 48; notably, all six were baseline HBsAg Next-reactive. In the prospective cohort (n = 156 enrolled), 37 patients achieved HBsAg loss by week 48 and ceased therapy; of these, four (10.8%) were HBsAg Next-reactive. During prospective follow-up, one patient experienced seroreversion by week 36, who was also baseline HBsAg Next-reactive. By week 48 post-EOT, all nine evaluable patients maintained HBsAg loss, eight of whom were HBsAg Next-non-reactive at baseline.Univariate analysis identified HBsAg Next reactivity ($p < 0.001$) and anti-HBs negativity ($p = 0.047$) as significant predictors of HBsAg seroreversion. Combined analysis further refined risk stratification ($p < 0.001$), identifying the HBsAg Next (+)/anti-HBs(-) subgroup as the highest-risk population, with a seroreversion rate of 38.5% (5/13). Enrollment and follow-up are ongoing.
Conclusion: The ultra-sensitive HBsAg Next assay is an effective tool for the early prediction of HBsAg seroreversion. Furthermore, combining HBsAg Next reactivity with anti-HBs status significantly enhances predictive performance, providing a robust framework for identifying patients at high risk of relapse following functional cure.

SAT-604

Prevalence and impact of hepatic steatosis on clinical outcomes in a U.S. multi-ethnic cohort of chronic hepatitis B

Jonathan R Lim[1], Matthew Kim[1], Zahra Sarrafan Chaharsoughi[1], Sungyoung Auh[1], Ifeoma Kwentoh[1], David E Kleiner[2], Christine Hsu[1], Marc G Ghany[1]. *[1]National Institute of Diabetes and Digestive and Kidney Diseases (NIDDK), Bethesda, United States; [2]National Cancer Institute (NCI), Bethesda, United States*
Email: jonathan.lim2@nih.gov

Background and aims: Previous studies suggest that hepatic steatosis (HS) is associated with faster fibrosis progression and HCC development in chronic hepatitis B (CHB). However, many of these studies were conducted in Asia, used non-invasive tests to evaluate fibrosis, and did not evaluate liver-related events (LREs) Aim: To determine the prevalence of steatosis and its contribution to liver disease outcomes in a U.S. multi-racial cohort of CHB.
Method: Untreated CHB patients who underwent liver biopsy from 1975 to 2022 were included. Demographic, clinical, virological, and histological factors were retrospectively extracted from the EMR. Liver biopsies were scored using the HAI scoring system for inflammation and fibrosis, and steatosis by the proportion of hepatocytes exhibiting fat: 0/trace (<5%), 1 (6–33%), 2 (34–66%), 3 (>66%). Chi-square and logistic regression were used to identify predictors of steatosis. LREs (hepatic decompensation and HCC), all-cause mortality, and HBsAg loss were assessed by Kaplan-Meier and Cox Proportional Hazards Model.
Results: Of 903 HBsAg+ patients, after exclusion of those with acute HBV, children, viral co-infection, LREs prior to biopsy, there were 349 untreated persons with a biopsy. The median age was 40 years (IQR 31, 51), and median follow up was 7.90 years (IQR 2.32, 15.48). 73% were male. 52% were White, 15% Black, 31% Asian, and 2% multiracial or unknown. Use of antivirals after biopsy was similar between those with and without HS (75% and 74% respectively). 12% had cirrhosis and 14% had severe hepatic inflammation. Overall, HS was present in 103 (29.5%) patients. In a univariate analysis, HS was associated with older age ($p = 0.002$), higher BMI ($p < 0.0001$), diabetes ($p = 0.016$), severe fibrosis when compared to mild ($p = 0.0015$), and prior tobacco use ($p = 0.007$). Current tobacco use was associated with lower risk of HS ($p = 0.007$) when compared to no use. In an age-adjusted multivariate analysis, only BMI (OR = 1.18, $p < 0.0001$) and prior tobacco use (OR = 2.56, $p = 0.015$) remained independent predictors of HS. 28 (8%) persons developed a LRE, 97 (28%) died, and 46 (13%) experienced HBsAg loss. In a time-to-event analysis, HS was associated with development of LREs ($p = 0.0131$), HCC ($p = 0.035$), and all-cause mortality ($p < 0.0001$), but not HBsAg loss.
Conclusion: In a multi-racial cohort of CHB, hepatic steatosis was associated with higher BMI, prior tobacco use, development of LREs, death, and HCC. Measures to reduce steatosis should be considered in CHB.

SAT-605

End-of-treatment HBV RNA, HBsAb, and HBcAb levels predict durability of Peg-IFN induced HBsAg loss in CHB patients

Yuqi Liu[1], Yifei Guo[1], Xiaoting Zhao[1,2], Yidi Jia[1], YuanYuan Xu[1], Haoxiang Zhu[1], Jiming Zhang[1]. *[1]Department of Infectious Diseases, Shanghai Key Laboratory of Infectious Diseases and Biosafety Emergency Response, Shanghai Institute of Infectious Diseases and Biosecurity, National Medical Center for Infectious Diseases, Huashan hospital, Fudan University, Shanghai, China; [2]The First Affiliated Hospital of Xinxiang Medical University, xinxiang, China*
Email: liuyq25@m.fudan.edu.cn

Background and aims: Hepatitis B surface antigen (HBsAg) loss, can be achieved through the pegylated interferon (PEG-IFN)-based therapy. However, it is an unignorable fact that a small proportion of patients who achieved functional cure develop HBsAg reversion (HRV) and the related factors are not well described. As a novel virological marker of hepatitis B virus (HBV), HBV RNA is attracting extensive attention, but its correlation with HBsAg remains unclear. We developed a study to investigate the predictive value of serum HBV RNA for HRV in chronic hepatitis B (CHB) patients who have achieved HBsAg loss.
Method: This study prospectively enrolled Hepatitis B e antigen (HBeAg) negative 435 patients who experienced PEG-IFN therapy at Huashan Hospital from January 2020 to October 2024,and among whom 124 patients achieved at least one test of HBsAg loss (HBsAg <0.05 IU/mL). Serum were collected and measured HBV RNA levels at the end of treatment(EOT), and patients were divided into the HBV RNA positive (HRP) group and the HBV RNA negative (HRN) group based on the RNA results. All participants were then followed up ever 24 weeks to 96 weeks.The dynamic changes and correlations between HBsAb and HBcAb was analyzed between the two groups and the predictive values of them for HRV.
Results: 124 patients achieved HBsAg seroclearance, among whom 14 patients' serum were HBV RNA positive at EOT. Then the patient were divided into HRP group (N = 14) and HRN group (N = 108).There was no significance in HBsAg,HBsAb,HBeAg level between the two groups,when HRP group has a higher level of ALT(median: 26.0 vs 49.5 U/L,$p = 0.04$). After 72 weeks of follow-up,HRP group showed a more pronounced decrease in HBsAb (median:7.975 vs 108.8 IU/mL, $p = 0.007$) and HRV occurred in 23 patients(HRP: 4/14 vs. HRN: 19/108). Univariate analysis showed lower levels of HBsAb are independently associated with HRV. ROC analysis identified the optimal EOT cut-off values for HBsAb, HBcAb, and HBV RNA as 44.75 IU/mL, 8.25 S/CO, and 0.645 copies/mL. In addition, combining HBsAb with HBV RNA yielded a higher AUC for predicting HRV compared with individual markers (HBsAb: 0.592; HBcAb: 0.607; RNA–HBsAb: 0.624).
Conclusion: The combination of EOT HBV RNA status with HBsAb and HBcAb levels plays a crucial role in predicting HBsAg reversion after treatment discontinuation among patients who have achieved HBsAg clearance.

SAT-606

Probability of functional cure after nucleos(t)ide analogue withdrawal in chronic hepatitis B: the impact of malignancy and chemotherapy exposure

Yen-Chun Liu[1], Hsin-Che Lin[1], Chao-Wei Hsu[1], Rachel Wen-Juei Jeng[1], Rong-Nan Chien[1]. [1]*Department of Gastroenterology and Hepatology, Chang Gung Memorial Hospital, Linkou branch, Taiwan, College of Medicine, Chang Gung University, Taiwan, Taoyuan, Taiwan*
Email: yenchun923@gmail.com

Background and aims: Functional cure of chronic hepatitis B (CHB), defined by HBsAg seroclearance, is increasingly achieved after nucleos(t)ide analogue (NUC) withdrawal in immune-competent patients. CHB patients with malignancy commonly receive NUC therapy as prophylaxis during chemotherapy, representing a distinct immunological context in which post-NUC HBsAg clearance remains insufficiently characterized. Both malignancy and chemotherapy exposure may influence host immune milieu, yet the relative impact of specific agents such as rituximab remains unclear. We aimed to compare the probability of HBsAg loss after NUC withdrawal across three clinically relevant contexts: (1) rituximab-containing chemotherapy, (2) chemotherapy without rituximab, and (3) immune-competent non-cancer CHB.
Method: This retrospective cohort study included non-cirrhotic, HBeAg-negative CHB patients. The cancer-CHB group comprised 248 patients receiving prophylactic NUC ≥12 weeks beyond chemotherapy, categorized into non-rituximab-treated (n = 131) and rituximab-treated (n = 117) subgroups. The reference cohort included 939 patients who discontinued NUC per APASL criteria (Off-NUC cohort). Inverse probability of treatment weighting (IPTW) balanced covariates (age, sex, HBV DNA, end-of-treatment HBsAg) across groups. Cumulative HBsAg loss was compared using weighted log-rank tests.
Results: Before weighting, cancer-CHB patients were older, less often male, and had lower baseline HBV DNA than off-Nuc patients. The unadjusted 5-year cumulative HBsAg loss was 11% in the off-NUC cohort, 6% in cancer-CHB without rituximab, and 9% in rituximab-treated lymphoma-CHB ($p = 0.10$). After IPTW, the corresponding rates were 11%, 2%, and 4%, respectively ($p < 0.01$). Off-Nuc patients had a significantly higher probability of HBsAg loss than both cancer-CHB subgroups, whereas no significance was observed between cancer-CHB patients with and without rituximab exposure ($p = 0.13$). In multivariate Cox regression, EOT qHBsAg <2 $\log_{10}$ IU/mL was independently associated with HBsAg loss, while cancer-CHB status was associated with a markedly lower probability of functional cure. Rituximab exposure was not independently associated with HBsAg loss.
Conclusion: After covariate adjustment, cancer-CHB patients showed substantially lower HBsAg loss rates after Nuc withdrawal compared with immune-competent CHB patients, regardless of rituximab exposure, suggesting that malignancy-associated immune alterations may represent a major barrier to functional cure.

Email: mluetgehetmann@uke.de

Background and aims: Hepatitis D virus (HDV) RNA quantification is crucial for diagnosing HDV infection and monitoring treatment response, but access to reliable, automated assays is limited. The Cobas® HDV assay (not approved for clinical use) is a dual-target assay for use on Cobas 5800/6800/8800 systems, standardised to the WHO HDV RNA international standard. We evaluated clinical performance for detection of HDV infection and measurement of longitudinal HDV RNA titre changes in patients with chronic hepatitis D (CHD).
Method: This multicentre study tested serum and plasma samples from anti-HDV-positive patients, with/without detectable HDV RNA, using Cobas HDV and a CE-marked comparator (RoboGene HDV RNA Quantification Kit 2.0). Performance parameters, i.e., limit of detection (LOD), lower limit of quantification (LLOQ), clinical sensitivity and specificity were established across HDV genotypes; method comparison analysis was performed. In anti-HDV-treated patients, concordance between the two quantitative methods was assessed on longitudinal HDV RNA titre data; changes over time were evaluated and the proportion of responders compared for non-inferiority. Liver function was evaluated via longitudinal changes in alanine and aspartate aminotransferase (ALT and AST).
Results: Serum LOD was 9.91 IU/mL for HDV-1, 2 and 6–8; LODs were 3x higher for HDV-3, and 1.5× higher for HDV-4 and -5. Plasma LOD was 3.34 IU/mL for HDV-1, 2 and 5–8; LODs were 3× higher for HDV-3, and 1.5× higher for HDV-4. LLOQ for HDV-1 was 25 IU/mL. HDV RNA samples from 199 anti-HDV-positive patients (detectable RNA: 135; undetectable RNA: 64) were evaluated. Clinical sensitivity and specificity of Cobas HDV (95% confidence intervals [CI]) were 97.8% (93.7–99.2) and 92.2% (83.0–96.6), respectively. Cobas HDV showed good agreement in quantitative HDV RNA results with the comparator assay (mean difference: –0.005 $\log_{10}$ IU/mL [95% CI: –0.081–0.071]). Concordance was high in treated patients (100% [95% CI: 98.7–100] for quantifiable results; n = 302); both assays showed a similar decline in HDV RNA titres over time, confirming that Cobas HDV is non-inferior for patient monitoring. Mean ALT and AST values decreased markedly from visit 1 to 2, alongside the most prominent decline in HDV RNA titre.
Conclusion: Results demonstrate the utility of Cobas HDV to accurately detect and quantify HDV RNA for diagnosis and treatment monitoring. This standardised, automated assay provides benefits for diagnosing HDV infection and managing patients with CHD.

Background and aims: Knowledge on genetic diversification within the HDV ribozyme (essential for viral replication) and HDAg domains, which drive replication and harbor cytotoxic T lymphocyte epitopes (CTLEs), is limited. We investigated HDV genetic conservation in ribozyme and HDAg regions and their correlation with virological and biochemical markers.
Method: 178 individuals with chronic HDV infection were enrolled. Full-length HDV genomes were sequenced by Illumina (median [IQR] reads/patient: 69282 [38127–181165]). Genotypes (Gt) were assigned by phylogeny. Nucleotides and amino acids were considered conserved if not mutated in ≥99% of sequences. HDAg domains and CTLEs (N = 18) were defined according to Pascarella 2010 and Kohsar 2021.
Results: Individuals were 58% males, median age 51 (37–59) years, mainly Italians (ITs, 43.7%), followed by Eastern Europeans (EEs, 34.8%) and Africans (AFs, 21.5%). Median HDV-RNA and ALT were 5.4 (4.5–6.1) logIU/ml and 94 (62–151) U/L. The most prevalent Gts were 1e (57.8%) and 1c (20.8%), followed by 1b (9.5%), 1a (7.8%), 5 (2.2%), 7 (1.1%) and 6 (0.5%). Gt 1e predominated in ITs (64%, P < 0.001), 1c in EEs (81%, P < 0.001), while 1a, 1b, 5, 6, and 7 were found only in AFs. HDV ribozyme showed 100% nucleotide conservation whereas HDAg exhibited marked variability: conservation was lower in N-terminal (aa1–107) than in C-terminal domains (aa108–214, known to be crucial for HDAg activity) (14.7% vs 32.2%, P < 0.005). CTLE conservation ranged from 0% in $CTLE_{aa26-34}$ and $CTLE_{aa43-51}$ to 50% in $CTLE_{aa140-149}$. In Gt 1e, the aa conservation was significantly reduced in individuals >40 years (68.2% vs 30.8%, P < 0.0001), particularly within 6 CTLEs. The N12G mutation (median intra-patient prevalence 99%) correlated with higher ALT (101[63–152] vs 86 [69–174] U/l, P = 0.01) and was enriched in individuals with 2xULN ALT (77% vs 50%, P = 0.005), suggesting enhanced cytolytic activity. Conversely, T180A (median intra-patient prevalence 63%) correlated with lower HDV-RNA and HBsAg levels (4.9 vs 5.6 logIU/ml, P = 0.04 and 3.7 vs 3.9 logIU/ml, P = 0.03), indicating impaired viral fitness.
Conclusion: HDAg exhibits conspicuous genetic diversification, particularly in N-terminal domains and CTLEs, with progressive enrichment in older individuals, suggesting ongoing antigenic drift. Specific mutations may modulate viral fitness and HDV-driven cytolytic activity, warranting further in vitro studies. The highly conserved ribozyme represents a promising target for RNA interference-based therapeutic strategies.

SAT-609

Comparing health-related quality of life for chronic hepatitis B patients with and without treatment cessation: findings from the prospective multicentre COIN-B trial

Background and aims: Nucleos(t)ide analogues (NUC) are the current first line treatment for chronic hepatitis B (CHB). The drugs efficiently suppress viral replication, but HBV seroclearance often requires decades of continuous therapy. While NUC cessation is increasingly explored as a strategy to induce functional cure, its impact on health-related quality of life (HRQoL) is unknown. We evaluated HRQoL in patients who discontinued NUC therapy with those continuing treatment within the COIN-B trial (NCT04779970, EudraCT 2021-001003-32).
Method: This prospective multicentre study was conducted across 26 Belgian hospitals. HRQoL was assessed at baseline and at weeks 4, 12, 24, and 72, using the EQ-5D-5L with EQ-Visual Analogue Scale (VAS), and were valued using the Belgian value set. Descriptive statistics were calculated for each time point and study arm. Determinants of EQ-5D-5L utility values were explored using linear mixed-effects models with random intercepts for patients to account for within-subject correlation.
Results: A total of 146 patients were included (91 stop treatment arm; 55 control arm). Patients who discontinued NUC treatment consistently reported high mean EQ-5D-5L utility (>0.9) at all time points. Mean utilities in the control arm were slightly lower but remained

close to 0.9 throughout follow-up. Mean (SD) utilities in the stop arm were between 0.92 (0.12) at baseline and 0.94 (0.15) at week 72, which were higher than the Belgian population norm at a similar age (0.83, $p < 0.01$). EQ-VAS scores showed a similar pattern. Mixed-effects models showed lower utilities for patients in the control arm, older, female, those with more advanced fibrosis stage, other liver diseases, BMI ≥25 or <18.5, non-Caucasian race and birth or parental birth outside Belgium, but coefficients were small and not statistically significant ($p > 0.05$).

Conclusion: NUC discontinuation was associated with sustained high HRQoL. Mean utilities were consistently higher than in the control arm and significantly above age-matched population norms. This may partly reflect a highly motivated patient population and long-term coping with CHB, resulting in high self-reported health status. Importantly, these findings support the feasibility of NUC cessation strategies in appropriately selected patients and provides a robust empirical basis for future health economic evaluation.

The longitudinal impact of anti-HBe on qHBsAg decline in chronic hepatitis B

Andrew Mendlowitz[1,2,3], Sanam Tabataba Vakili[1], Leila Amiri[1], Grishma Hirode[1,2], Aaron Vanderhoff[1,2], Saima Naim[1], Harry L.A. Janssen[4], Scott K. Fung[1], Adam Gehring[1], Jordan J. Feld[1,2]. *[1]Toronto Centre for Liver Disease, University Health Network, Toronto, Canada; [2]Viral Hepatitis Care Network, University Health Network, Toronto, Canada; [3]Institute of Health Policy, Management and Evaluation, University of Toronto, Toronto, Canada; [4]Erasmus University Medical Centre, Rotterdam, Netherlands*
Email: andrew.mendlowitz@alumni.utoronto.ca

Background and aims: HBeAg loss is a well-recognized milestone in the natural history of chronic hepatitis B infection (CHB). However, the importance of anti-HBe as a marker of immune fitness or evolution of disease trajectory is less understood. Current guidelines recommend that nucleos(t)ide analogues can be stopped in patients who are anti-HBe-positive, as the probability of flares are higher in those anti-HBe-negative. Using large cohort data, we aimed to characterize the association between anti-HBe emergence and qHBsAg dynamics over time.

Method: We followed CHB patients with at least one qHBsAg measurement from their earliest HBeAg-positive date (index) until their last HBeAg status. Visits were classified relative to HBeAg loss (pre/post), with time measured from the start of the pre- or post-HbeAg loss period. Seroconversion was identified from the first positive anti-HBe test onward. We modeled qHBsAg using a linear mixed-effects model incorporating anti-HBe seroconversion and time relative to HBeAg loss, adjusting for demographics, treatment, cirrhosis and baseline qHBsAg, reporting model-adjusted levels and changes over time. The model was also applied to patients only ever HBeAg-negative, using follow-up time from first HBeAg status.

Results: From 2010 to 2022, 1,701 HBeAg-positive patients (median age 38 years; 54% male) were included, of whom 675 (40%) experienced HBeAg loss. Among these, 538 (80%) were anti-HBe-positive; 95 (18%) at index and 443 (82%) who developed anti-HBe during follow-up. Of the 443, 292 (66%) seroconverted on/after HBeAg loss, 262 (59%) within two years, with time to seroconversion ranging from immediately after HBeAg loss to 11 years afterward. Average qHBsAg declined from 2,100 IU/mL before HBeAg loss to 1,081 IU/mL after, with the rate of decline accelerating from −0.024 log IU/mL/year to −0.055 log IU/mL/year ($p < 0.001$). Average qHBsAg was 1,901 IU/mL before anti-HBe appearance and 1,195 IU/mL afterwards, with the rate of decline changing from −0.029 log IU/ml/year to −0.044 log IU/ml/year ($p < 0.001$). Baseline qHBsAg, sex, age, and cirrhosis were also significant determinants of qHbsAg in multivariable analysis. In contrast, among 6,228 always HBeAg-negative patients, 6,022 (97%) were anti-HBe-positive, and anti-HBe appearance was not significantly associated with qHBsAg level ($p = 0.67$).

Conclusion: Anti-HBe appearance was associated with lower qHBsAg levels seen with HBeAg loss but had minimal effect in those starting HBeAg-negative, suggesting plateauing over time.

SAT-611

Integrating double reflex hepatitis D virus testing to reduce diagnostic gaps and streamline clinical pathways

Almuthana Mohamed[1,2], Andrew Watson[1,2], Sara Lucas[2], Arron Jones[2], Anna Jeffery-Smith[2], Anna Riddell[2], Apostolos Koffas[1,2], Upkar Gill[1,2], Patrick Kennedy[1,2]. *[1]Blizard Institute, Barts and the London school of medicine and dentistry, Queen Mary University of London, London, United Kingdom; [2]Barts Health NHS Trust, London, United Kingdom*
Email: almuthana700@gmail.com

Background and aims: Hepatitis delta virus (HDV) remains an underdiagnosed cause of severe liver disease in patients with chronic hepatitis B (CHB). Variable testing practices can delay diagnosis and access to treatment. We implemented a double reflex testing pathway at Barts Health NHS Trust, where all hepatitis B surface antigen (HBsAg)-positive patients automatically undergo HDV antibody (HDV Ab) testing, with reflex HDV RNA testing for HDV Ab-positive cases. The aim was to accelerate HDV case-finding and streamline linkage to specialist care, including access to licensed therapy, bulevirtide (BLV), and recruitment into clinical trials of novel therapies for HDV.

Method: Double reflex HDV testing was rolled out across all sites at Barts Health NHS Trust (Royal London, Whipps Cross, Newham, and St Bartholomew's Hospitals). HBsAg-positive patients underwent reflex HDV Ab testing. HDV Ab-positive samples triggered automatic reflex HDV RNA testing, achieving ≥99% compliance. Patients with detectable HDV RNA were promptly referred to specialist hepatology services for treatment assessment, including eligibility for BLV and clinical trial enrolment.

Results: In total, 7,218 HBsAg-positive patients underwent reflex HDV Ab testing. Of those screened, 458 (6.3%) were HDV Ab positive, and 168 (2.3%) had confirmed active HDV infection with detectable HDV RNA. Demographically, the population was predominantly male (85%), of Eastern European background, with a median age of 38 years (IQR = 6). Following identification, patients were streamlined into management pathways. Currently, 48 (29%) patients are being assessed for BLV, 19 (11%) are receiving BLV, 17 (10%) are enrolled in HDV clinical trials, and 84 (50%) of newly identified HDV RNA-positive patients are either not eligible for BLV (n = 23, 14%) or awaiting specialist clinic review (n = .61, 36%). Our cohort showed no significant difference in HDV RNA reduction between patients treated with BLV and those enrolled in HDV clinical trials, matched at 6 months (P = 0.774), with follow-up ongoing.

Conclusion: Large-scale double reflex testing successfully embedded HDV detection into routine CHB care across East London, identifying substantial numbers of HDV patients, reducing delays to specialist review and access to treatment. Reflex testing has facilitated access to both licensed therapy (BLV) and clinical trials of novel agents. This approach is scalable and could serve as a model for wider NHS adoption to improve access to HDV diagnosis and treatment nationally.

Hepatitis B virus outcomes in people with HIV after cessation of tenofovir-containing antiretroviral therapy: a systematic review and meta-analysis

Amir Mohareb[1], Bonolo Phinius[2], Motswedi Anderson[2], Shahin Lockman[2], Julie Bottero[3], George Yendewa[4], Arthur Kim[1], Anders Boyd[5]. [1]*Massachusetts General Hospital, Harvard Medical School, Boston, United States;* [2]*Botswana Harvard Health Partnership, Gaborone, Botswana;* [3]*National Public Health Establishment of Fresnes, Fresnes, France;* [4]*Case Western Reserve University, Cleveland, United States;* [5]*Inselspital, Bern University Hospital, Bern, Switzerland*
Email: amohareb@mgh.harvard.edu

Background and aims: Anti-retroviral therapy (ART) regimens without tenofovir are being used more frequently in people living with HIV. Tenofovir cessation has risks related to hepatitis B virus (HBV) infection. We aimed to determine the HBV outcomes in people with HIV who discontinue tenofovir-containing ART.
Method: We conducted a systematic review and meta-analysis by searching Medline, Google Scholar, and the Cochrane database for studies related to tenofovir cessation in people with HIV and three different HBV serologic profiles: (1) active HBV: positive HBV surface antigen (HBsAg); (2) resolved HBV: positive HBV core antibody (HBcAb) without HBsAg; and (3) susceptibility to HBV: negative HBsAg, HBcAb, and HBV surface antibody. We used a random effects model to calculate the pooled incidence rate of HBV reactivation (in resolved HBV) or new HBV infection (in those susceptible to HBV) after tenofovir cessation. We used meta-regression to compare pooled outcomes across subgroups.
Results: Of 116 abstracts and articles, 39 underwent full-text review and 17 observational studies were included. In seven studies of active HBV infection, only descriptive data could be retrieved: HBV DNA increase or hepatitis flares did occur after tenofovir cessation or interruption. In nine observational studies of resolved HBV infection, pooled incidence of HBV reactivation was 0.97 per 100 person-years (95% confidence interval (CI) = 0.31–3.06; I^2 = 95.2%). HBV reactivation was 4.23 per 100 person-years (95% CI = 1.90–9.41) in prospective compared with 0.24 per 100 person-years (95% CI = 0.18–0.31) in retrospective studies ($p < 0.001$). Five observational studies reported new HBV infection in susceptible people following transition to tenofovir-sparing ART (pooled incidence = 2.05 per 100 person-years, 95%CI = 0.23–18.45; I^2 = 83.5%).
Conclusion: In people with HIV, tenofovir-sparing ART is associated with risks related to HBV infection. Clinicians using tenofovir-sparing ART should screen for HBV serologic markers, vaccinate against HBV, and monitor for reactivation. Higher quality and larger prospective studies are needed in people with HIV and resolved HBV who stop tenofovir.

Background and aims: Hepatitis B (HBV) is a major cause of hepatocellular carcinoma (HCC) in Australia, despite availability of subsidised treatment that reduces HCC risk. We aimed to describe the cascade of care and clinical characteristics among people with HBV-related HCC.
Method: We conducted a retrospective and prospective cohort study of all HCC cases diagnosed across six tertiary health networks in Melbourne. Bi-variable analysis was performed using chi square test. Multivariable logistic regression modelling was used to determine variables associated with HBV treatment and surveillance uptake. Cox proportional hazards modelling was used to identify variables associated with survival from HCC diagnosis.
Results: 1203 incident HCC cases were identified, of which 219 were due to HBV. Most people with incident HBV-HCC were male(89%) and of Asian ethnicity(60%). Compared to people with HCC due to other aetiologies, people with HBV-related HCC were more likely to have a family history of HCC. 60% of people with HBV-HCC were eligible for HBV treatment at the time of HCC diagnosis, yet 27% were not on treatment. 85% of those referred by specialist hepatology services were enrolled in surveillance compared to 16% among those referred by primary care and non-liver specialists. Median survival from time of HCC diagnosis was longer among those with HBV compared to non-HBV HCC. On multivariable analysis, factors associated with greater mortality were low performance status, alcohol misuse and advanced BCLC stage at diagnosis. Attending a liver specialist service, being enrolled in surveillance and being on HBV treatment were all associated with early BCLC stage HCC at diagnosis.
Conclusion: HBV-related HCC incidence is reducing in Australia, however a significant proportion of people with HBV-related HCC are not receiving guideline-based care. Greater investment in non-specialist health-worker education and training in HBV care, coupled with a national registry approach to HCC surveillance are urgently needed.

SAT-617

Development of a new model for identifying HBV-related pre-ACLF patients among those with progressive total hyperbilirubinemia

Yuhang Nie[1], Dachuan Cai[1]. [1]*Department of Infectious Diseases, Key Laboratory of Molecular Biology for Infectious Diseases (Ministry of Education), Institute for Viral Hepatitis, The Second Affiliated Hospital, Chongqing Medical University, Chongqing, China*
Email: Komori0g0@outlook.com

Background and aims: The concept of "pre-acute-on-chronic liver failure (Pre-ACLF)" was proposed to describe a transitional stage before patients progress to full ACLF. Early intervention at this stage can significantly improve prognosis. However, the clinical characteristics of Pre-ACLF remain insufficiently understood, and accurately identifying these patients is challenging. This study aimed to analyze the biochemical indicators and disease progression in Pre-ACLF patients to clarify their clinical features and establish a diagnostic model for their identification.
Method: A retrospective analysis was conducted on 214 hospitalized chronic hepatitis B (CHB) patients who experienced significant clinical deterioration. Their clinical characteristics and progression were analyzed. Multivariate logistic regression was used to identify independent risk factors for progression to ACLF, based on which a diagnostic scoring model was developed.
Results: Among the 214 CHB patients with significant deterioration, the majority were male (79.0%). 58.9% had underlying cirrhosis, and among these cirrhotic patients, 48.4% experienced acute decompensation events, primarily ascites (78.7%). Analysis of disease progression revealed that 48.1% of patients progressed to ACLF within 28 days, defining them as Pre-ACLF patients. The main triggers for progression were untreated high viral load (55.3%), drug withdrawal leading to viral rebound (27.2%), and acute decompensation events (9.7%). Among 148 patients with persistently elevated bilirubin, 39.2% progressed to ACLF within 28 days. Multivariate LASSO-Logistic regression analysis identified Prothrombin Activity (PTA), the rate of change in PTA (VΔPTA), and the rate of change in TB (VΔTB) as

independent risk factors for disease progression. A new diagnostic model was constructed: logit(P) = 1.8303–0.0630 * PTA–0.8821 * VΔPTA + 0.0801 * VΔTB. Patients with a logit(P) score > 0.39 had a higher risk of progressing to ACLF. The model showed an AUC of 0.889 (95% CI: 0.837∼0.941). The calibration curve indicated good model calibration. Decision Curve Analysis (DCA) suggested that the model provided high clinical net benefit across a wide range of threshold probabilities (0∼75%).

Conclusion: The newly developed model can accurately identify Pre-ACLF patients among those with persistently elevated bilirubin, providing evidence-based support for early clinical diagnosis and intervention.

Email: mariabutiferret@gmail.com

Background and aims: Despite treatment guidance, advances in antiviral therapy and the World Health Organization's 2030 target of viral hepatitis elimination, HBV and HDV remain major global public health challenges. Knowledge gaps among providers may hinder the elimination efforts. We aimed to assess provider knowledge, confidence, and management practices for HBV and HDV.

Method: An international panel of experts from the Global Liver Council (GLC) developed a 37-item, anonymous, online survey to evaluate providers' knowledge and clinical practice patterns in managing HBV and HDV.

Results: A total of 611 clinicians [hepatologists/gastroenterologists (Hep/GI 68%), infectious disease (ID 11.5%), and other specialties (20.5%] participated in the survey from June-September 2025. Self-reported adequate or superior HBV knowledge was highest (93%) among Hep/GI followed by ID (78%) and others (56%), $p < 0.001$, with corresponding differences in confidence. European Association for the Study of the Liver guidelines were most frequently followed (46%). Overall, 81% initiated HBV treatment for HBV DNA >2,000 IU/mL, either with elevated ALT (66%) or regardless of ALT (14%). Liver disease severity was mainly assessed using non-invasive tests (45%). Use of liver biopsy for assessment of liver disease severity and decisions on treatment was used infrequently (1%) except for patients in the grey zone (50%). Hep/GI clinicians were more likely to initiate therapy at low HBV DNA levels (<2,000 IU/mL) in the presence of increased liver stiffness (≥8 kPa) ($p < 0.01$). Routine HDV screening of all HBsAg (+) was reported by 46% including reflex testing in 5%.

Nearly all respondents performed HCC surveillance in all (48.5%) or high risk (50.6%) HBsAg (+) patients, most commonly using ultrasound and serum tumor markers (93%). Most respondents (65.9%) would initiate therapy in HBsAg (+) patients during early pregnancy or prior to conception, preferentially using tenofovir disoproxil fumarate (77%). Treatment of HBsAg (+) with normal ALT and high HBV DNA was limited to selected cases by 48% while 26% would treat all and 26% would treat none. Treatment of all HDV patients regardless of fibrosis stage was selected by 81% of participants; bulevirtide (37%), pegylated interferon-α (37%) and both (11%).

Conclusion: Despite overall guideline alignment, substantial variability in HBV and HDV screening and management persist, highlighting that social, infrastructural and awareness barriers remain.

SAT-619

High burden of active HDV infection and broad genetic diversity of HDV in Cameroon: insights from molecular diagnostics and whole-genome sequencing

Lorenzo Piermatteo[1], Eugenie Lebomo Etogo[2], Cindy Lobe[3], Alessia Magnapera[1], Luca Carioti[4], Lavinia Fabeni[5], Giulia Torre[1], Ilaria Grossi[1], Stefano D'Anna[1], Guy Pascal Ngaba[6], Emilia Lyonga[2], Francesca Ceccherini Silberstein[4], Romina Salpini[1], Judith Torimiro[7], Valentina Svicher[1]. *[1]Department of Biology, University of Rome Tor Vergata, Rome, Italy; [2]Department of Microbiology, Virology, Parasitology, Hematology and Infectious Diseases, Faculty of Medicine and Biomedical Sciences, University of Yaounde I, Yaounde, Cameroon; [3]Department of Biomedical Sciences, Faculty of Sciences, University of Ngaoundere, Ngaoundere, Cameroon; [4]Department of Experimental Medicine, University of Rome Tor Vergata, Rome, Italy; [5]Laboratory of Virology and Laboratories of Biosafety, National Institute for Infectious Diseases Lazzaro Spallanzani-IRCCS, Rome, Italy; [6]Department of Microbiology, Faculty of Medicine and Pharmaceutical Sciences, University of Douala, Douala, Cameroon; [7]Department of Biochemistry, Faculty of Medicine and Biomedical Sciences, University of Yaounde I, Yaounde, Cameroon*

Email: lorenzo.piermatteo@uniroma2.it

Background and aims: Cameroon is endemic for HBV infection. However, limited data are available on epidemiology, genetic diversity and accurate diagnosis of HDV infection.

Method: We conducted a cross sectional study on 117 HBsAg+ patients from two hospitals in Cameroon, and 42 patients with an already known anti-HDV positivity. For the 117 HBsAg+ patients, anti-HDV was performed using the Diasorin Liaison XL analyser. HDV-RNA was tested by two different assays: RoboGene HDV-RNA quantification kit v3.0 using the Felix automated extraction instrument (LOD <6 IU/ml) and the fully automated Altostar platform for extraction and HDV RT-PCR v1.5 (LOD 1.12 IU/ml). Whole genome HDV sequencing was assessed on Illumina MiSeq. The correlation between HDV-RNA values by Robogene and Altostar assays was assessed by Spearmann test.

Results: Overall, 21/117 (18%) patients were positive to anti-HDV, highlighting a high rate of HDV seroprevalence. The percentage of anti-HDV positive patients ranged from 15.1% (11/73) in the Littoral region up to 22.7% (10/44) in the East region, highlighting local hotspot with high HDV endemicity. HDV-RNA was tested in the 21 newly diagnosed patients and in the 42 with previously known anti-HDV positivity for a total of 63 patients. Among them, 61% had detectable HDV-RNA by Robogene (median [IQR]:5.4 [3.3–6.0]logIU/ml), supporting a conspiscous circulation of active HDV infection with an intense HDV replication. Overall, HDV-RNA quantification by Robogene and Altostar showed a high degree of correlation (Rho = 0.91). Such degree of correlation was reduced for HDV-RNA values ≥5logIU/ml (Rho = 0.82 for HDV-RNA ≥5logIU/ml vs Rho = 0.99 for HDV-RNA <5logIU/ml). Among the 38 samples with HDV-RNA >1000IU/ml by Robogene, 26 were successfully sequenced. Phylogenetic analysis revealed the circulation of a large variety of HDV genotypes/subgenotypes with subgenotype 1b being the most frequent (61.5%), followed by 1a (19.3%), genotype 7 (7.8%), genotype 6, 5 and 1e present in 3.8% of patients each. The correlation between HDV-RNA quantification by Robogene and Altostar was very high in all identified genotypes/subgenotypes with a slight decrease in 1b (Rho = 0.96 for genotypes/sub-genotypes other than 1b and 0.82 for 1b.

Conclusion: These findings show a significant burden of active HDV infection in Cameroon, thus highlighting the urgent need of developing accessible and affordable diagnostic algorithms and surveillance tools for HDV infection in Cameroon to reduce HDV-associated morbidity.

Background and aims: Metabolic dysfunction-associated steatotic liver disease (MASLD) and chronic hepatitis B virus (HBV) infection are among the most common liver diseases worldwide. This study aimed to characterize the relationship between HBV infection and MASLD in the general population.
Method: This study enrolled participants from the general population of six centers in China, who underwent standardized liver health examinations, including transient elastography for hepatic steatosis, serological testing for HBV infection, and assessment of metabolic risk factors. Multivariable logistic regression models were applied to evaluate the independent association of HBV infection with MASLD, and stratified analyses were conducted to examine whether this association varied across demographic and metabolic subgroups. In addition, we assessed the effects of HBV infection and MASLD on liver fibrosis risk, and further evaluated the association of HBV infection with fibrosis specifically within MASLD.
Results: A total of 10,418 participants were included in the final analysis, of whom 400 (3.84%) were HBsAg-positive. MASLD was diagnosed in 4,256 individuals (40.85%), including 139 participants (1.33%) with concurrent HBV infection. The prevalence of MASLD was significantly lower in HBV-positive individuals than in HBV-negative controls (34.75% vs. 41.10%, p = 0.013). This inverse association was consistently observed across sex, age, and BMI categories. After multivariable adjustment, HBV infection was independently associated with a lower risk of MASLD (adjusted odds ratio [aOR] = 0.63, 95% CI: 0.49–0.81, p < 0.001), while both HBV and MASLD showed significant effects on liver fibrosis. Notably, HBV infection showed a stronger independent association with significant liver fibrosis, and this elevated fibrotic risk persisted even among individuals with MASLD (aOR = 2.51, 95% CI: 1.72–3.56, p < 0.001).
Conclusion: HBV infection was associated with a lower risk of MASLD but independently increased the risk of liver fibrosis, even among individuals with MASLD, underscoring the need for careful monitoring in populations with coexisting HBV and metabolic liver disease.

SAT-621

A pilot study on hepatitis b core related antigen (HBCRAG) as novel marker for monitoring anti-viral therapy in chronic hepatitis B patients

Pravinkumar Rejliwal[1], Premashis Kar[1], Natasha Dhingra[2]. *[1]Max Super-Specialty Hospital Vaishali, Maulana Azad Medical College New Delhi, Ghaziabad, India; [2]Medanta, Gurugram, India*
Email: pk.rejliwal@gmail.com

Background and aims: Chronic Hepatitis B (CHB) patients on long-term nucleos(t)ide analogue (NA) therapy often achieve virological suppression, but relapse after treatment cessation remains a challenge due to persistent intrahepatic cccDNA activity. Hepatitis B core–related antigen (HBcrAg) reflects cccDNA transcriptional activity and may complement HBV DNA in predicting post-treatment outcomes. This study evaluated the role of HBcrAg, alongside HBV DNA, in monitoring patients undergoing NA discontinuation and in identifying relapse during off-therapy follow-up.
Method: This prospective pilot study included 59 adults with CHB (HBeAg-positive and negative) on long-term follow-up at a tertiary liver clinic. Eligible patients had received ≥4 years of NA therapy (entecavir, TDF, or TAF), had no cirrhosis, and achieved undetectable HBV DNA at end-of-therapy. Baseline assessment included clinical profile, liver biochemistry, and HBV serology. HBV DNA was quantified by real-time PCR (LOD 2000 IU/mL), and HBcrAg was measured at treatment completion and during follow-up using an ELISA-based antigen assay. Patients with concurrent HBV DNA and HBcrAg negativity were enrolled into off-therapy monitoring and followed for 6–12 months at 3-monthly intervals. Relapse was defined as HBV DNA >2000 IU/mL, HBcrAg positivity, and/or ALT/AST >1.5 × ULN with viral reactivation; relapsed patients were restarted on NA therapy.
Results: Among 59 patients (mean age 35.9 years; 45 males), 10 (16.9%) were HBeAg-positive and 49 (83.1%) HBeAg-negative. Following NA cessation in eligible patients with dual biomarker negativity, most maintained sustained virological and biochemical remission. Relapse occurred in 3 patients (5.1%), all showing re-positivity of both HBV DNA and HBcrAg with associated ALT rise, requiring therapy re-initiation. End-of-therapy HBcrAg negativity correlated strongly with sustained remission across both HBeAg subgroups.
Conclusion: Dual HBV DNA and HBcrAg negativity at treatment cessation was associated with a high likelihood of sustained remission after NA withdrawal, whereas relapse was linked to re-elevation of both markers. HBcrAg provides incremental value beyond HBV DNA in post-therapy risk stratification and may

support biomarker-guided treatment-stop strategies. Larger prospective studies are needed to validate these findings and refine HBcrAg-based clinical decision pathways.

Email: lasse.rossvoll@gmail.com

Background and aims: Chronic hepatitis B (CHB) infection usually requires long-term monitoring. However, previous studies have shown high rates of loss to follow-up (LTFU) in CHB care. We aimed to identify predictors of LTFU in a large real-life CHB cohort study in Ethiopia.
Method: A prospective CHB cohort was established at four public hospitals in Ethiopia in 2021/22. HIV-negative adults with CHB were enrolled and simplified treatment criteria applied, based on clinical assessment and available blood tests. All individuals were scheduled for an initial 3-month follow-up; subsequent visits were scheduled every 6 months for individuals who were initiated on treatment and annually for non-treated individuals. In the present analysis the primary outcome was LTFU, defined as no clinical contact within the past 15 months. Kaplan-Meier method was applied to estimate probability of LTFU over time, and Cox regression models allowing for time-varying effects were used to identify predictors of LTFU.
Results: A total of 6,034 patients (median age 30 years; 49.1% female) were enrolled between December 2021 and December 2023, of whom 1,680 (27.8%) fulfilled the treatment criteria and were started on tenofovir disoproxil at baseline. The median follow-up time was 11.8 months (IQR 0.1–24.5). At data extraction, 3,303 (54.7%) patients were classified as LTFU, 2,203 (36.5%) remained in care, 202 (3.3%) had died, 189 (3.1%) had been transferred out and 137 (2.3%) had withdrawn from the study. The estimated probability of LTFU after 3, 12 and 24 months was 36.9% (95% CI 35.6–38.1), 48.2% (95% CI 46.9–49.4) and 55.7% (95% CI 54.4–56.9), respectively. Independent predictors of LTFU were younger age (18–25 compared to > 35 years; adjusted hazard ratio [AHR] 1.26; 95% CI 1.16–1.38), decompensated cirrhosis (AHR 1.20; 95% CI 1.03–1.40), not receiving treatment (AHR 1.51; 95% CI 1.37–1.66) and greater distance to clinic, which was strongly associated with early LTFU (≤ 90 days; per 10 km increase; AHR 1.06; 95% CI 1.06–1.06) but attenuated over time (p for interaction < 0.001).
Conclusion: The probability of LTFU was high, particularly early after enrolment. Not receiving treatment and greater distance to clinic was associated with higher probability of LTFU. More inclusive treatment criteria and decentralization of care can be impactful interventions to reduce attrition.

Quantitative HBsAg identifies individuals unlikely to achieve spontaneous functional cure of chronic hepatitis B

Juan Carlos Ruiz-Cobo[1], Ariadna Rando-Segura[2], Elena Vargas-Accarino[3], Javier Pérez Garreta[2], Judit Vico Romero[4], Adriana Palom[3], David Tabernero[5,6], Maria Francesca Cortese[2], Mar Riveiro Barciela[1], Maria Buti[1]. *[1]Liver Unit, Vall d'Hebron University Hospital, Barcelona, Departament de Medicina, Universitat Autònoma de Barcelona, Barcelona, Centro De Investigación Biomédica En Red De Enfermedades Hepáticas y Digestivas (CIBERehd), Barcelona, Spain; [2]Microbiology Department, Vall d'Hebron University Hospital, Barcelona, Barcelona, Spain; [3]Vall d'hebron Research Institute (VHIR), Barcelona, Centro De Investigación Biomédica En Red De Enfermedades Hepáticas y Digestivas (CIBERehd), Barcelona, Spain; [4]Vall d'hebron Research Institute (VHIR), Barcelona, Departament d'Infermeria i Salut, Universitat de Barcelona, Barcelona, Barcelona, Spain; [5]Microbiology Department, Vall d'Hebron University Hospital, Barcelona, Centro De Investigación Biomédica En Red De Enfermedades Hepáticas y Digestivas (CIBERehd), Barcelona, Spain; [6]Instituto de Salud Carlos III, Centro de Investigación Biomédica en Red de Enfermedades Hepáticas y Digestivas (CIBERehd), Madrid, Spain*
Email: juancarlosrcobo@gmail.com

Background and aims: Loss of hepatitis B surface antigen (HBsAg) is the closest outcome to a functional cure in chronic hepatitis B (CHB), but it is rarely achieved. Quantitative HBsAg reflects the transcriptional activity of HBV and may identify patients with a low likelihood of HBsAg clearance. We aimed to analyze qHBsAg levels in patients with chronic HBV infection and to estimate the proportion potentially eligible for novel therapies.
Method: We conducted a retrospective, longitudinal cohort study of patients with HBV infection (chronic infection (CI) or chronic hepatitis (CH), HBeAg-positive or -negative) with a follow-up of ≥1 year. Patients with hepatic decompensation prior to the start of follow-up were excluded. HBsAg was quantified using a chemiluminescent immunoassay (CLIA; LLQ 0.05 IU/mL).
Results: A total of 929 patients were included; 61% were male, with a median age of 47 years (IQR 36–58) and a median follow-up of 5.1 years (IQR 2.9–8.0). Ethnicity distribution was 58% Caucasian, 17% African, 12% Asian, 7% Latin American, and 5% Middle Eastern/North African. Compensated cirrhosis was present in 6% of patients. At baseline, median qHBsAg was 1,808 IU/mL (IQR 250–8,128), and 59% (552/929) had qHBsAg >1,000 IU/mL. Regarding infection phase at baseline, most patients had HBeAg-negative CI (73%) or HBeAg-negative CH (21%). During follow-up, 86 patients (9%) achieved HBsAg loss. This occured in 21% (81/377) with baseline qHBsAg ≤1,000 IU/mL compared with 0.9% (5/552) among those with qHBsAg >1,000 IU/mL. Most cases ocurred in HBeAg-negative CI (86%), with an HBsAg loss rate of 11% (74/676), similar to HBeAg-positive CH (11%; 5/46), and higher than in HBeAg-negative CH(3.5%; 7/199) or HBeAg-positive CI (0/8). In addition, 27/54 patients (50%) achieved HBeAg seroconversion. At the end of follow-up, 843 patients remained HBsAg-positive. Of these, 234 (28%) were classified as CH and were receiving nucleos(t)ide analogue therapy; among them, 118/234 (50%) had qHBsAg levels >1,000 IU/mL.
Conclusion: In this large real-world cohort, more than half of patients with chronic HBV infection had high baseline qHBsAg levels and a very low probability of spontaneous HBsAg loss. Patients with HBeAg-negative chronic hepatitis were also unlikely to achieve HBsAg loss. These findings suggest a large proportion of patients could be candidates for novel therapies aimed to achieve functional cure, which is unlikely to occur spontaneously.

SAT-624

Comorbid hepatic steatosis among people with HBV monoinfection and HBV/HIV coinfection in the hepatitis B in Africa collaborative network (HEPSANET): prevalence, predictors, and association with fibrosis

Email: michael.vinikoor@cidrz.org

Background and aims: Metabolic dysfunction-associated steatotic liver disease (MASLD) is an important comorbidity of hepatitis B virus (HBV) infection; however, data are very limited in the Africa region, where 5% of adults have chronic HBV.
Method: We analyzed data from the Hepatitis B in Africa Collaborative Network (HEPSANET), a collaboration of leading HBV clinical and research cohorts. Adults (>18 years) with chronic HBV monoinfection ('HBV alone') and HBV/HIV coinfection ('HBV/HIV') were analyzed if they underwent transient elastography with controlled attenuated parameter (CAP; Fibroscan; Echosens) at least once. We excluded participants with hepatitis C/D. Stratified by HIV status, we described the prevalence of mild/moderate steatosis (grade 1/2; CAP 248–279 dB/ml) and severe steatosis (grade 3; CAP ≥280 dB/m). With logistic regression, we examined correlates of any steatosis grade including demographic factors (age, sex, education, country) and body mass index (BMI), and assessed the association between steatosis and significant hepatic fibrosis (defined as liver stiffness ≥7 kPa), adjusting for confounders.
Results: 1436 participants (1113 with HBV alone and 323 with HBV/HIV) from 6 countries (Burkina Faso, Egypt, Nigeria, Senegal, South Africa, and Zambia) had a CAP measurement, representing 11.1% of HEPSANET. Their median age was 42 years, 37% were female, 53% had college education, 32% were overweight (BMI 25–30), and 16% had obesity (BMI >30). Steatosis was present in 345 (31.0%) participants with HBV alone (175 [15.7%] severe) and in 38 (11.7%) participants with HBV/HIV (21 [6.5%] severe). Obesity was associated with steatosis in HBV alone (adjusted odds ratio [AOR], 6.9; 95% confidence interval [CI], 4.7–10.2) and in HBV/HIV (AOR, 4.3; 95% CI, 1.3–12.8). Additionally, in HBV alone, increasing age, male sex, overweight, and secondary education (vs. none-primary) were also associated with steatosis (all P < 0.05). Severe steatosis (vs. none) was associated with significant fibrosis in HBV/HIV (AOR, 3.9; 95% CI, 1.6–9.7); a similar but attenuated association was seen in HBV alone (AOR, 1.44; 95% CI, 0.97–2.14).
Conclusion: MASLD was common among individuals with HBV alone and HBV/HIV and strongly associated with obesity, an increasing problem in Africa. The association between severe steatosis and liver fibrosis, particularly in HBV/HIV, supports integrating metabolic risk screening and targeted interventions into HBV clinical care across Africa.

SAT-625

Surveillance threshold and risk stratification of hepatocellular carcinoma by prediction model in Asian patients receiving antiviral treatment for chronic hepatitis B: a nationwide population-based cohort study

Won Sohn[1], Danbee Kang[2], Ju-Yeon Cho[3], Jung Hee Kim[4], Yong Han Paik[5]. *[1]Kangbuk Samsung Hospital, Sungkyunkwan University School of Medicine, Seoul, Korea, Rep. of South; [2]Sungkyunkwan University, Seoul, Korea, Rep. of South; [3]Saint Louis University, Seoul, Korea, Rep. of South; [4]Hallym University Dongtan Sacred Heart Hospital, Seoul, Korea, Rep. of South; [5]Samsung Medical Center, Seoul, Korea, Rep. of South*
Email: hand0827@naver.com

Background and aims: Despite the use of antiviral agents, the risk of hepatocellular carcinoma (HCC) still remained in chronic hepatitis B (CHB). It is important to determine a high-risk group for HCC development in CHB. This study aimed to investigate the annual incidence rate of HCC corresponding survival thresholds and risk stratification of HCC by prediction risk score in CHB patients receiving antiviral treatment.
Method: A nationwide population-based cohort study comprised 199,413 CHB patients receiving antiviral treatment from the Korean National Health Insurance Service between 2012 and 2023. The difference in annual incidence rates of HCC was compared in the low-risk (n = 125,935), intermediate-risk (n = 57,961), and high-risk (n = 15,517) groups by HCC-RESCUE score. Also, we calculated HCC-RESCUE scores corresponding to surveillance thresholds in CHB (0.2%, 1.5%, and 3.0%).
Results: The mean age was 47.2 years. The proportion of male sex was 61.8%. During a median follow-up of 7.3 years (interquartile range, 3.9–10.3 years), 15,233 patients developed HCC. The annual incidence rates were 0.31%, 1.09%, and 1.856% in the low-risk, intermediate-risk, and high-risk groups, respectively. After multivariable adjustment, the risk of HCC was higher in the intermediate- (hazard ratio [HR] 3.48, 95% confidence interval [CI] 3.35–3.61), and high-risk groups (HR 5.90, 95% CI 5.62–6.19) compared with the low-risk group (p < 0.001). The HCC-RESCUE scores corresponding 0.2%, 1.5%, and 3.0% of the annual incidence rates were 47, 66, and 90.
Conclusion: The prediction risk score is useful to stratify the risk of HCC in CHB patients receiving antiviral treatment. Also, the prediction score-based approach considering the annual incidence rate of HCC corresponding survival thresholds is helpful to optimize surveillance strategies in Asian patients with CHB.

SAT-626

HBcrAg as a multifaceted biomarker in chronic hepatitis B: Implications for immune activity and HCC prediction

Myeong Jun Song[1], Kwon Yong Tak[1], Seok-Hwan Kim[1]. *[1]Internal medicine, The College of Medicine, The Catholic University of Korea, Seoul, Korea, Rep. of South*
Email: mjsong95@gmail.com

Background and aims: Hepatitis B core-related antigen (HBcrAg) is a promising biomarker reflecting intrahepatic cccDNA activity. While quantitative HBsAg (qHBsAg) and HBV DNA are traditional markers, their utility in stratifying indeterminate phases or predicting hepatocellular carcinoma (HCC) under antiviral suppression can be limited. This study evaluated the clinical utility of HBcrAg, measured by a high-sensitivity assay, in classifying immune phases and predicting HCC in patients with chronic hepatitis B (CHB), with a specific focus on comparing its performance against qHBsAg.
Method: This retrospective study included 284 CHB patients. HBcrAg levels were measured using the iTACT-HBcrAg assay, and qHBsAg by electrochemiluminescence immunoassay. Patients were classified into immune phases (Immune Active [IA], Immune Tolerant [IT], Immune Inactive [II]) according to HBV guidelines. The diagnostic performance for phase classification and HCC prediction was assessed using area under the receiver operating characteristic (AUROC) curves. Correlations with host factors, including age and liver fibrosis, were also analyzed.
Results: HBcrAg levels differed significantly among immune phases, demonstrating superior discriminatory power compared to qHBsAg and HBV DNA. HBcrAg effectively distinguished HBeAg-positive IA from IT (AUC 0.97, cut-off 3.3 LogU/mL) and HBeAg-negative IA from II (AUC 0.83, cut-off 2.6 LogU/mL). In contrast, qHBsAg and HBV DNA showed poor discriminatory value (AUCs <0.55) for these differentiations. Regarding HCC prediction, HBcrAg was the only significant predictor among viral markers. In HBeAg-negative IA patients, a cut-off of 3.8 LogU/mL was associated with higher HCC prevalence (AUC 0.69). Notably, in the HBeAg-negative II phase, low HBcrAg (<3.8 LogU/mL) was universally associated with the absence of HCC (AUC

1.00, NPV 100%). In HBeAg-positive IA patients, the optimal threshold was 4.9 LogU/mL (AUC 0.71). Age showed a significant inverse correlation with HBcrAg ($r = -0.31$, $p < 0.0001$), consistent with immune senescence. However, liver fibrosis severity did not correlate with HBcrAg levels.
Conclusion: HBcrAg outperforms qHBsAg in distinguishing CHB immune phases and stratifying HCC risk. Despite age-related decline, elevated thresholds remain predictive of HCC. HBcrAg identifies high-risk immune-active patients and reliably excludes HCC risk in inactive carriers, offering prognostic insights beyond traditional markers.

Are hepatitis B vaccination programmes in Africa visible to healthcare workers?

Wendy Spearman[1], Manal El-Sayed[2], Karin Siebelt[3], Maria Buti[4].
[1]University Of Cape Town, Cape Town, South Africa; [2]Ain Shams University, Cairo, Egypt; [3]Academic Medical Education, Amsterdam, Netherlands; [4]Hospital Universitari Valle Hebron, Barcelona, Barcelona, Spain
Email: wendy.spearman@uct.ac.za

Background and aims: Hepatitis B affects an estimated 65 million people in Africa. Vaccination, particularly the hepatitis B birth dose (HB-BD), together with vaccination of adolescents and high-risk groups, is central to elimination strategies. Effective implementation relies on healthcare workers (HCWs) being aware of national vaccination policies. We assessed healthcare workers' knowledge of hepatitis B vaccination programmes across Africa and compared awareness of HB-BD implementation with WHO/UNICEF data.
Method: A brief, two-item web-based survey on preventive hepatitis B vaccination programmes was distributed through the Society on Liver Disease in Africa (SOLDA) network. Responses from countries with more than five participants were analysed.
Results: A total of 292 HCWs from 19 African countries participated. Awareness of HB-BD vaccination programmes varied widely between countries. Knowledge of an existing HB-BD programme was high in Burkina Faso and Côte d'Ivoire (100%) and Nigeria (91%) but substantially lower in Zambia (36%). Awareness that HB-BD is provided universally to all newborns ranged from 29% in Zambia to 100% in Burkina Faso and Côte d'Ivoire. Knowledge of hepatitis B vaccination programmes for adolescents was consistently low across all regions, with no awareness of programs reported in several countries (Malawi, Cameroon, South Africa and Zimbabwe), and reaching only 27% in Egypt. Awareness of vaccination programmes for at-risk populations (including HCWs, people living with HIV and household contacts) was highly variable, ranging from 0% in Mozambique and Senegal to 100% in Malawi. In contrast, WHO/UNICEF data indicate that HB-BD vaccination is universally implemented in almost all African countries that have adopted this strategy, except Mauritius and South Africa, where targeted approaches are used.
Conclusion: Despite widespread implementation of HB-BD vaccination in Africa, substantial gaps exist in HCWs' awareness of vaccination strategies, particularly for adolescents and high-risk groups. This disconnect between policy and frontline knowledge may hinder hepatitis B elimination efforts. Strengthening communication and training on national vaccination programmes should be prioritised. GAVI support for HB-BD vaccination in low and middle income countries is essential.

SAT-628-YI

Long-term risk of hepatocellular carcinoma in strictly defined immune tolerant patients with chronic hepatitis B - Results from the global RADICAL consortium

Background and aims: Patients with immune tolerant (IT) chronic hepatitis B (CHB), also referred to as HBeAg+ chronic infection, have a high viral load and both minimal inflammation and fibrosis. However, there is conflicting evidence regarding the risk of hepatocellular carcinoma (HCC). Therefore, we studied the risk of HCC in strictly defined IT patients and compared this to HBeAg+ treated CHB patients.
Method: Within the RADICAL consortium we studied a large cohort of mono-infected CHB patients from 13 sites around the globe. The IT-phase was strictly defined as HBeAg+, ALT≤40 U/L and HBV DNA >7 log IU/mL persistent during the 1st year after baseline (BL), the 1st clinic visit at investigational site. The control group included non-cirrhotic HBeAg+ CHB patients (ALT>40 U/L) treated with NUCs, with BL defined as therapy initiation. Cumulative HCC incidences with confidence intervals were estimated with the KM method. IT patients were censored 1 year after start of therapy. A sensitivity analysis was performed restricted to HCC during the IT phase, also censored for transition out of the IT phase, i.e. HBeAg loss, ALT>40 U/L or HBV DNA ≤7 logIU/mL.
Results: In total, 951 IT patients and 891 treated patients were included. IT patients were more often female (61 vs. 35%,$p < 0.001$), younger (33 vs. 37 years,$p < 0.001$), had lower ALT (26 vs. 140 U/L,$p < 0.001$), and higher HBV DNA levels (8.4 vs. 8 logIU/mL, $p < 0.001$) at BL. IT patients were followed for a median of 13 (IQR 9–17) years, compared to 7 (4–13) years in the treated group. In total, 8/951 IT patients developed HCC, compared to 21/891 patients in the treated group. The median age at HCC diagnosis was 41 (37–54) years in IT patients vs. 55 (50–62) years in treated CHB. The 5-, 10-, and 15-year cumulative incidences of HCC in IT patients were 0.5% (0–0.9%), 0.7% (0.1–1.1%), and 1.1% (0.1–2%) compared to 1.3% (0.5–2.1%), 2.9% (1.5–4.3%), and 3.5% (1.9–5.1%) in the treated cohort (HR:2.91, 95%CI 1.29–6.58,$p = 0.010$). Due to low event rates an appropriate multivariable analysis was not performed. Of the 8 IT patients with HCC, 4 patients developed HCC after transitioning out of the IT phase (age at diagnosis: 54 [IQR 45–57]), and 4 while persistently in the IT phase

(age at diagnosis: 38 [36–41]). The 15-year cumulative incidence of HCC during the IT phase was 0.5% (0–0.9%).
Conclusion: This unique global cohort of well-defined IT patients exhibited a very low risk of HCC after 15 years of follow-up, with a risk lower than that observed in treated HBeAg+ CHB patients.

Email: arno.furquimdalmeida@uantwerpen.be

Background and aims: Determinants of outcomes after nucleos(t)ide analogue (NUC) cessation remain incompletely defined. Ethnicity has been proposed as a stopping criterium, but prospective validation is lacking. We evaluated the impact of ethnicity and HBV genotype (gt) on off-treatment outcomes.
Method: In the multicentre prospective COIN-B trial, start-of-treatment HBeAg-, long-term NUC-suppressed patients without advanced liver fibrosis were followed for 72 weeks after NUC cessation. Recruitment was matched for Caucasian and non-Caucasian ethnicity and stratified by sex and age. The primary endpoint was off-treatment HBV DNA ≤2000 IU/mL + ALT ≤2×ULN at week 72. Ethnicity was defined by country of birth. Ancestry inference was determined using population-specific SNPs.
Results: Of 91 included patients, 84 completed follow-up (Caucasian: n = 41; non-Caucasian: n = 43). Both groups had comparable end-of-treatment (EOT) quantitative HBsAg levels (p = 1.00). Caucasians were exclusively infected with gt A or gt D, whereas non-Caucasians showed broad gt diversity (A-E). The primary endpoint was reached in 41.5% of Caucasian versus 30.2% of non-Caucasian patients (p = 0.28), and retreatment rates did not differ (31.7% vs 48.8%, p = 0.11). HBsAg loss (7.1%) occurred exclusively in patients of European or North-African/Middle-Eastern ancestry. In multivariate analyses, including either SNP ancestry or gt, lower EOT HBsAg was consistently associated with the primary endpoint, HBsAg loss, and ≥1 log HBsAg decline at week 72, but not retreatment. Compared to European ancestry and adjusted for EOT HBsAg, Asian and Sub-Saharan African ancestries were less likely to have ≥1 log HBsAg decline (OR 0.01, p < 0.001; OR 0.002, p = 0.007), while Asian ancestry was associated with higher retreatment rates (OR 2.83, p < 0.05). Compared to gt A and adjusted for EOT HBsAg, gt C (OR 0.13, p = 0.02) and gt D (OR 0.20, p = 0.009) were less likely to achieve the primary endpoint and more likely to require retreatment (OR 11.9, p = 0.002; OR 3.72, p = 0.03), while gt B (OR 0.01, p = 0.008) and gt C (OR 0.04, p = 0.01) were less likely to have ≥1 log HBsAg decline.
Conclusion: In this prospective ethnicity-matched trial, off-treatment outcomes did not differ between Caucasian and non-Caucasian patients. EOT HBsAg is the dominant predictor of viral control, HBsAg loss and HBsAg decline with differential impacts of ancestry and HBV genotypes. These results call for a more granular definition of ethnicity as stopping criterium.

SAT-633

The impact of longitudinal hepatitis B virus genotypic diversity and viral dynamics on hepatocellular carcinoma risk in chronic hepatitis B

Ding-Lian Wang[1,2], Mei-Hung Pan[3], Chih-Jen Huang[3], Rachel Wen-Juei Jeng[4,5], Chien-Jen Chen[3], Hwai-I Yang[3]. *[1]Graduate Institute of Life Science, National Defense Medical University, Taipei, Taiwan; [2]Genomic Research Center, Academia Sinica, Taipei, Taiwan; [3]Genomics Research Center, Taipei, Taiwan; [4]Department of Gastroenterology and Hepatology, Linkou Chang Gung Memorial Hospital, Taoyuan, Taiwan; [5]College of Medicine, Chang Gung University, Taoyuan, Taiwan*
Email: dl.wang19971224@gmail.com

Background and aims: Hepatocellular carcinoma (HCC) remains a leading cause of cancer-related mortality worldwide, with chronic hepatitis B virus (HBV) infection as a major etiological factor. While HBV genotype and viral load are established predictors of HCC, most studies rely on single time-point genotype classification, neglecting within-host genotypic diversity and its longitudinal evolution. This study investigates the impact of HBV genotypic diversity, its temporal dynamics, and underlying drivers on HCC risk using high-resolution long-read sequencing.
Method: We analyzed 439 chronic HBV carriers from the community-based REVEAL-HBV cohort in Taiwan. Full-length HBV genomes were sequenced using PacBio long-read technology (mean ~5,000 reads per subject) and aligned to 35 NCBI reference sequences. Participants were classified by primary genotype proportion: Class 1 (100%), Class 2 (100% > proportion ≥ 99.89%), and Class 3 (<99.89%). A total of 250 participants with repeated sampling were included in longitudinal analyses. Linear mixed-effects models evaluated temporal trajectories of HBsAg, HBV DNA, and ALT, while Cox and time-dependent Cox models assessed associations between HBV genotypic diversity and HCC risk.
Results: Individuals with primary genotype C2 had a significantly higher HCC risk than those with B2, both at baseline (HR = 3.27, 95% CI = 2.00–5.35) and during follow-up (HR = 2.28, 95%CI = 1.14–4.57). Time-dependent Cox regression analysis revealed that greater HBV diversity (Class 3 vs. Class 1+2) was associated with increased HCC risk when assessed as a baseline characteristic (HR = 1.80, 95%CI = 1.03–3.17), but not as a time-varying covariate (HR = 1.11, 95%CI = 0.61–2.03). HBV DNA levels declined over time in all groups, with a significantly slower decline in genotype C compared with genotype B (B2 vs C2 Estimate = – 0.054; p = 0.008). In contrast, no significant

longitudinal differences were observed in HBV diversity proportions within the same genotype (Class1+2 vs Class 3 Estimate = – 0.002; p = 0.998).
Conclusion: Primary HBV genotype remains a strong predictor of long-term HCC risk. Baseline genotypic diversity reflects cumulative oncogenic potential, whereas short-term temporal changes show limited prognostic value. The slower viral load decline in genotype C may partly explain its stronger association with HCC. These findings underscore the value of integrating high-resolution viral sequencing with longitudinal analyses to improve HCC risk stratification in chronic HBV infection.

Long-term clinical outcomes in chronic hepatitis B patients with nucleos(t)ide analogue treatment who achieved HBsAg <100 IU/mL
Jian Wang[1,2], Shaoqiu Zhang[1], Li Zhu[3], Tao Fan[4], Ye Xiong[4], Chao Jiang[5], Juan Xia[1], Xiaomin Yan[1], Xingxiang Liu[6], Chuanwu Zhu[3], Chao Wu[1,2,4], Rui Huang[1,2,4,5]. *[1]Department of Infectious Diseases, Nanjing Drum Tower Hospital, Affiliated Hospital of Medical School, Nanjing University, Nanjing, China; [2]Institute of Viruses and Infectious Diseases, Nanjing University, Nanjing, China; [3]Department of Infectious Diseases, The Affiliated Infectious Diseases Hospital of Soochow University, Suzhou, China; [4]Department of Infectious Diseases, Nanjing Drum Tower Hospital Clinical College of Nanjing University of Chinese Medicine, Nanjing, China; [5]Department of Infectious Diseases, Nanjing Drum Tower Hospital Clinical College of Jiangsu University, Nanjing, China; [6]Department of Clinical Laboratory, Huai'an No. 4 People's Hospital, Huai'an, China*
Email: doctor_hr@126.com

Background and aims: Chronic hepatitis B (CHB) patients who achieve HBsAg <100 IU/mL spontaneously have favorable clinical outcomes. However, the difference of clinical outcomes between patients who achieve HBsAg <100 IU/mL after antiviral treatment and those who achieve it spontaneously remains unclear. We compared long-term outcomes between patients with treatment-associated and spontaneously achieved HBsAg <100 IU/mL.
Method: This multi-center retrospective study included 886 non-cirrhotic CHB patients from three sites. These patients had HBeAg negativity, undetectable HBV DNA, HBsAg levels <100 IU/mL, and normal ALT levels (616 in the spontaneous group and 270 in the treatment-induced group). We used the inverse probability of treatment weighting (IPTW) and propensity score matching (PSM) to balance baseline characteristics between the treated and untreated groups. The study outcomes included HBsAg seroclearance and liver-related events (LREs) (cirrhosis and hepatocellular carcinoma).
Results: During a median follow-up of 3.0 years, 102 patients achieved HBsAg seroclearance, and 7 patients developed LREs in overall cohort. In the IPTW cohort, no significant difference of 6-year cumulative incidence of HBsAg seroclearance was found between the spontaneous and treatment-induced groups (43.7% vs. 27.3%, P = 0.199) or LREs (0.8% vs. 1.5%, P = 0.782). Baseline HBsAg <15 IU/mL (adjusted hazard ratio [aHR]: 5.48, 95% confidence interval [CI]: 2.95–10.18, P < 0.001) and antiviral treatment (aHR: 1.77, 95% CI: 1.01–3.10, P = 0.047) were associated with a higher likelihood of achieving HBsAg sreoclearance in the multivariate Cox analysis. However, antiviral treatment was not significantly associated with the development of LREs (HR: 1.07, 95% CI: 0.24–4.83, P = 0.928). However, in the PSM cohort, antiviral treatment did not significantly associate with either HBsAg seroclearance or LREs.
Conclusion: Both treatment-induced and spontaneous achievement of HBsAg <100 IU/mL in CHB patients were associated with favorable outcomes, including a low risk of LREs and a high likelihood of HBsAg seroclearance.

SAT-635
Antiviral therapy reduces liver-related events in chronic hepatitis B patients with low HBsAg
Jian Wang[1,2], Li Zhu[3], Zhiyi Zhang[4], Qun Zhang[5], Shaoqiu Zhang[1], Tao Fan[6], Ye Xiong[6], Shengxia Yin[1], Yuxin Chen[7], Chuanwu Zhu[3], Huali Wang[8], Xingxiang Liu[9], Rui Huang[1,2,6], Chao Wu[1,2,6]. *[1]Department of Infectious Diseases, Nanjing Drum Tower Hospital, Affiliated Hospital of Medical School, Nanjing University, Nanjing, China; [2]Institute of Viruses and Infectious Diseases, Nanjing University, Nanjing, China; [3]Department of Infectious Diseases, The Affiliated Infectious Diseases Hospital of Soochow University, Suzhou, China; [4]State Key Laboratory Cultivation Base of Research, Prevention and Treatment for Oral Diseases, Jiangsu Province Engineering Research Center of Stomatological Translational Medicine, The Affiliated Stomatological Hospital of Nanjing Medical University, Nanjing, China; [5]Department of Infectious Diseases, Zhongda Hospital, School of Medicine, Southeast University, Nanjing, China; [6]Department of Infectious Diseases, Nanjing Drum Tower Hospital Clinical College of Nanjing University of Chinese Medicine, Nanjing, China; [7]Department of Laboratory Medicine, Nanjing Drum Tower Hospital, Affiliated Hospital of Medical School, Nanjing University, Nanjing, China; [8]Department of General Practice, Nanjing Second Hospital, Nanjing University of Chinese Medicine, Nanjing, China; [9]Department of Clinical Laboratory, Huai'an No. 4 People's Hospital, Huai'an, China*
Email: dr.wu@nju.edu.cn

Background and aims: The long-term benefit of antiviral treatment in patients with chronic hepatitis B (CHB) who have detectable HBV DNA but normal or mildly elevated alanine aminotransferase (ALT) remains debated, particularly among those with low hepatitis B surface antigen levels (HBsAg). We aimed to explore whether nucleos(t)ide analogue (NA) therapy improves long-term clinical outcomes in patients with HBsAg <100 IU/mL and ALT <2 × the upper limit of normal (ULN).
Method: This multi-center study retrospectively included 701 non-cirrhotic CHB patients with HBsAg <100 IU/mL, detectable HBV DNA, and ALT <2 × ULN from five hospitals in China, including 211 in the NAs treatment group and 490 in the untreated group. The incidence rates of liver-related events (LREs) (cirrhosis and hepatocellular carcinoma) and HBsAg seroclearance were compared between groups.
Results: The median age of patients was 48.5 years, and 60.2% of patients were male. In the overall patients, 13 (1.9%) patients developed LREs and 30 (5.4%) patients achieved HBsAg seroclearance during a median follow-up period of 2.1 years. The 6-year cumulative incidence of LREs was significantly lower in the treated patients than in the untreated patients (1.2% vs. 7.5%, P = 0.038). In multivariable Cox regression analysis, antiviral therapy was associated with a significantly low risk of LREs (adjusted hazard ratio [HR]: 0.05, 95% CI: 0.01–0.48, P = 0.010). However, the 6-year cumulative incidence of HBsAg seroclearance was comparable between treated and untreated patients (19.5% vs. 13.4%, P = 0.287). However, antiviral therapy was not independently associated with HBsAg seroclearance (adjusted HR: 1.48, 95% CI: 0.66–3.35, P = 0.341).
Conclusion: NAs therapy reduced the risk of LREs in CHB patients with low HBsAg (<100 IU/mL), detectable HBV DNA, and normal or mildly elevated ALT levels.

Email: Maria.pfefferkorn@medizin.uni-leipzig.de

Background and aims: In the prospective STOP-NUC trial, discontinuation of long-term nucleos(t)ide analogue (NUC) treatment in HBeAg-negative patients resulted in HBsAg loss or transition to disease stages with or without treatment indication in many patients with HBsAg levels < 1000 IU/mL. We investigated the experimental biomarkers of covalently closed circular DNA (cccDNA) activity. Large (LHBs), middle (MHBs), and small (SHBs) HBsAg isoforms, as well as HBV RNA, provide additional predictive value for clinical outcomes after NUC cessation.
Method: Serum samples from 79 patients randomized to NUC discontinuation collected at baseline (BL) and weeks 12, 24 and 48 were retrospectively assessed for HBV DNA, HBV RNA, total HBsAg, LHBs and MHBs. Based on week-96 outcomes, patients were classified as re-treatment (ReT; n = 11), no re-treatment, but detectable HBV DNA (n = 54), virologic response (undetectable HBV DNA, VR; n = 6) or HBsAg loss (functional cure; FC; n = 8).
Results: Patients achieving FC after NUC discontinuation showed significantly lower median BL levels of total HBsAg, LHBs and MHBs compared to all other response groups ($p < 0.001$). Thus, median proportions (%) of LHBs and MHBs were lowest in FC (4.9 and 0.7) compared to all patients without FC (6.5 and 5.8, $p = 0.538$ and $p = 0.023$). Proportions of LHBs and MHBs were higher in patients with VR (4.9 and 3.7), in those without ReT but detectable HBV DNA (6.1 and 5.4) and highest in patients with ReT (9.0 and 9.4), respectively. Over 48 weeks after NUC discontinuation, median proportions of LHBs and MHBs declined to 0.9 and 1% in patients with VR and to 0% in patients with FC, but remained high in patients with ReT at all time points. HBV DNA and HBV RNA were undetectable in 77/79 and 58/79 patients at BL. Detectable HBV RNA levels at BL (AUC = 0.735) and week 12 (AUC = 0.787) were strongly associated with ReT. From week 24 onward, HBV RNA became undetectable in all FC patients, whereas patients in the ReT group persistently showed detectable HBV RNA levels (2.14, 2.52 and 3.01 log cp/mL at 12, 24 and 48 weeks).
Conclusion: Low proportions of LHBs and MHBs were associated with FC already before NUC discontinuation and may reflect cccDNA activity and therefore response to NUC discontinuation. Detectable HBV RNA after NUC cessation was associated with a high risk of retreatment, supporting its role as safety marker.

SAT-637
Integrated model nurse clinic reduces adverse pregnancy outcomes of pregnant women with chronic hepatitis B

Vicki Wing-Ki Hui[1], Mandy Sze-Man Lai[1], Jimmy Che-To Lai[1], Vincent Wai-Sun Wong[1], Terry Cheuk-Fung Yip[1], Grace Lai-Hung Wong[1]. [1]*The Chinese University of Hong Kong, Sha Tin, Hong Kong*
Email: wonglaihung@cuhk.edu.hk

Background and aims: An integrated model nurse clinic (IMNC) was established in Hong Kong as a pivotal part of the Hong Kong Hepatitis Action Plan 2020–2024 to achieve hepatitis elimination by 2030. IMNC has led to a major increase in HBsAg and HBV DNA testing in women of child-bearing age. This study evaluated the impact of IMNC on adverse pregnancy outcomes, namely miscarriages and preterm deliveries of babies.
Method: Individuals with CHB were identified from a territory-wide database from year 2000 to 2024. Adverse pregnancy outcomes were defined with diagnosis and/or procedure codes for miscarriages and preterm deliveries of babies.
Results: A total of 1,341,841 pregnancies identified; 72,082(5.4%) individuals were diagnosed with chronic HBV infection. From 2000 to 2024, miscarriage proportions increased in both groups, rising from 12.0% (95% CI 10.7%–13.2%) in HBV pregnancies and 9.9% (9.6%–10.1%) in non-HBV pregnancies in 2000 to 16.6% (14.4%–18.8%) and 14.8% (14.4%–15.2%) in 2024; the highest proportions were 17.2% (15.7%–18.7%) in HBV pregnancies in 2018 and 19.7% (19.3%–20.1%) in non-HBV pregnancies in 2023. Preterm delivery proportions increased from 2000 (HBV 6.9%, 5.9%–7.9%; non-HBV 7.3%, 7.1%–7.5%) to a peak among HBV pregnancies in 2011 (19.1%, 17.9%–20.3%), followed by a decline to 2024 (HBV 11.1%, 9.2%–13.1%; non-HBV 11.3%, 10.9%–11.6%). After IMNC implementation in 2020, miscarriage among IMNC attendees decreased from 8.9% (1.5%–16.4%) in 2020 to 1.2% (0.0%–3.6%) in 2024, whereas non-attendees increased from 9.9% (8.2%–11.5%) to 12.4% (9.7%–15.0%). Preterm delivery among IMNC attendees increased in 2021–2022 to 18.4% (11.9%–24.9%) and 18.9% (11.9%–25.8%), then decreased from 2023 onwards to 8.4% (2.5%–14.4%) in 2024.
Conclusion: Newly diagnosed HBV rates showed substantial increases in pregnant women born before the era of universal HBV vaccination, while remained steadily low in those born in the era of universal HBV vaccination. These findings provide important data for the allocation of resources in IMNC, with more targeted screening, education and pre-emptive antiviral therapy for pregnant women born before the era of universal HBV vaccination in order to minimise MTCT of HBV.

SAT-638
Dynamic modeling of hepatitis B surface antigen trajectories enables prediction of hepatocellular carcinoma: a large-scale long-term follow-up cohort study

Tianyi Xue[1], Xin Wen[1], Yanpei Mai[1], Suzhen Jiang[1], Xiangsha Kong[1], Feng Liu[1], Huiying Rao[1], Zixing Wang[1]. [1]*Peking University Hepatology Institute, Beijing, China*
Email: wangzixing@pkuph.edu.cn

Background and aims: Accurate and timely risk stratification is essential for optimizing hepatocellular carcinoma (HCC) surveillance in patients with chronic hepatitis B (CHB). Quantitative hepatitis B surface antigen (HBsAg) reflects viral–host interaction, but longitudinal information is underutilized in current static prediction models. We aimed to develop a dynamic prediction framework based on longitudinal HBsAg trajectories to improve individualized HCC risk assessment.
Method: We developed dynamic prediction models in a large cohort of adult patients with CHB, split into training and validation sets at a 2:1 ratio. Longitudinal log-transformed HBsAg measurements were modeled using linear mixed-effects models and linked to time to HCC through joint modeling. Patient-specific HCC risk was estimated at baseline and updated at follow-up visits using all available HBsAg data. Predictive performance was assessed using time-dependent area under the receiver operating characteristic curve (AUC) at 1, 2, 3, and 5 years.
Results: The training and validation sets included 9,886 and 4,223 patients, respectively, with 227 and 94 incident HCC events,

respectively, during a maximum follow-up of 12.8 years. At baseline, the model achieved AUCs of 0.79, 0.80, 0.81, and 0.82 for predicting 1-, 2-, 3-, and 5-year HCC risk in the training set, respectively. Model performance improved with follow-up assessments, for instance, with AUCs at the first follow-up increasing to 0.81, 0.82, 0.82, and 0.82 across the four time horizons. In the validation set, baseline prediction yielded AUCs of 0.81, 0.83, 0.81, and 0.83 at 1, 2, 3, and 5 years, respectively. During follow-up, discrimination further improved, with AUCs at the first follow-up reaching 0.85, 0.86, 0.86, and 0.88, and sustained improvement was observed at later follow-up assessments.
Conclusion: Dynamic modeling of longitudinal HBsAg trajectories enables accurate and early updating of HCC risk prediction in chronic hepatitis B. Incorporating biomarker information from previous and present visits provides consistent improvement in short- and long-term risk discrimination and supports personalized surveillance strategies.

SAT-639
HBcrAg predicts post-IFN-α therapy HBV relapse in CHB
Linmei Yao[1]. [1]*Department of Hepatology Division 2, Beijing Ditan Hospital, Capital Medical University, Beijing, China*
Email: 18703498538@163.com

Background and aims: Several hepatitis B virus (HBV) serum markers have been identified as predictors of pegylated interferon-alpha (Peg-IFN-α) antiviral outcomes. However, serum markers for determining virologic relapse following Peg-IFN-α discontinuation (post-Peg-IFN-α virologic relapse) have not been established. This study aimed to identify the association of serum pregenomic RNA (pgRNA) and hepatitis B core-related antigen (HBcrAg) levels with Peg-IFN-α antiviral outcomes and post-Peg-IFN-α virologic relapse in treatment-naïve chronic HBV infection patients.
Method: A total of 371 treatment-naïve chronic HBV (CHB) infection patients participated in this study. All patients received Peg-IFN-α therapy. Biochemical, serological, and virological parameters were quantified using standard laboratory procedures. Serum pgRNA and HBcrAg levels were measured via PCR-fluorescent probe detection and ELISA, respectively.
Results: A total of 327 patients underwent follow-up. One hundred and twelve patients (34.25%) achieved a response to Peg-IFN-α therapy. Sixteen patients experienced post-Peg-IFN-α virologic relapse (14.29%) [during a median follow-up of 12 months (IQR 9–18)]. Baseline serum pgRNA (OR, 0.571; 95% confidence interval [CI], 0.388–0.838), HBcrAg (OR, 0.539; 95% CI, 0.348–0.835), and HBsAg (OR, 0.356; 95% CI, 0.223–0.567) levels correlated with Peg-IFN-α antiviral therapy efficacy. Baseline serum pgRNA, HBcrAg, and HBsAg levels demonstrated predictive value for Peg-IFN-α antiviral therapy efficacy, with areas under the receiver operating characteristic (ROC) curve of 0.821 (95% CI, 0.758–0.874), 0.879 (95% CI, 0.822–0.923), and 0.781 (95% CI, 0.719–0.835), respectively. Serum HBcrAg level at the Peg-IFN-α discontinuation point predicted post-Peg-IFN-α virologic relapse, with an area under the ROC curve of 0.790 (95% CI, 0.703–0.861).
Conclusion: These findings demonstrate that serum pgRNA, HBcrAg, and HBsAg levels in treatment-naïve chronic hepatitis B (CHB) patients correlate with Peg-IFN-α treatment response. Notably, baseline HBcrAg levels independently predict post-treatment virologic relapse, offering a potential biomarker for identifying high-risk patients following Peg-IFN-α discontinuation.

SAT-640
HBV screening in rheumatology: a significant gap in HBV DNA testing for HBsAg-negative, anti-HBc-positive patients
Senlin You[1,2], Hong Tang[1,2], Hong Li[1,2]. [1]*Center of Infectious Diseases, West China Hospital of Sichuan University, Chengdu, China;* [2]*Laboratory of Infectious and Liver Diseases, Institute of Infectious Diseases, West China Hospital of Sichuan University, Chengdu, China*
Email: senlinyou_912918@126.com

Background and aims: Hepatitis B virus (HBV) reactivation is a potentially life-threatening yet preventable complication in rheumatology patients receiving immunosuppressive therapy. Current international guidelines (e.g., EASL 2025, AGA 2025) recommend initial serology screening (HBsAg and anti-HBc) followed by mandatory HBV DNA testing for all HBsAg-positive and HBsAg-negative/anti-HBc-positive patients prior to treatment. This study aimed to characterize HBV screening practices in a large patient cohort.
Method: We conducted a retrospective cohort analysis of consecutive inpatients admitted to the Rheumatology Department of West China Hospital between January 2020 and December 2024. Data for the recommended HBV screening panel (HBsAg, anti-HBc, and HBV DNA) were systematically extracted from electronic medical records. Descriptive statistics were used for analysis, with results reported as proportions and 95% confidence intervals (95% CI).
Results: Among 8,758 patients, 8,417 (96.1%) underwent HBsAg screening. Of these, 339 (4.0%) were HBsAg-positive. Subsequent HBV DNA testing was performed in 289 (85.3%) of these positive patients, with detectable viremia found in 204 (70.6%). Antiviral therapy was initiated in 165 (80.9%) of those with detectable viremia. Among the 8,078 HBsAg-negative patients, 4,029 (49.9%) were anti-HBc-positive and thus should have undergone HBV DNA testing according to guidelines. However, only 1,373 (34.1%; 95% CI: 32.6–35.6%) completed this testing. Detectable viremia was found in 24 of these patients, of whom only 17 received antiviral therapy. Among the 4,029 HBsAg-negative/anti-HBc-positive patients, 3258 (80.9%) were anti-HBs-positive.
Conclusion: In this Chinese cohort, nearly half of HBsAg-negative patients were anti-HBc-positive, yet most did not receive recommended HBV DNA testing. This disparity between seroprevalence and guideline adherence highlights a significant and actionable gap in the prevention of HBV reactivation.

Email: rongfansmu@163.com

Background and aims: Quantitative hepatitis B surface antigen (qHBsAg) is a key marker for evaluating therapeutic approaches in chronic hepatitis B (CHB). However, HBV genotype-specific kinetics across therapies - particularly novel agents - remain poorly characterized. We compared qHBsAg kinetics between HBV genotypes (GTs) B and C under diverse treatment regimens.
Method: The study purposely included CHB cohorts with diverse profiles: i) two treatment-naïve (TN) cohorts with HBeAg-positive patients receiving a nucleos(t)ide analogue (NA, n = 596) for 3–84 months or pegylated interferon (Peg-IFN, n = 262) for 48–96 weeks; ii) one real world cohort with treatment-experienced (TE) patients receiving NA and/or Peg-IFN for 6–96 months (n = 875, HBeAg +: 44.7%); and iii) one TE cohort with pre-enrolment virally suppressed patients receiving siRNA for 48 weeks (n = 50, HBeAg +: 42.0%). The qHBsAg was tested serially at predefined protocol time-points.
Results: A total of 1,783 non-cirrhotic patients infected with GT B/C (833/950), with median duration of follow-up 18.0–85.6 months, median age 28.0–37.0 years, and male predominance 77.0%–84.9%, were analyzed. Among the two TN cohorts, baseline qHBsAg was significantly higher in GT B than in GT C (4.5 vs 4.1 $\log_{10}$ IU/mL; 4.4 vs 4.0 $\log_{10}$ IU/mL; all $p < 0.05$). GT B exhibited a more rapid decline at week 12 (proportion of ≥ 1.0 $\log_{10}$ IU/mL reduction: 34.9% vs 13.5%; 26.9% vs 14.8%; all $p < 0.05$), resulting in consistently lower qHBsAg than GT C through the end-of-treatment (EOT) (3.2 vs 3.5 $\log_{10}$ IU/mL; 3.1 vs 3.3 $\log_{10}$ IU/mL; all $p < 0.05$). Among the two TE cohorts, the qHBsAg of GT B were consistently lower than those of GT C from baseline (3.0 vs 3.1 $\log_{10}$ IU/mL; 2.9 vs 3.6 $\log_{10}$ IU/mL; all $p < 0.05$) to EOT (2.5 vs 2.7 $\log_{10}$ IU/mL; 0.6 vs 2.0 $\log_{10}$ IU/mL; all $p < 0.001$). During the 24- and 48-week post-treatment period, GT B exhibited numerically smaller qHBsAg rebounds (0.1–0.2 $\log_{10}$ IU/mL less) than GT C. Multivariate analysis identified GT B as an independent predictor for achieving qHBsAg < 1000 IU/mL at EOT in NA- and Peg-IFN-treated cohorts (adjusted OR: 1.6–2.2; all $p < 0.05$). Moreover, linear mixed-effects analyses confirmed a significantly faster qHBsAg decline in GT B than GT C in four cohorts (all $p < 0.001$).
Conclusion: GT B exhibits consistently favourable qHBsAg kinetics than GT C - with sharper initial decline, sustained suppression, and minimal rebound - highlighting the importance of genotype-informed novel therapeutic strategies in CHB management.

SAT-642
Comparison of the proportion of chronic hepatitis B patients with indeterminate phase based on the 2025 EASL and the 2025 AASLD guidelines

Shaoqiu Zhang[1], Jian Wang[1,2], Chao Jiang[3], Tao Fan[4], Ye Xiong[4], Renling Yao[1], Juan Xia[1], Xiaomin Yan[1], Huali Wang[5], Qun Zhang[6], Xingxiang Liu[7], Chuanwu Zhu[8], Rui Huang[1,2], Chao Wu[1,2].

Email: dr.wu@nju.edu.cn

Background and aims: The European Association for the Study of the Liver (EASL) and the American Association for the Study of Liver Diseases (AASLD) released the updated guidelines on the management of chronic hepatitis B (CHB) in 2025. The impact of these updated guidelines on the proportion of patients with indeterminate phase is unclear. We compared the proportion of patients with indeterminate phase based on the 2025 EASL and 2025 AASLD guidelines.
Method: A total of 13,231 treatment-naïve patients with CHB without liver cirrhosis were retrospectively collected from five medical centers. The classification of clinical phases of patients were defined based on the 2025 AASLD and 2025 EASL guidelines, respectively. Patients who did not fall into the defined clinical phases of the guidelines were classified into the indeterminate phase.
Results: The study population had a median age of 36.3 years. 59.4% of patients were male and 26.0% were HBeAg-positive. The proportion of patients with indeterminate phase was significantly higher based on the 2025 AASLD guidelines than based on the 2025 EASL guidelines (41.5% vs. 25.7%, $P < 0.001$). In the subgroup analyses stratified by sex, HBeAg status and age, similar results were found ($P < 0.001$). All patients classified as indeterminate phase according to the 2025 EASL guidelines were also classified as indeterminate phase according to the 2025 AASLD guidelines.
Conclusion: A substantial proportion of patients fell into the indeterminate phase under both the 2025 AASLD and 2025 EASL guidelines, with a significantly higher proportion classified as indeterminate according to the 2025 AASLD guidelines.

SAT-643
Gut microbiome functional profiles associated with fibrosis outcomes in chronic hepatitis B

Zhe Zhang[1], Saisai Zhang[1], Lu Li[1], Meng Zhao[1], Lung-Yi Mak[2], Man-Fung Yuen[2], Wai-Kay Seto[2]. *[1]Department of Medicine, School of Clinical Medicine, The University of Hong Kong, Hong Kong, China; [2]Department of Medicine, School of Clinical Medicine, The University of Hong Kong, State Key Laboratory of Liver Research, The University of Hong Kong, Hong Kong, China*
Email: zhzhe@connect.hku.hk

Background and aims: Chronic hepatitis B (CHB) lead to liver fibrosis and cirrhosis. Despite effective viral suppression with long-term nucleos(t)ide analogue (NA) therapy, fibrosis regression varies. Emerging evidence implicates the gut microbiome in hepatic inflammation and fibrogenesis, yet its role in determining fibrosis outcomes in treated CHB remains unclear. This study aimed to investigate the association between gut microbiome profiles and fibrosis regression in NA-treated CHB patients.
Method: We characterized the fecal microbiome of 30 NA-treated CHB patients with baseline liver fibrosis (liver stiffness measurement [LSM]≥7 kPa) over a three-year follow-up period. Fibrosis regression was defined as more than 30% LSM reduction. Using full-length 16SrRNA gene sequencing (PacBio platform) and functional inference (PICRUSt2), we analyzed microbial function associated with outcomes. In-vitro experiments were conducted using LX-2 human hepatic stellate cells stimulated with arachidonic acid (AA), and the inflammatory gene expression was assessed.
Results: The cohort (median age 67, 77% male) achieved significant fibrosis regression in 12(40%) patients after at least three years NA therapy. All patients were HBeAg-negative with suppressed HBV DNA levels (<10 IU/mL). Baseline mean LSM was 16.12(±2.001) kPa. Functional and taxonomic analyses revealed an enrichment of *Ruminococcus torques* in patients without fibrosis regression (linear discriminant analysis score3.41, $p = 0.015$), while no significant differences were observed in gut microbial alpha or beta diversity between groups. The relative abundance of *Ruminococcus torques* was positively correlated with circulating white blood cell counts, neutrophils, and monocytes ($r = 0.42$, $p = 0.023$; $r = 0.52$, $p = 0.004$; $r = 0.40$, $p = 0.032$). Additionally, *Ruminococcus torques* abundance

was positively associated with the AA metabolism pathway (r = 0.38, p = 0.039). In-vitro AA treatment (10μg/mL) significantly upregulated the mean mRNA levels of inflammatory cytokines in LX-2 cells compared to controls (IL-6:2.81 ± 2.89vs.1.03 ± 0.02, p = 0.0079; MCP-1:1.72 ± 0.06vs.1.04 ± 0.08, p = 0.0079), without affecting fibrogenesis-related genes (alpha-SMA and Collagen typeI).
Conclusion: Fibrosis regression is linked to specific microbial functional signatures in treated CHB. The enrichment of *Ruminococcus torques* and its association with systemic inflammatory markers and arachidonic acid metabolism suggest a potential role for microbiome-driven inflammatory pathways in impeding fibrosis regression.

Risk factors for abnormal ALT in postpartum women with chronic hepatitis B : a systematic review and meta-analysis
Chengxuan Yao[1], Yunxia Zhu[2], Shuiweizhi Dai[1], Xiang Gao[2], Jinhua Wang[2], Huaibin Zou[3]. *[1]Beijing Key Laboratory of Liver Regeneration and Artificial Liver Transformation Research, Beijing, China; [2]Department of Obstetrics, Beijing You 'an Hospital, Capital Medical University, Beijing, China; [3]Department of Liver Diseases, Beijing You 'an Hospital, Capital Medical University, Beijing, China*
Email: zhbin03@126.com

Background and aims: Currently, antiviral therapy during pregnancy followed by postpartum treatment cessation for the prevention of mother-to-child transmission has become standard practice for pregnant women with hepatitis B virus (HBV). However, the postpartum period remains a high-risk phase for HBV-infected women. The underlying causes of postpartum liver function abnormalities in this population have not yet been fully elucidated. This systematic review and meta-analysis aimed to identify risk factors associated with postpartum liver function abnormalities in women with chronic HBV infection.
Method: PubMed, Web of Science, Embase, the Cochrane Library, CNKI, and WangFang databases were systematically searched from database inception to December 10, 2025. The primary clinical outcome was defined as alanine aminotransferase (ALT) elevation >1 × the upper limit of normal (ULN) at any time during the postpartum period.
Results: A total of 18 cohort studies (6 retrospective and 12 prospective), comprising 6,608 postpartum women with chronic HBV infection, were included. Pooled analyses showed that ALT levels at delivery (crude odds ratio [OR] 1.05; 95% CI [1.03–1.07]; $I^2 = 0\%$), HBeAg positivity (crude OR 3.03; 95% CI [1.91–4.81]; $I^2 = 0\%$), elevated baseline HBV DNA levels (OR 1.64; 95% CI [1.25–2.41]; $I^2 = 0\%$), and genotype C (OR 1.10; 95% CI [0.98–1.24]; $I^2 = 0\%$) were potential risk factors for postpartum ALT abnormalities. In contrast, older maternal age (OR 0.93; 95% CI [0.87–0.99]; $I^2 = 0\%$), antiviral therapy during pregnancy (random-effects model, OR 0.77; 95% CI [0.64–0.92]; $I^2 = 0\%$), and continuation of antiviral therapy postpartum (OR 0.50; 95% CI [0.21–1.16]; $I^2 = 0\%$) were identified as key protective factors against postpartum liver function abnormalities. Additionally, baseline ALT levels (random-effects model, OR 1.00; 95% CI [0.99–1.01]) were not associated with postpartum ALT elevation ($I^2 = 11.4\%$; p for heterogeneity = 0.336).
Conclusion: Potential risk factors for postpartum liver function abnormalities in women with chronic HBV infection include elevated ALT levels at delivery, HBeAg positivity, higher baseline HBV DNA levels, non-C genotype, younger maternal age, absence of antiviral therapy during pregnancy, and immediate discontinuation of antiviral therapy after delivery. These findings underscore the need for close monitoring of this high-risk population starting from pregnancy and warrant further investigation into the underlying mechanisms of postpartum ALT elevation.

Viral hepatitis B and D – Current therapies

Email: elisabetta.degasperi@policlinico.mi.it

Background and aims: Bulevirtide (BLV) monotherapy yields high rates of virological and biochemical response in chronic hepatitis Delta (CHD) patients with cirrhosis, however data on hard clinical outcomes are lacking.
Method: Consecutive CHD patients with cirrhosis treated with BLV 2 mg/day for 3 years in the SAVE-D retrospective multicenter European study were compared with two BLV-untreated cohorts (cohort #1 from Italy and cohort #2 from France). Liver-related events (LRE: hepatocellular carcinoma [HCC], decompensation) occurring within the first 3 years were compared by inverse probability of treatment weighting (IPTW) analysis. Baseline data was set at BLV start (BLV-treated cohort) or cirrhosis diagnosis (untreated controls).
Results: A total of 642 patients were included: 344 BLV-treated and 298 untreated controls. Treated patients were older (50 *vs.* 40 years, $p < 0.0001$), more frequently women (males 62% *vs.* 78%, $p = 0.001$), Caucasian (84% *vs.* 62%, $p < 0.0001$), on NUC (91% vs. 40%, $p < 0.0001$) and with higher HDV RNA (5.4 *vs.* 4.9 Log_{10}IU/mL, $p = 0.002$). By contrast, the proportion of patients with previous decompensation, HCC or CSPH was similar. The 3-year cumulative incidence of LREs was lower in BLV-treated patients *vs.* untreated: 8.9% (95%CI 4–12%) *vs.* 16.2% (95% CI 11–22%), respectively ($p = 0.03$). The corresponding figures for decompensation were 2.7% (95%CI 1–4%) *vs.* 11.3% (95%CI 7–16%) ($p = 0.001$) and for HCC 6.1% (95%CI 3–8%) *vs.* 6.6% (95% CI 3–11%) ($p = 0.49$), respectively. In IPTW-adjusted Cox regression analysis, BLV-treated *vs.* untreated controls had significantly lower risk of developing LREs (HR 0.44, 95% CI 0.27–0.72, $p = 0.001$) or decompensation (HR 0.16, 95% CI 0.07–0.36, $p < 0.0001$). These results were confirmed by IPTW-adjusted competing risks regression model both in the combined untreated cohorts (SHR 0.16, 95%CI 0.06–0.40, $p < 0.0001$) and in each individual untreated cohort (cohort#1: SHR 0.16, 95%CI 0.05–0.47, $p < 0.001$; cohort #2: SHR 0.19, 95%CI 0.06–0.62, $p < 0.005$). Conversely, the HCC risk was similar across all cohorts. Lower baseline albumin values independently predicted LREs, both in the BLV-treated cohort (HR 0.22, 95% CI 0.08–0.64, $p = 0.006$) and untreated controls (HR 0.38, 95%CI 0.20–0.72, $p = 0.002$).
Conclusion: In CHD patients with cirrhosis observed for up to 3 years, BLV monotherapy reduced the risk of LREs and decompensation, but not HCC, compared to an untreated IPTW-matched population.

Background and aims: Long-term therapy with bulevirtide (BLV) is currently recommended for most patients with chronic hepatitis D (CHD). Preliminary data from the pivotal MYR-301 study, together with limited real-world evidence, suggest that finite BLV therapy may be feasible in only a small subset of patients. In contrast, uncontrolled discontinuation of BLV has been associated with severe hepatitis flares and hepatic decompensation. The BUL-STOP trial aims to assess whether BLV therapy can be safely discontinued in carefully selected patients with CHD and to explore potential biomarkers associated with sustained control of HDV infection after cessation of BLV treatment.
Method: BUL-STOP is a still ongoing investigator-initiated multi-center-study in Germany and Italy supported by the EU-funded D-SOLVE consortium and the HEP-NET Study House. Patients with CHD and compensated liver disease who have been treated with BLV for 48 weeks or longer were eligible if HDV RNA was less than 100 IU/ml for at least 24 weeks. A close post-treatment monitoring and biomarker sampling including fine-needle-aspiration is performed for 48 weeks after stopping BLV therapy or until re initiation of BLV therapy was deemed necessary.
Results: A total of 21 patients were enrolled. BLV discontinuation was not feasible in three patients due to screening failure; therefore, 18 patients (10 females, 8 males; median age 57 years [range 34–75]; median ALT 26 U/l [range 14–39]; liver stiffness measurement (LSM) > 10.2 kPa in two patients > 15.2 kPa in one patient) are currently being followed after BLV discontinuation. The median duration of BLV therapy prior to discontinuation was 144 weeks (range 53–250). HDV RNA was undetectable in 16/18 patients at screening, 15/18 at baseline, 12/18 at 4-weeks off-therapy, and 7/14 at 12-weeks off-therapy. By December 31, 2025, BLV therapy had been re-initiated in eight patients (44%) after 65–198 days. ALT elevations exceeding three times the upper limit of normal were observed in four patients. No episodes of hepatic decompensation occurred during the study. Final follow-up data will be presented at the meeting.
Conclusion: Discontinuation of BLV therapy may be feasible in a subset of patients with CHD, allowing for finite treatment. However, post-treatment relapse can be associated with hepatitis flares, necessitating timely re-initiation of BLV therapy. Biomarker analyses to identify pre-discontinuation factors predictive of sustained long-term control of HDV infection are ongoing.

Background and aims: Bulevirtide (BLV) 2 mg/day is approved for the treatment of chronic hepatitis Delta (CHD), but real-world data on virological breakthroughs (VBK) during long-term BLV monotherapy remain limited. We evaluated the incidence and timing of VBK during BLV 2 mg/day monotherapy in two multicenter real-life cohorts (SAVE D and D SHIELD).
Method: CHD patients treated with BLV 2 mg/day monotherapy from the retrospective/prospective multicenter, observational, real-world SAVE-D and D-SHIELD studies with available paired baseline-week 24–48–72 or 96 data were included. VBK was defined as ≥1 Log_{10} HDV RNA increase compared to a previous timepoint (nadir). Virological (HDV-RNA undetectable or ≥2 Log_{10} decline *vs.* baseline), biochemical (BR, ALT<40 U/L), combined response (CR, biochemical +virological), HDV RNA undetectability and liver-related events were also assessed.
Results: Among a total of 900 CHD patients enrolled in the SAVE-D and D-SHIELD studies, a total of 276 patients with available paired baseline-W72 data (111 with available week 96 data) were included: at baseline (BLV start), median age was 52 (IQR 42–60) years, 55% males, 73% with cirrhosis, median ALT 81 (45–144), liver stiffness measurement (LSM) 14.0 (6.1–25.0) kPa, HBsAg 3.7 (3.2–4.2) Log_{10}IU/mL, HDV RNA 5.3 (3.9–6.4) Log_{10}IU/mL. Overall, rates of response at week 48 were 68% (VR), 67% (BR), 52% (CR) and 28% (HDV RNA undetectable), while the corresponding figures at week 96 were 68% (VR), 65% (BR), 50% (CR) and 38% (HDV RNA undetectable), respectively. During BLV monotherapy, a VBK occurred in 15 (5%) patients at week 48, 24 (9%) at week 72 and 8 (7%) at week 96. At VBK, a BR was maintained in 7/14 (50%) patients at week 48, 10/24 (42%) at week 72, and 7/8 (87%) at week 96. Occurrence of VBK was independent of baseline ALT levels ($p = 0.08$), HDV RNA ($p = 0.72$) and cirrhosis status ($p = 0.15$). VBK was stable at two consecutive timepoints in 7 (15%) patients, while in the remnants VBK was only transient and resolved at the following treatment timepoint. None of the patients with VBK developed a de novo liver-related event.
Conclusion: During BLV 2 mg/day monotherapy up to 96 weeks, 17% of the patients experienced VBK that however were transient and not associated with increased ALT levels in most cases.

Background and aims: Chronic hepatitis Delta (CHD) confers high risk of cirrhosis and hepatocellular carcinoma (HCC). However, disease-specific risk stratification tools are yet to be defined to guide HCC surveillance strategies in CHD.
Method: CHD patients with cirrhosis from the retrospective multi-center real-world European SAVE-D study were included. PAGE-B and AMAP scores were calculated at BLV start as previously described. PAGE-B was defined as low (<10) *vs.* intermediate (10–17) *vs.* high (≥18) risk profile. AMAP was defined as low (<50) vs. medium (50–59) vs. high (≥60) risk profile. HCC incidence rates in the different PAGE-B and AMAP groups during Bulevirtide (BLV) monotherapy were assessed. Patients with previous HCC were excluded.
Results: 391 patients with cirrhosis treated with BLV monotherapy up to 240 weeks were included: age 49 (IQR 40–57) years, 60% men, median platelet (PLT) count 102 (69–148) × 10^9/L. At BLV start, 117 (30%) patients had low risk PAGE B score, 255 intermediate risk (65%), and 19 (5%) had high-risk PAGE B score. Median PLT count in the PAGE B high risk score was 75 (60–90), median age 64 (62–67). AMAP score could be calculated in 387 patients: 10 patients (3%) had low risk AMAP score (3%), 84 (22%) intermediate, and 293 (76%) high risk AMAP score. During 240 weeks of BLV monotherapy, 17 de-novo HCC occurred. When analyzing incidence of de novo HCC according to HCC risk scores, 2 (12%) HCC developed in the PAGE-B low-risk group, 11 (65%) in the intermediate-risk group, and 4 (24%) in the high-risk group. The corresponding 240-week cumulative incidence in the 3 groups was 2.2%, 5.7%, and 30.9%, respectively. Concerning AMAP score, no HCC developed in the low-risk group, 1 (6%) in the intermediate risk score, and the remaining 16 (94%) in the high-risk score. No HCC occurred in the 4 patients for whom AMAP could not be calculated due to missing data. The corresponding 240-week cumulative incidence of HCC in the 3 AMAP groups was: 0%, 1.3% and 7.7%, respectively. Median time to HCC was 46 (39–100) weeks. At baseline lower albumin levels (HR 0.22, 95% CI 0.09–0.56, p = 0.001), higher bilirubin (HR 2.02; 95% CI 1.12–3.65, p < 0.001), and higher LSM (HR 1.05; 95% CI 1.02–1.08, p = 0.003) independently predicted HCC development.
Conclusion: PAGE-B and AMAP scores seem clinically useful in CHD patients HCC risk stratification during long-term BLV monotherapy.

Background and aims: Bulevirtide (BLV) was licensed in Italy in May 2023 for patients with chronic hepatitis delta (CHD), but no real-life studies have addressed differences in responses rates among patients with and without cirrhosis.
Method: CHD patients starting BLV 2 mg/day monotherapy were included in a multicenter prospective real-life Italian study (D-SHIELD). Patients' features and treatment responses were assessed at baseline and trimonthly afterwards. Virological response (VR) (≥2 LogIU/mL HDV-RNA decline *vs.* baseline or HDV RNA undetectable), biochemical and combined responses (BR and CR), incidence of virological breakthroughs (VBK; >1 Log HDV RNA increase *vs.* previous timepoint), and safety were assessed comparing patients with and without cirrhosis.
Results: 486 patients treated with BLV monotherapy up to 72 weeks from 46 centers were enrolled, 354 (73%) with cirrhosis and 132 without cirrhosis. At baseline, patients without cirrhosis were younger (56 *vs.* 50, p < 0.001), were less commonly treated with NA (91% *vs.* 98%, p < 0.001), had lower LSM values (8.0 *vs.* 15.8 kPa, p < 0.001) and higher HDV RNA levels (5.5 *vs.* 5.2 Log U/L p = 0.03). During BLV monotherapy, median HDV RNA and ALT levels declined to a similar extent in patients with and without cirrhosis (baseline 5.2 *vs.* 5.5 LogIU/mL and 74 *vs.* 75 U/L; week 72: 2.9 *vs.* 3.4 LogIU/mL and 31 *vs.* 33 U/L, respectively, p = ns at all timepoints). No significant differences were observed in VR, BR and CR rates at all timepoints in patients with and without cirrhosis, 70% *vs.* 63% patients achieving a VR (p = 0.24), 74% *vs.* 71% a BR (p = 0.36), and 60% *vs.* 47% a CR (p = 0.12). Only HDV RNA undetectability rates at week 72 differed (32% *vs.* 13% p = 0.01, p = ns for other timepoints). 3% (10/78) of patients with VR at week 24 experienced a VBK at week 48, all with cirrhosis; 15% (17/111) of those with a VR at week 48 experienced a VBK at week 72, 65% with cirrhosis (p = 0.08). No significant differences were observed in the incidence of adverse events among patients with and without cirrhosis, (15% *vs.* 15%, p = 1.00), with mild and transient pruritus and injection site reaction being the most common. Patients with cirrhosis showed higher baseline and on-therapy bile acids levels (p < 0.001 at all time-points).
Conclusion: The effectiveness and safety profile of BLV monotherapy did not differ in patients with or without compensated cirrhosis in this large prospective multicenter Italian study.

Email: tarik.asselah@bjn.aphp.fr

Background and aims: Bulevirtide (BLV) is approved in the European Economic Area and other regions for treating patients with chronic hepatitis delta (CHD). BLV monotherapy demonstrated favourable safety in an integrated safety analysis at week (W) 48 of two Phase 2 studies (MYR203 and MYR204) and one Phase 3 study (MYR301). Here, we present an integrated safety analysis of longer-term, W96 data from the MYR301 and MYR204 studies, focusing on BLV 2 mg and 10 mg monotherapy.
Method: In a pooled analysis at W96, treatment-emergent adverse events (AEs), serious AEs (SAEs), and laboratory abnormalities were assessed in participants (pts) treated with BLV 2 mg or 10 mg given subcutaneously once daily.
Results: A total of 199 pts were included in the W96 analysis: 49 received BLV 2 mg; 150 received BLV 10 mg. Baseline characteristics of BLV-treated pts: mean (SD) age 42 (8.4) years, 62% male, 84% White,

44% with compensated cirrhosis, 98% with hepatitis D virus (HDV) genotype 1; 53% were interferon-experienced; mean (SD) HDV RNA was 5.13 (1.345) $\log_{10}$ IU/mL, and mean (SD) alanine aminotransferase was 108 (79.7) U/L. Most AEs occurred by W48, with no new AEs reported between W48 and W96. At W96, AE rates remained similar between BLV 2 mg (96%) and BLV 10 mg (91%). The incidence of Grade ≥3 AEs at W96 was similar with BLV 2 mg (18%) and BLV 10 mg (17%), with the most frequent events being associated with background disease (neutropenia, leucopenia, thrombocytopenia). No SAEs were considered related to BLV. One pt (0.7%) in the BLV 10 mg group experienced an AE of myalgia considered related to BLV, which led to premature discontinuation by W96. The AE profile was generally consistent between groups. Injection-site reactions occurred at similar frequencies in the BLV 2 mg and 10 mg groups (20% vs 19%). Bile acid (BA) elevations were more pronounced with the BLV 10 mg dose, as expected based on the mechanism of action of BLV. However, BA levels were not associated with the presence or absence of AEs including pruritus or vitamin D deficiency. Safety outcomes were similar in pts with and without cirrhosis.

Conclusion: BLV monotherapy at both 2 mg and 10 mg was safe and well tolerated over 96 weeks, including in pts with compensated cirrhosis. Most AEs were mild to moderate in severity, and the incidence of Grade ≥3 AEs and SAEs was comparable across BLV dosage levels. No association was observed between BA levels and AEs of interest. These findings support the safety of longer-term BLV treatment for CHD.

Email: kalishabheemraj@gmail.com

Background and aims: To prevent liver-related deaths and new chronic infections, a major strategy for hepatitis B virus (HBV) elimination is the provision of antiviral therapy to suppress HBV viral load (VL). However, data on real-world virological effectiveness of antiviral therapy is lacking in Africa, the region lagging most in hepatitis elimination and with major social and structural barriers to achieving and sustaining viral suppression.

Method: We performed a longitudinal analysis of HIV negative individuals > 18 years, living with chronic HBV who initiated antiviral therapy and had at least one HBV DNA measurement during follow-up. Individual viral trajectories were observed over time on treatment and population-average was modelled using linear mixed-effects with natural splines for time on treatment, adjusting for age, sex and location. Viral suppression (VS) was defined as HBV DNA <50 IU/mL. VL monitoring were described as the proportion with available HBV DNA results, and among those with results, we described proportions with VS. Proportions of participants achieving first VS were evaluated across follow-up intervals defined by the maximum time point at which VL measurements were captured.

Results: Of 13,359 cohort individuals, 2077 were included in analysis. Median age was 34 years (IQR 28–43, 67% male). Median follow-up time on treatment was 2.61 years (IQR 1.16–4.75). Pre-treatment median HBV DNA (log10 IU/mL) was 3.88 (2.83–5.76). Rapid decline in mean HBV DNA was observed during the first year of therapy, followed by sustained suppression over time. Overall, 1256 (60%) achieved VS within 1–2 years of treatment. Proportion of participants with HBV DNA monitoring was 303 (15%) at 0–1 years, 354 (17%) at 1–2 years, 278 (13%) at 2–3 years and 1142 (55%) beyond 3 years. Among participants with available HBV DNA results, the proportion with complete suppression was 174/303 (57%) at 0–1 year, 270/354 (76%) at 1–2 years, 231/278 (83%) at 2–3 years and 1004/1142 (88%) beyond 3 years of monitoring.

Conclusion: VL monitoring of antiviral therapy for chronic HBV was suboptimal in Africa. Among those with monitoring, levels of viral suppression were comparable to clinical trials and other regions, supporting the feasibility of HBV elimination through treatment.

Bulevirtide effectiveness in hepatitis delta infection across geographic origins and genotypes: real-world data from Portugal

Mariana Cardoso[1], Joana Branco[2], Rúben Carvalho[3], Catarina Gouveia[4], Inês Costa Santos[5], Cristiana Margarida Fernandes Batouxas[6], Ana Aboim Horta[7], Francisco Javier Velasco Rubio[8], Mariana Machado[9], Pedro Filipe Mesquita[10], Dalia Fernandes[11], Alexandra Martins[2], Cristina Valente[3], Manuela Canhoto[4], Filipe Calinas[1]. *[1]Unidade Local de Saúde de São José, Lisbon, Portugal; [2]Unidade Local de Saúde de Amadora/Sintra, Amadora, Portugal; [3]Unidade Local de Saúde de Coimbra, Coimbra, Portugal; [4]Unidade Local de Saúde de Loures/Odivelas, Loures, Portugal; [5]Unidade Local de Saúde de Almada/Seixal, Almada, Portugal; [6]Unidade Local de Saúde do Nordeste, Bragança, Portugal; [7]Unidade Local de Saúde de Santo António, Porto, Portugal; [8]Unidade Local de Saúde do Algarve, Faro, Portugal; [9]Unidade Local de Saúde do Estuário do Tejo, Vila Franca de Xira, Portugal; [10]Unidade Local de Saúde de Gaia e Espinho, Vila Nova de Gaia, Portugal; [11]Unidade Local de Saúde de Braga, Braga, Portugal*
Email: marianafcardoso@gmail.com

Background and aims: The epidemiology of hepatitis delta virus (HDV) infection in Portugal is strongly influenced by immigration, notably from Western Africa, where HDV genotype 5 (HDV-5) predominates. Bulevirtide (BLV) has been available in Portugal for patients experienced or not eligible for interferon since 2022, initially for those with advanced fibrosis/cirrhosis and, since May 2025, for all fibrosis stages. Data on BLV efficacy in HDV genotypes other than HDV-1 remain limited. We aimed to characterize HDV patients treated with BLV, assess treatment effectiveness, and compare outcomes by geographic origin (Europe/Asia vs Africa).

Method: Multicentric retrospective study including patients who initiated BLV 2 mg between 2022 and 2025. Virological response (VR) was defined as undetectable HDV RNA or a ≥ 2 $\log_{10}$ decline, biochemical response (BR) as ALT < 40 IU/L, and complete response (CR) as VR plus BR. Group comparisons were performed using Fisher's exact test.

Results: Thirty-three patients (43 ± 10 years; 61% male) from 11 centres were included, with a median on-treatment follow-up of 53 weeks. Most patients were immigrants, from Africa (46%, mainly Guinea-Bissau), Eastern Europe (12%), and Central Asia (6%), while 36% originated from Portugal. Genotype was available in 14 patients: HDV-1 (n = 6; Portugal/Eastern Europe), HDV-5 (n = 7; Western Africa), and HDV-8 (n = 1; Southern Africa). HIV co-infection was present in 20%. Median liver stiffness was 16 kPa, and 73% were cirrhotic (Child-Pugh A). BLV was discontinued before w24 in 5 patients due to adverse events (n = 2), loss to follow-up (n = 1), or non-compliance (n = 2). In the subgroup of patients who reached w24 (n = 21), BR at w24, w48 and w72 were 67% (14/21), 63% (10/16) and 92% (11/12), VR were 38% (8/21), 64% (9/14) and 42% (5/12), and CR

were 24% (5/21), 33% (5/15) and 42% (5/12). Response rates at w24 in patients from Europe/Asia (n = 15; 6 genotyped as HDV-1) and Africa (n = 6; 3 genotyped as HDV-5) were compared: BR was 67% in both groups (p = 1.000), VR 47% vs 17% (p = 0.336), and CR 27% vs 17% (p = 1.000).
Conclusion: Response rates to BLV were globally comparable to published data. Despite not reaching statistical significance, VR was numerically inferior in patients from Africa compared with those from Europe/Asia, raising the hypothesis of genotype-related differences in BLV response. However, these findings are exploratory and limited by small sample size and incomplete genotyping, warranting confirmation in larger cohorts.

FRI-590
Modeling HBsAg during liver transplantation reveals insights into the role of HBIG and mechanisms of HBsAg clearance
Leeor Hershkovich[1], Sara Battistella[2], Adquate Mhlanga[1], Louis Shekhtman[1], Anna Pocurull Aparicio[2], Thais Leonel[2], Sergio Rodriguez-Tajes[2], Yilliam Fundora[3], Sabela Lens[2], Sofía Pérez-del-Pulgar[2], Scott Cotler[1], Harel Dahari[1], Xavier Forns[2].

Email: harel.dahari@gmail.com

Background and aims: Consensus is lacking on the optimal dose and duration of hepatitis B Immunoglobulin (HBIG) and even whether it is necessary in patients receiving nucleos(t)ide analogues (NUCs) during liver transplantation (LT). LT provides a unique clinical setting to observe HBsAg dynamics both in the anhepatic phase (AHP) and under controlled perturbations including HBIG administration, post-reperfusion phase (PRP), and immunosuppression. We aim to provide insights into the impact of HBIG on HBsAg serodynamics and its clearance mechanism via mathematical modeling of frequent HBsAg sampling during AHP and PRP.
Method: Seven LT recipients with undetectable HBV DNA were prospectively enrolled. All participants were treated with NUCs before and after LT, including 3 patients who additionally received an intravenous HBIG dose of 5000 IU during the AHP and on the first day post-LT, followed by daily 1000 IU doses until day 7 post-LT. We developed mathematical models to explain HBsAg clearance and to explore the impact of HBIG on HBsAg clearance during AHP and PRP.
Results: HBsAg remained at pre-AHP levels during AHP in patients who received NUCs alone. HBIG group had a median decline of ~1.2 log in the AHP, which was explained by modeling as a 23–60-fold enhancement of HBsAg clearance from circulation due to extra-hepatic clearance mechanisms. During PRP, HBsAg declined in a biphasic manner in all patients with a rapid 1st phase that lasted about 8 hours followed by a slower 2nd phase decline until HBsAg became undetectable. Participants who received HBIG had an estimated 4.3-fold higher rate of HBsAg decline during the 1st phase compared to no-HBIG patients. The HBIG group reached HBsAg undetectable earlier compared to the no-HBIG group (median 5 vs 52 days). Modeling suggested that HBsAg clearance during PRP occurs through hepatic and extrahepatic mechanisms. A majority (3/4) of patients in the no-HBIG group had a longer HBsAg $t_{1/2}$ (51–94 hours) compared to the HBsAg $t_{1/2}$ previously described in immunocompetent patients ($t_{1/2}$ range: 21–43 hours; PMID: 32398799).
Conclusion: HBIG enhances both hepatic and extra-hepatic mechanisms of HBsAg clearance in LT recipients. The relatively long HBsAg $t_{1/2}$ observed in LT recipients could reflect attenuation of immunologic clearance due to immunosuppressive medications. For patients with ~3 log HBsAg pre-LT, a single dose of 5000 HBIG pre-LT may be sufficient for yielding the HBsAg-suppressive effects of HBIG, which is an observation that requires confirmation.

Email: liyaping8605@xjtu.edu.cn

Background and aims: Chronic hepatitis B (CHB) is the leading cause of hepatocellular carcinoma (HCC) in China. Functional cure characterized by HBsAg loss may reduce long-term HCC risk, particularly in high-risk patients. However, evidence comparing peginterferon-based strategies with nucleos(t)ide analogue (NA) monotherapy in this population is limited. This study assessed short-term virological and serological responses to peginterferon alfa-2b (PegIFNα-2b) versus NA monotherapy in high-risk CHB patients, with ongoing evaluation of HCC outcomes.
Method: This ongoing prospective multicenter cohort study (ChiCTR2200066281) enrolled high-risk CHB patients from 21 hospitals in China. High-risk status was defined by a family history of cirrhosis or HCC, abnormal HCC serum markers, imaging-confirmed hepatic nodules, or HBV-related compensated cirrhosis. Patients received PegIFNα-2b (Pegbing®, Xiamen Amoytop Biotech Co., Ltd.)–based therapy (monotherapy or combined with NAs) or NAs monotherapy for ≥48 weeks, with planned HCC surveillance up to 4 years. The present analysis included patients completing 48 weeks, and primary endpoints were HBsAg decline and loss.
Results: A total of 538 patients were included, with 447 receiving PegIFNα-2b–based therapy and 91 receiving NAs monotherapy. Median age was 43.0 (35.0–51.0) years, 67.3% were male, and 34.6% were HBeAg-positive. Median baseline HBsAg and HBV DNA levels were 2.73 (2.06–3.39) and 1.54 (1.04–2.84) $\log_{10}$ IU/mL, respectively. At week 24, PegIFNα-2b treatment resulted in a greater median HBsAg decline than NA monotherapy (0.37 [0.00–1.40] vs. 0.00 [−0.02–0.05] $\log_{10}$ IU/mL; $p < 0.001$), with HBsAg decline ≥1.0 $\log_{10}$ and HBsAg loss in 30.9% and 13.4% of patients, respectively, while no HBsAg loss occurred in the NAs group. At week 48, PegIFNα-2b therapy remained superior, with greater HBsAg decline (0.57 [0.14–2.24] vs. 0.06 [-0.03–0.17] $\log_{10}$ IU/mL), higher rates of HBsAg decline ≥1.0 $\log_{10}$ (38.5% vs. 1.1%) and HBsAg loss (18.1% vs. 0%) (all $p < 0.001$). Complete virological response rates were comparable (58.5% vs. 47.8%, p = 0.170). Superior serological responses were observed with PegIFNα-2b across all high-risk subgroups (all $p < 0.01$). One case of HCC occurred within 48 weeks in a PegIFNα-2b treated patient with multiple baseline risk factors.

Conclusion: PegIFNα-2b therapy achieved higher HBsAg loss rates than NA monotherapy in high-risk chronic hepatitis B patients. Long-term follow-up is ongoing to evaluate its impact on hepatocellular carcinoma incidence.

FRI-592

Progressive decline of HBcrAg levels in patients with chronic hepatitis Delta long-term treated with Bulevirtide monotherapy

Email: elisabetta.degasperi@policlinico.mi.it

Background and aims: Serum HBcrAg has been proposed as a useful Hepatitis B virus (HBV) biomarker, however its role in patients with chronic hepatitis Delta (CHD) under Bulevirtide (BLV) treatment is currently unknown.
Method: CHD patients treated with BLV 2 mg/day monotherapy in a single center from the European SAVE-D study were enrolled. Serum HBcrAg levels were quantified by LUMIPULSE® G HBcrAg assay (Fujirebio Europe, LLOQ 3 Log_{10} U/mL). Virological (HDV RNA undetectable or ≥2 Log_{10} decline *vs.* baseline), biochemical (ALT < 40 U/L) and combined responses were assessed.
Results: 405 serum samples were collected from 79 patients treated with BLV up to Week (W) 144. At BLV start, median age was 55 (IQR 37–43) years, 53% males, 100% with cirrhosis, 100% on NUC, median ALT 97 (52–151) U/L, HBsAg 3.7 (3.4–3.9) Log_{10}IU/mL, 92% HBeAg-negative, 90% HBV DNA undetectable, HDV RNA 5.5 (4.2–6.2) Log_{10}IU/mL. HBcrAg tested positive in 63 (80%) patients [4.0 (3.5–4.8) Log_{10}U/mL]. HBcrAg positively correlated with HBsAg ($r = 0.37$, $p = 0.002$) and HDV RNA levels ($r = 0.30$, $p = 0.01$), but not with ALT or HBV DNA. At BLV W144, rates of virological, biochemical, combined response and HDV RNA undetectability were 70%, 64%, 52% and 33%, respectively. HBcrAg levels significantly declined during therapy: –0.31 Log_{10} (W48, $p = 0.02$), –0.63 Log_{10} (W96, $p = 0.003$), and –0.62 Log_{10} (W144, $p = 0.01$). HBcrAg levels did not correlate with HDV RNA levels at single on-treatment timepoints but maintained a positive correlation with HBsAg levels overtime (W48: $r = 0.35$, $p = 0.007$; W96: $r = 0.45$, $p = 0.006$; W144: $r = 0.50$, $p = 0.01$). Neither baseline nor on-treatment HBcrAg levels predicted virological response or HDV RNA undetectability rates during therapy. Overall, HBcrAg levels became negative in 10 patients (W48 in 5, W96 in 3; W144 in 2): at HBcrAg negativity, 7 had achieved a virological response (HDV RNA undetectable in 3). Conversely, HBcrAg levels became positive in 5 patients who tested negative at baseline (<3.5 Log_{10}U/mL in all cases; 4 at W48, 1 at W144): at HBcrAg positivity, 3 had achieved a virological response (HDV RNA undetectable in 2). No significant changes of HBsAg levels were observed during BLV.
Conclusion: In CHD patients with cirrhosis treated with BLV monotherapy up to W144, baseline low HBcrAg levels were detectable in most patients and correlated with HBsAg and HDV RNA. During BLV, HBcrAg levels declined and correlated with HBsAg levels, but not with HDV virological responses.

FRI-593

Therapeutic drug monitoring of Bulevirtide plasma levels in chronic hepatitis Delta patients

Elisabetta Degasperi[1], Amedeo De Nicolò[2], Dana Sambarino[1], Alice Palermiti[2], Alessandra Manca[2], Maria Paola Anolli[1], Marta Borghi[1], Riccardo Perbellini[1], Roberta Soffredini[1], Sara Monico[1], Floriana Facchetti[1], Antonio D'Avolio[2], Pietro Lampertico[1,3,4]. *[1]Division of Gastroenterology and Hepatology, Foundation IRCCS Ca' Granda Ospedale Maggiore Policlinico, Milan, Italy; [2]Laboratory of Clinical Pharmacology and Pharmacogenetics, Department of Medical Sciences, University of Turin, Turin, Italy; [3]CRC "A. M. and A. Migliavacca" Center for Liver Disease, Department of Pathophysiology and Transplantation, University of Milan, Milan, Italy; [4]D-SOLVE consortium, an EU Horizon Europe funded project (No 101057917), Milan, Italy*
Email: elisabetta.degasperi@policlinico.mi.it

Background and aims: Bulevirtide (BLV) monotherapy achieves efficient responses in patients with chronic hepatitis Delta (CHD), however little is known about plasma drug concentrations. Aim of the study was to evaluate BLV levels in CHD patients treated in a real-world setting.
Method: Consecutive CHD patients treated with BLV in an Italian center underwent single timepoint plasma sampling for BLV quantification between November 2024 and April 2025. BLV plasma levels were assessed through a validated ultra-high performance liquid chromatography coupled with tandem-mass spectrometry method (UHPLC-MS/MS).
Results: 72 CHD patients were enrolled: at sampling, median age was 56 (IQR 43–61) years, 53% males, BMI 25 (23–27), 81% with cirrhosis (100% CPT-A; CPT A6 in 28%), ALT 32 (26–43) U/L, bile acids 20 (9–36) µmol/L, vitamin D 16 (11–20) ng/mL, HBsAg 3.7 (3.1–3.9) Log_{10}IU/mL, HDV RNA 2.3 (0.7–3.3) Log_{10}IU/mL. Patients had been under BLV treatment for a median of 84 (72–138) weeks; 78% had achieved virological response, 24% target not detected. At sampling, 70/72 (97%) of the patients had detectable BLV plasma levels, overall median values were 1.8 (0.6–7.8) ng/mL. BLV levels did not correlate with age ($p = 0.17$), sex ($p = 0.78$), BMI ($p = 0.22$), and presence of cirrhosis ($p = 0.44$). Among the 56 patients with cirrhosis, BLV levels were similar across CPT subclasses [A5 vs A6: 1.5 (0.6–7.2) ng/mL *vs.* 4.5 (1.1–9.5) ng/mL, $p = 0.27$]. When analyzing biochemical and virological features at sampling, BLV levels did not correlate with ALT ($p = 0.44$), bile acids ($p = 0.67$), vitamin D ($p = 0.20$), and HDV RNA ($p = 0.74$), while there was a trend towards an inverse correlation with HBsAg levels ($r = 0.23$; $p = 0.06$). BLV levels did not differ according to time interval between BLV injection and sampling (≤12 *vs.* >12 hours, $p = 0.13$), and duration of BLV treatment: concentrations were 1.5 (0.8–2.9) ng/mL in patients treated with BLV for ≤48 weeks *vs.* 2.9 (1.5–8.6) ng/mL for 49–96 weeks *vs.* 1.7 (0.6–9.3) ng/mL for 97–144 weeks *vs.* 0.6 (0.4–2.5) ng/mL for >144 weeks, respectively ($p = 0.13$). BLV levels were also independent of virological response ($p = 0.67$).
Conclusion: In a preliminary cross-sectional single-timepoint analysis of BLV concentrations performed in a single-center cohort of CHD patients, BLV plasma levels were quantifiable in 97% of patients 12–24 hours after the last administration but did not significantly correlate with patient features and/or virological outcomes.

Email: scott.fung@uhn.ca

Background and aims: Tenofovir alafenamide (TAF) is a preferred first-line antiviral for chronic hepatitis B virus (HBV) infection, particularly for patients at risk for bone- or kidney-related adverse events (AEs) associated with tenofovir disoproxil fumarate (TDF), including those of older age. This analysis focused on outcomes in patients aged ≥ 60 years (Y) enrolled in two 8Y clinical trials of TAF.
Method: Patients were randomised to receive TAF 25 mg or TDF 300 mg once daily for 2Y or 3Y, then open-label TAF through Y8. Efficacy (HBV DNA < 29 IU/mL) and open-label safety (AEs, changes in hip and spine bone mineral density [BMD] and estimated glomerular filtration rate [Cockcroft-Gault method; $eGFR_{CG}$]) were assessed for older (≥60Y) vs younger (< 60Y) patients.
Results: Of 1632 patients, 91 (6%) were aged ≥ 60Y. Patients ≥ 60Y had higher rates of comorbidities and lower baseline renal function and BMD than those aged <60Y. At Y8, virologic suppression rates in all treatment groups were 100% and 93%–96% among older and younger patients, respectively. Treatment-related AE incidence was similar across age groups. Older patients experienced greater declines in $eGFR_{CG}$ and hip and spine BMD than younger patients and had smaller decreases with TAF vs TDF. In older patients receiving continuous TAF, median $eGFR_{CG}$ change from baseline was −6.1, −3.1, and −12.1 mL/min at Y2, Y3, and Y8; median changes from baseline in hip and spine BMD were −0.43% and −0.89% at Y2, −1.46% and 0.00% at Y3, and −2.70% and +1.51% at Y8. Among older patients who received TDF for 2Y, median $eGFR_{CG}$ change from baseline was −6.7 mL/min at Y2; after switching to TAF, it improved to −2.1 mL/min at Y3 and was −7.5 mL/min at Y8; median changes from baseline in hip and spine BMD were −2.06% and −5.36% at Y2 and improved to −0.45% and −1.60% at Y3, and +0.68% and +3.46% at Y8. Older patients who received TDF for 3Y showed median $eGFR_{CG}$ change from baseline of −10.6 mL/min at Y3; it improved to −6.7 mL/min at Y4 after switching to TAF and was −9.2 mL/min at Y8; median changes from baseline in hip and spine BMD were −1.82% and −1.51% at Y3, −2.45% and −0.39% at Y4, and −3.04% and +3.46% at Y8.
Conclusion: TAF is effective and well tolerated in patients with chronic HBV aged ≥ 60Y followed for up to 8Y. Switching from TDF to TAF stabilised or modestly improved renal and bone parameters, supporting guideline recommendations.

FRI-595

Validation of a sequencing-based HBV genotyping assay with serological backup for DNA-suppressed patients

Sanne Gils[1], Joël Meyboom[1], Bernhard Kleter[1]. *[1]Cerba Research, Rijswijk, Netherlands*
Email: sanne.vangils@cerbaresearch.com

Background and aims: HBV genotyping traditionally relies on sequencing plasma HBV DNA. However, in clinical trials aiming for functional cure in virologically suppressed individuals, HBV DNA is often undetectable, creating a need for alternative approaches. HBV RNA remains detectable in a subset of these patients, offering an opportunity for genotyping when DNA is absent. Our goal was to validate a sequencing assay using HBV plasma and serum samples containing both RNA and DNA; we also implemented a serological backup method to ensure genotype determination for samples that failed amplification.
Method: For the primary assay, reverse transcription was performed on extracted HBV RNA and DNA, followed by outer and nested PCR amplification of a fragment spanning the S-gene and RT-domain. Libraries were prepared from the PCR products and sequenced using Illumina short-read technology. Genotypes were assigned through phylogenetic analysis against reference sequences. When amplicons are negative, genotyping is performed using the IMMUNIS HBV Genotype EIA, which detects genotype-specific PreS2 epitopes to classify genotypes A–D.
Results: The primary sequencing assay resulted in a sensitivity of 79 copies/mL of HBV RNA and 6 copies/mL of HBV DNA. For the IMMUNIS HBV Genotype EIA assay the sensitivity of the kit insert, 3 IU/mL, was confirmed. Sequencing was successful on the panel of 15 samples containing genotypes A-G. IMMUNIS provided accurate results for genotypes A–D. Genotypes E and G were classified as D, and F was unclassified, as expected from kit limitations.
Conclusion: The combined approach of sequencing and serological backup provides a robust solution for HBV genotyping in virologically suppressed individuals. By using HBV RNA for sequencing and IMMUNIS when amplification fails, this workflow ensures reliable genotype determination across diverse clinical scenarios. This strategy supports accurate monitoring in trials evaluating new therapeutic regimens aimed at achieving functional cure.

FRI-596

Effects of retreatment on HBsAg loss following Nucleos(t)ide analogue withdrawal: a multicenter cohort study accounting for time-varying confounding

Yao-Chun (Holden) Hsu[1], Ying-Nan Tsai[2], Jia-Ling Wu[1], Cheng-Hao Tseng[2], Edo J. Dongelmans[3], Harry L. A. Janssen[3], Tzeng-Hue Yang[4], Teng-Yu Lee[5], Jen-Hao Yeh[6], Tzu-Haw Chen[1], Mindie Nguyen[7], Jaw-Town Lin[1]. *[1]E-Da Hospital, I-Shou University, Kaohsiung, Taiwan; [2]E-Da Cancer Hospital, Kaohsiung, Taiwan; [3]Erasmus MC University Medical Center Rotterdam, Rotterdam, Netherlands; [4]Lotung Poh-Ai Hospital, Yilan, Taiwan; [5]Taichung Veterans General Hospital, Taichung, Taiwan; [6]E-Da DaChang Hospital, Kaohsiung, Taiwan; [7]Stanford University, Stanford, United States*
Email: holdenhsu@gmail.com

Background and aims: Nucleos(t)ide analogue (NA) withdrawal in patients with chronic hepatitis B (CHB) may promote HBsAg loss but often triggers viral reactivation requiring reinitiation of antiviral therapy. Whether retreatment affects the probability of achieving HBsAg loss remains unclear. We aimed to estimate the causal effect of retreatment on HBsAg loss.
Method: Non-cirrhotic CHB patients who discontinued first-line NAs according to Asian-Pacific standards after ≥2 years of continuous therapy and virological suppression were prospectively enrolled at 5 hospitals in Taiwan between 2011/08/19 and 2025/12/18, with serial

collection of data and biopecimens. The primary outcome was HBsAg loss (<0.05 IU/mL by a quantitative assay). The decision for retreatment was largely guided by the national reimbursement criteria. Patients were also followed for virological relapse (VR), clinical relapse (CR), and ALT flare (ALT >200 U/L). Time-dependent Cox models were developed with laboratory data updated at 3-month intervals. We employed marginal structural model (MSM) with inverse probability of treatment weighting to estimate the effect of retreatment on HBsAg loss.

Results: This analysis enrolled 234 patients followed for a median duration of 6.9 years. Among them, 172 (73.5%), 123 (52.6%), and 61 (26.1%) experienced VR, CR, and ALT flare, respectively, with 10-year cumulative incidences of 78.2% (95% CI, 72.2–83.7%), 60.2% (95% CI, 52.2–68.3%), and 33.1% (95% CI, 25.6–42.1%), respectively. Overall, 118 (50.4%) patients restarted treatment and 38 (16.2%) cleared HBsAg, with 10-year cumulative incidences of 61.1% (95% CI, 52.9–69.4%) and 27.0% (95% CI, 20.0–35.8%), respectively. Time-varying HBsAg (adjusted HR, 1.16 per log IU/mL), time-varying ALT (adjusted HR 1.70 per log U/L), and age (adjusted HR, 1.02 per year; 95% CI, 1.004–1.03) independently predicted retreatment following VR. In the MSM analysis, retreatment was not significantly associated with HBsAg loss (adjusted OR, 0.51; 95% CI 0.17–1.51; p = 0.223), while HBsAg levels remained the dominant significant factor (adjusted OR, 0.23 per log IU/mL; p < 0.001).

Conclusion: Reinitiating antiviral therapy after NA cessation was not independently associated with HBsAg loss after accounting for time-varying confounding. The probability of HBsAg loss was predominantly determined by HBsAg levels regardless of retreatment, indicating that clinicians can reinitiate treatment when clinically indicated without undue concerns of reducing patients' prospects for HBsAg loss.

FRI-597

Impact of baseline hepatic steatosis on Peg-IFN-α therapy efficacy in chronic hepatitis B: a cohort study

Tiantian Hu[1,2], Yuqi Liu[1,2], Jie Tong[1], Baoyue Sheng[1], Haoxiang Zhu[1,2], Jinyu Wang[1,2], Jiming Zhang[1,2,3]. *[1]Department of Infectious Diseases, Shanghai Key Laboratory of Infectious Diseases and Biosafety Emergency Response, National Medical Center for Infectious Diseases, Huashan Hospital, Fudan University, Shanghai, China; [2]Shanghai Institute of Infectious Diseases and Biosecurity, Key Laboratory of Medical Molecular Virology (MOE/MOH), Shanghai Medical College, Fudan University, Shanghai, China; [3]Department of Infectious Diseases, Jing'An Branch of Huashan Hospital, Fudan University, Shanghai, China*
Email: 23111170004@m.fudan.edu.cn

Background and aims: Pegylated interferon-α (Peg-IFN-α) achieves functional cure in a minority of HBeAg-negative chronic hepatitis B (CHB) patients. Hepatic steatosis may influence host immunity and antiviral response. This study evaluated whether baseline controlled attenuation parameter (CAP), as a surrogate of hepatic steatosis, predicts 48-week HBsAg clearance during Peg-IFN-α therapy.

Method: We conducted a two-center observational cohort combining a retrospective cohort (2015–2020) and a prospective cohort (2021–2022). HBeAg-negative CHB patients with baseline CAP, HBV DNA ≤ 10,000 IU/mL, and HBsAg ≤ 3000 IU/mL receiving standard Peg-IFN-α for 48 weeks were included. Clinical, virologic, and FibroScan®-derived indices were collected at baseline and follow-up. The primary endpoint was rate of HBsAg clearance at week 48; secondary endpoints included 1 $\log_{10}$ IU/mL HBsAg decline at week 48. All analyses were performed in R (version 4.4.1; R Foundation for Statistical Computing, Vienna, Austria) with RStudio (Posit, Boston, USA).

Results: A total of 413 patients were included in the analysis, comprising 275 retrospective and 138 prospective cases. The overall HBsAg clearance rate at week 48 was 24.7% (102/413). Low CAP (≤259 dB/m) was significantly associated with higher rates of HBsAg clearance in both cohorts (retrospective: 26.39% vs. 17.8%, $p = 0.023$; prospective: 30.83% vs. 6.25%, $p = 0.041$). Kaplan–Meier analysis demonstrated significantly higher cumulative HBsAg clearance and ≥1 $\log_{10}$ decline in HBsAg in patients with low CAP compared with those with higher CAP values (all log-rank $p < 0.05$).

Conclusion: Lower baseline hepatic steatosis, reflected by CAP ≤259 dB/m, independently predicts superior HBsAg clearance and serologic response to Peg-IFN-α therapy at week 48 in HBeAg-negative CHB patients. CAP may serve as a noninvasive marker for response stratification.

FRI-601

Real-world 12-month outcomes of Bulevirtide therapy in chronic hepatitis D: interim results from a prospective romanian cohort

Liana Gheorghe[1,2], Mihaela Ghioca[2], Mirela Chitul[1], Anca Trifan[3,4], Laura Huiban[3,4], Daniela Larisa Sandulescu[5], Ionut Gheonea[5], Corina Radu[6], Bogdan Procopet[6], Roxana Sirli[7], Corina Pop[1,8], Nicoleta Tiuca[1,8], Bogdan Ungureanu[5], Adina Turcu-Stiolica[5], Speranta Iacob[1,2]. *[1]Carol Davila University Of Medicine And Pharmacy, Bucharest, Romania; [2]Fundeni Clinical Institute, Bucharest, Romania; [3]Spitalul Clinic Județean de Urgență Sfântul Spiridon Iași, Iași, Romania; [4]Universitatea de Medicină și Farmacie 'Grigore T. Popa' Iași, Iași, Romania; [5]Universitatea de Medicina și Farmacie Craiova, Craiova, Romania; [6]Iuliu Hațieganu University of Medicine and Pharmacy, Cluj-Napoca, Romania; [7]Universitatea de Medicină și Farmacie Victor Babeș, Timișoara, Romania; [8]Spitalul Universitar de Urgență București, București, Romania*
Email: drlgheorghe@gmail.com

Background and aims: Chronic hepatitis D (CHD) remains a severe form of viral hepatitis with limited real-world data on bulevirtide (BLV) effectiveness and on-treatment predictors of response. The ENHANCE D study is an ongoing multicenter, observational trial designed to evaluate virologic, biochemical and clinical outcomes, together with adherence, persistence and quality of life, in CHD patients treated with BLV 2 mg subcutaneously once daily in routine Romanian practice.

Method: Adults with confirmed HDV infection and detectable HDV RNA starting bulevirtide 2 mg daily were enrolled across 5 Romanian centers with planned 12-month follow-up at baseline, month 6 and month 12. Interim analyses included 177 patients with available clinical and laboratory data, assessing changes in ALT, AST, HDV RNA and FibroScan over time and exploring baseline predictors of virological response. Adherence and quality of life (QoL) were prespecified outcomes, but remain under analysis.

Results: We enrolled 177 patients (57.1% male), with 51.4% from Bucharest and 40.1% from Iași, reflecting national referral patterns for chronic hepatitis D. Baseline fibrosis stage, steatosis grade, comorbidities (diabetes, hypertension), and prior antiviral therapy did not differ by gender, but alcohol use/history was more frequent in males (p = 0.0033). At baseline, 67.8% had Child-Pugh A cirrhosis, and 12.5% had clinically significant portal hypertension (liver stiffness >25 kPa). Esophageal varices were significantly more common in males (67.1% vs 45.9%, p = 0.01). A virologic response (HDV RNA decline >2log) was achieved in 53.4%, and 21.9% had a partial response (1–2log decline). ALT and AST levels decreased significantly by months 6 and 12 (p < 0.0001), along with a modest but significant reduction in liver stiffness (p = 0.01). The only baseline factor significantly associated with a >2 log HDV RNA decline was lower GGT, independently predictive of virologic response (132.6 ± 129.4 vs 186.7 ± 151.8 U/L, p = 0.036); other demographic, virologic, and liver disease parameters showed no significant associations.

Conclusion: In this real-world cohort, BLV demonstrated robust antiviral and biochemical effectiveness over 12 months. While no major baseline predictors of virologic response were identified, lower GGT levels were significantly associated with response, suggesting a potential role as predictive marker of virologic response. Analyses of adherence and QoL are ongoing and expected to refine patient profiling strategies.

Email: dryuriim@gmail.com

Background and aims: The sodium taurocholate co-transporting polypeptide (NTCP) serves as the hepatic entry receptor for hepatitis D virus (HDV) and represents the target of bulevirtide (BLV). Genetic variants of NTCP may influence disease progression and treatment response. The aim of this ongoing study is to analyse the association between NTCP polymorphisms, disease severity, and BLV effectiveness in a real-world chronic hepatitis D (CHD) cohort.

Method: Adults with CHD from 21 centres in Germany, Austria, and Switzerland were consecutively enrolled between 10/2021 and 10/2025. NTCP genotyping for rs17556915 (A/G) was performed using Sanger sequencing. Clinical outcomes including liver cirrhosis, portal hypertension, and hepatocellular carcinoma (HCC) were recorded. In patients receiving BLV (2 mg/day), treatment response was defined as virological (greater than or equal to 2 log HDV-RNA decline), biochemical (ALT normalisation), combined (both), or non-response. Here, we describe the results of the baseline data.

Results: A total of 68 adults were included: 46/68 (68%) were male, 38/60 (63%) had liver cirrhosis, 16/53 (30%) suffered from portal hypertension, and 3/65 (3%) had HCC. HDV genotype was 1 in 41/53 (77%), 1d in 5/53 (9%), and 5 in 7/53 (17%). NTCP rs17556915 genotyping was available in 53 patients: GG was found in 41/53 (77%) and AG in 12/53 (23%); no AA homozygotes were detected. A larger proportion of patients with GG genotype suffered from cirrhosis (63% vs 36%), portal hypertension (34% vs 6%), and HCC (5% vs 0%) compared to AG carriers. 52/66 patients (79%) received BLV therapy. The overall virological response rate was 85% (35/41), but varied between GT1 (92%, 24/26), GT1d (33%, 2/3), and GT5 (67%, 1/3). Among patients with NTCP data, combined/virological response was achieved in 39% (9/23) of GG carriers versus 17% (4/6) of AG carriers.

Conclusion: In this multicentre CHD cohort, the NTCP rs17556915 GG genotype was associated with more severe liver disease but showed a trend towards higher BLV response rates compared to AG carriers. HDV GT5 was associated with treatment failure. These findings suggest that both host and viral genetic factors may serve as predictors of disease progression and treatment response in CHD.

FRI-603

Liver-related mortality and transplantation risk associated with self-discontinuation of nucleos(t)ide analogue therapy in HBeAg-negative chronic hepatitis B

Rachel Wen-Juei Jeng[1,2], Yen-Chun Liu[1,2], Chia-Ling Wu[1], Cheng Er Hsu[1,2], Chung-Wei Su[1,2], Rong-Nan Chien[1,2], Yun-Fan Liaw[1,2]. *[1]Linkou Chang Gung Memorial Hospital, Guishan District, Taiwan; [2]Chang-Gung University, Guishan District, Taiwan*
Email: rachel.jeng@gmail.com

Background and aims: Self-discontinuation of nucleos(t)ide analogue (Nuc) therapy without proper monitoring and loss to follow-up (LTFU) occur in real-world practice; the 10-year cumulative incidence approached 20% in HBeAg-ngative chronic hepatitis B (CHB) in our prior report. Long-term outcomes such as liver-related mortality and transplantation (LT) remain insufficiently defined. We aimed to evaluate the association between self-discontinuation/LTFU and liver-related mortality/LT in a large multi-center cohort with complete mortality ascertainment.

Method: Using the Chang Gung Research Database, we included HBeAg-negative CHB patients receiving entecavir or tenofovir (TDF/TAF) for ≥3 months (Jan 2004–Nov 2021) at three hospital branches. We excluded antiviral prophylaxis for chemotherapy/immunosuppression, HCV/HDV/HIV coinfection, or hepatocellular carcinoma within 5 years before NUC initiation. Time zero was first NUC initiation. Self-discontinuation/LTFU was failure to refill NUC for ≥2 consecutive months (chart-confirmed) and modelled as a time-varying exposure. Marginal structural models with stabilized inverse probability weighting were used to adjust time-varying confounders. Liver-related mortality and LT were ascertained via linkage to the national Cause of Death Registry; competing risks accounted for non–liver-related death.

Results: We included 1897 patients with 2211 treatment courses (ETV 1686; TDF/TAF 525). During median follow-up 2.17 years (IQR 1.22–3.01), 399 self-discontinuation/LTFU events occurred and 57 patients experienced liver-related death or LT. Annual liver-related mortality/LT incidence was higher with self-discontinuation than physician-guided therapy (3.32% vs 0.46%), in both cirrhosis (4.68% vs 1.80%) and non-cirrhosis (1.39% vs 0.03%) (all $P < 0.01$). In IPW-MSM analyses, self-discontinuation/LTFU was associated with increased risk of liver-related mortality/LT [subdistribution HR(sHR) 3.47, 95% CI 1.99–6.06; $P < 0.001$]. A dose–response relationship was observed, with increasing numbers of self-discontinuation/LTFU events associated with progressively higher risk (sHR 2.91, 95% CI 1.86–4.56; $P < 0.001$).

Conclusion: In HBeAg-negative CHB patients on long-term Nuc therapy, self-discontinuation/LTFU was independently associated with a markedly increased, dose-dependent risk of liver-related mortality/LT. Maintaining linkage to care is essential; structured, physician-guided finite therapy with scheduled monitoring is a much safter strategy when Nuc discontinuation is considered.

FRI-604

Untreated HBV-infected advanced fibrosis, if HBV-DNA is detectable, has HCC risk comparable to antivirals-treated cirrhosis

Seung Up Kim[1], Beom Kyung Kim[1], Victor de Lédinghen[2], Terry Cheuk-Fung Yip[3], Vincent Wai-Sun Wong[3]. *[1]Yonsei University College of Medicine, Seoul, Korea, Rep. of South; [2]Hospital Center University de Bordeaux, Bordeaux, France; [3]The Chinese University of Hong Kong, Sha Tin, Hong Kong*
Email: wongv@cuhk.edu.hk

Background and aims: The European Association for the Study of the Liver guideline on hepatitis B virus (HBV) recommends antiviral therapy (AVT) for advanced fibrosis (AdvF) with detectable HBV-DNA, which is a routine AVT criterion applied for liver cirrhosis (LC). Here, we compared hepatocellular carcinoma (HCC) risk between patients with untreated viremic AdvF vs. AVT-treated LC, with external validation.
Method: We assessed HCC risk for South Korean patients with untreated viremic AdvF not fulfilling conventional AVT criteria (n = 302), compared to AVT-treated LC ones (n = 1694). All belonged to Child-Pugh A. LC was defined using gross finding on imaging study or liver stiffness (LS) > 11 kPa. AdvF was as LS 8∼11 kPa without gross LC finding. Multivariable Cox-regressions and propensity-score (PS) matching (2:1) were used for comparison.
Results: In multivariable analyses, untreated viremic AdvF patients demonstrated HCC risk comparable to AVT-treated LC (adjusted hazard ratios [aHRs] 0.66∼0.70, all $P > 0.05$), irrespective of LS adjustment. Male, higher FIB-4, lower albumin, and higher bilirubin were independently associated with HCC risk. Likewise, in the Hong Kong cohort, untreated viremic AdvF patients (n = 103) showed HCC risk comparable to AVT-treated LC (n = 199) (aHR 0.94∼0.97, all $P > 0.05$), irrespective of LS adjustment. Male and lower albumin were independently associated with HCC risk. PS-matching confirmed these results in both cohorts (all P > 0.05).
Conclusion: Across two independent East-Asian cohorts, untreated viremic AdvF patients demonstrated HCC risk comparable to AVT-treated LC. So, AVT should be considered for viremic AdvF, although conventional AVT criteria are not met. Further prospective studies are required.

FRI-605

Impact of bulevirtide treatment on patient-reported outcomes among patients with hepatitis delta in Europe

Maria Buti[1,2], Fritha Hennessy[3], Tia Pennant[3], Daniel Graham[3], Fraser Barrable[3], Alastair Hinds[3], Caroline Burk[4], Chong Kim[4], Marvin Rock[4], Pietro Lampertico[5,6]. *[1]Liver Unit, Hospital Universitario Vall d'Hebron, Barcelona, Spain; [2]Centro de Investigación Biomédica en Red de Enfermedades Hepáticas y Digestivas (CIBEREHD) del Instituto Carlos III, Madrid, Spain; [3]Adelphi Real World, Bollington, United Kingdom; [4]HEOR – Global Value & Access, Gilead Sciences, Inc., Foster City, United States; [5]Division of Gastroenterology and Hepatology, Foundation IRCCS Ca' Granda Ospedale Maggiore Policlinico, Milan, Italy; [6]CRC "A. M. and A. Migliavacca" Center for Liver Disease, Department of Pathophysiology and Transplantation, University of Milan, Milan, Italy*
Email: pietro.lampertico@unimi.it

Background and aims: Bulevirtide (BLV) treatment improves virologic and biochemical responses in patients (pts) with hepatitis delta virus (HDV) infection. Evidence on the effect of BLV on health-related quality of life (HRQoL) is limited. We describe HRQoL outcomes of pts with HDV infection who received BLV or were treatment naïve (TN).
Method: Data were drawn from the Adelphi Real World Hepatitis II Disease Specific Programme™, a cross-sectional survey with retrospective data collection of physicians and their pts with HDV infection, from Jun–Dec 2024. Physicians provided data on ≤ 4 pts seen during routine care—2 prescribed BLV and 2 regardless of treatment status; BLV vs TN was analysed. Descriptive analyses included physician-reported pt demographics and HRQoL impact via pt-reported outcome measures (PROMs). The effect of BLV was estimated using bivariate analyses and inverse probability weighted regression adjustment (IPWRA; covariates: gender, born/lived in a high-risk region, time since hepatitis B diagnosis, and mild symptoms at diagnosis).
Results: Overall, 68 physicians (France, 9; Germany, 35; Italy, 7; Spain, 12; UK, 5) reported data on 195 pts (France, 22; Germany, 100; Italy, 19; Spain, 26; UK, 28). Mean (SD) pt age was 41 (12.9) years; 71% were male and 75% were White. Mean (SD) Hepatitis B QoL (HBQoL) global scores (0–100 scale; 100 = worst HRQoL) were significantly lower for BLV-treated (34.4 [18.7]) vs TN pts (42.5 [13.9]; bivariate analysis, p = .005; IPWRA, p < .001). In bivariate analyses, HBQoL scores for anticipation anxiety (p = .010), vitality (p = .004), stigma (p = .017), vulnerability (p = .017), transmission (p = .014), and viral response (p = .018) were lower in BLV-treated vs TN pts. Mean (SD) EQ-5D Visual Analog Scale (0–100 scale; 100 = best health) and EQ-5D 5-Level Germany (−0.661 to 1 scale; 1 = best health) scores showed no significant differences between groups (BLV, 69.2 [18.1] and 0.9 [0.2]; TN, 72.0 [17.7] and 0.9 [0.2], respectively; p >.05). No differences were observed between BLV-treated and TN pts in mean (SD) Work Productivity and Activity Impairment scores (0–100% scale; 100% = severe impairment) for overall work impairment (BLV, 28.5% [23.4%]; TN, 28.5% [25.1%]; p >.05) or Fatigue Severity Scale scores (scores ≥ 36 = fatigue; BLV, 35.9 [15.1]; TN, 35.6 [13.6]; p >.05).
Conclusion: Unlike generic and symptom-specific PROMs, which may be less sensitive, disease-specific PROMs show that BLV was associated with a positive effect on pt HRQoL at the survey date.

FRI-606

Pipecolic acid–associated amino acid remodeling predicts functional cure in nucleoside analogue–experienced chronic hepatitis B treated with pegylated interferon alpha plus programmed cell death protein 1 blockade

Yaping Li[1], Bin Cheng[2], Chenrui Liu[1], Meng Zhang[1], Muqi Wang[1], liu Yang[1], Xinyu Wang[1], Guoe Gou[1], Mei Li[1], Xiaoli Jia[1], Junliang Fu[3], Mengji Lu[2], Shuangsuo Dang[1]. *[1]The second affiliated hospital of Xi'an Jiaotong University, Xi'an, China; [2]University Hospital Essen, Essen, Germany; [3]The fifth medical center of Chinese PLA General Hospital, Beijing, China*
Email: liyaping8605@xjtu.edu.cn

Background and aims: Functional cure of chronic hepatitis B (CHB) remains rare under long-term nucleos(t)ide analogue (NA) therapy, and add-on pegylated interferon-α (Peg-IFN-α) achieves only modest improvements. PD-1 blockade has emerged as one of the most promising strategies for achieving functional cure, possibly by enhancing antiviral T-cell responses. This prospective study aimed to identify biomarkers associated with functional cure in NA-experienced patients who remained uncured after NA plus Peg-IFN-α therapy and subsequently received PD-1 blockade added to Peg-IFN-α.
Method: Twenty NA-experienced CHB patients who did not achieve HBsAg clearance after 48 weeks of NA plus Peg-IFN therapy continued NA and Peg-IFN-α through week 72, with add-on PD-1 inhibitor sintilimab (1.0 mg/kg, Q12w) administered at weeks 48 and 60. Plasma samples collected at T0-T3 (baseline, week 48, 60 and 72) underwent targeted metabolomics analysis, alongside parallel virological, biochemical, and immunological assessments. Functional cure was defined as sustained HBsAg loss and undetectable HBV DNA.
Results: By week 72, 6/20 patients (30%) achieved functional cure and maintained remission through week 96. OPLS-DA analysis at T3 showed a separation trend between cured and uncured groups, consistent with metabolite- and pathway-level differences. Targeted metabolomics identified differential amino acids distinguishing cured from uncured patients, including L-pipecolic acid, L-lysine, L-

aspartic acid, L-tryptophan, L-phenylalanine, and L-methionine. SMPDB-based pathway enrichment identified lysine degradation as the top pathway. Within this pathway, L-pipecolic acid showed the greatest increase in cured individuals (FC = 2.55, $p = 7.1 \times 10^{-4}$), while its precursor L-lysine decreased (FC = 0.24, p = 0.015). Correlation analysis showed that L-pipecolic acid inversely correlated with HBsAg (T3 r = –0.482, $p < 0.05$) and $CD8^{+}PD\text{-}1^{+}$ T cells (T3 r = –0.599, $p < 0.05$), whereas L-lysine negatively correlated with HBsAg at T2 and T3 (r = –0.57 and –0.576, respectively).
Conclusion: Sequential PD-1 blockade combined with Peg-IFN-α was associated with distinct amino acid metabolic alterations. L-pipecolic acid emerged as the most prominently increased metabolite in patients achieving functional cure and was consistently associated with HBsAg decline and immune activation. These findings suggest L-pipecolic acid as a potential metabolic biomarker of treatment response, warranting validation in larger cohorts and mechanistic studies.

FRI-607
End-of-treatment HBsAg level predicts functional cure and clinical relapse but not severe flare risk after Nucleos(t)ide analogue cessation in chronic hepatitis B
Hsin-Che Lin[1], Yen-Chun Liu[1], Rachel Wen-Juei Jeng[1], Rong-Nan Chien[1], Yun-Fan Liaw[1]. [1]*Linkou Chang Gung Memorial Hospital, Guishan District, Taiwan*
Email: rachel.jeng@gmail.com

Background and aims: Previous studies showed lower end-of-treatment (EOT) HBsAg levels, especially <100 IU/mL, associates with lower clinical relapse (CR) and higher HBsAg loss rate. A recent study involving 97 patients reported that only EOT qHBsAg <10 IU/mL, not 100 IU/mL, was significantly associated with low CR and higher HBsAg loss. This study aimed to test this unique finding in our large cohort of off Nucleos(t)ide Analogue (Nuc) HBeAg-negative patients.
Method: We included 1245 HBeAg-negative CHB patients who stopped therapy according to APASL guidelines and were stratified by EOT qHBsAg levels. CR was defined as HBV DNA ≥2000 IU/mL with ALT > 2x the upper limit of normal (ULN). Hepatitis flare was defined as HBV DNA ≥2000 IU/mL with ALT ≥5x ULN. Severe hepatitis flare was defined as ALT ≥1000 U/L or flare with ALT <1000 U/L with total bilirubin ≥3.5 mg/dL and/or INR ≥1.5. Kaplan-Meier analysis and log-rank tests were used to compare outcomes.
Results: Among 1245 patients, 1041 (84%) were male and 279 (23%) had cirrhosis. EOT qHBSAg <10 IU/mL were seen in 39 patients (3%), 10–100 IU/mL in 175 patients (14%), 101–1000 IU/mL in 762 patients (61%), and >1000 IU/mL in 269 patients (22%). Compared with EOT HBsAg 10–100 IU/mL patients, those with EOT HBsAg <10 IU/mL had lower proportion of pre-treatment HBsAg <1000 IU/mL (56% vs 73%, p = 0.039) and higher proportion of genotype C infection (23% vs 8%, p = 0.007). Age, sex, cirrhosis prevalence, pre-treatment HBV DNA level, treatment duration, and consolidation time were comparable between the two lowest HBsAg groups (all $p > 0.05$). The 5-year cumulative incidence of CR and hepatitis flare decreased progressively with lower EOT HBsAg levels [CR: 21% vs 43% vs 66% vs 73%, $p < 0.05$; flare: 19% vs 25% vs 47% vs 56%, $p < 0.01$]. The 5-year cumulative incidence of HBsAg loss was markedly higher in the <10 IU/mL group (59% vs 18% vs 12% vs 0%, $p < 0.01$). Importantly, the 5-year cumulative incidence of severe HBV flare (6% vs 6% vs 10% vs 8%, p = 0.32) and severity (median peak ALT: 260 vs 593 vs 420 vs 394 U/L, p = 0.21) were comparable across all EOT HBsAg groups.
Conclusion: Lower EOT HBsAg levels associate with lower rate of off-therapy flare and higher likelihood of HBsAg clearance. However, only 3% of patients achieved qHBsAg <10 IU/mL, and the incidence of severe flare was comparable across all EOT HBsAg levels. Therefore, EOT qHBsAg alone is not a practical indicator for deciding Nuc cessation, particularly due to its limited ability to discriminate severe flares.

FRI-608
Real-life adherence to bulevirtide monotherapy in chronic hepatitis D: a behavioral survey across Italian centers
Lorenzo Badia[1], Maurizia Brunetto[2], Alessia Ciancio[3], Massimiliano Conforti[4], Nicola Coppola[5], Marco Distefano[6], Antonio Izzi[7], Loreta Kondili[8], Pietro Lampertico[9], Alessia Rianda[10], Alessandro Loglio[11]. Vanvitelli University Hospital, Naples, Italy;* [6]*UOSD Hepatology Unit, ASP Siracusa, Siracusa, Italy;* [7]*Department of Infectious Diseases, Cotugno Hospital, Naples, Italy;* [8]*National Center for Global Health, Istituto Superiore di Sanità, Rome, Italy;* [9]*Division of Gastroenterology and Hepatology, Foundation IRCCS Ca' Granda Ospedale Maggiore Policlinico, Milan, Italy;* [10]*Infectious Diseases Hepatology Unit-National Institute for Infectious Diseases L. Spallanzani - IRCCS (INMI), Rome, Italy;* [11]*Gastroenterology, Hepatology and Transplantation Division, ASST Papa Giovanni XXIII, Bergamo, Italy*
Email: aloglio@asst-pg23.it

Background and aims: Treatment adherence may influence outcomes in chronic Hepatitis Delta (CHD) patients. While clinical trials report excellent adherence to bulevirtide (BLV), real-world data remains unknown: we investigated factors influencing adherence in real-life settings in Italy.
Method: This cross-sectional study surveyed patients receiving BLV across 12 Italian centers between May and September 2025, regardless of treatment initiation date. An updated COM-B (Capability, Opportunity, Motivation–Behavior) questionnaire assessed behavioral drivers and unmet needs, and in-depth interviews with six patients, conducted with the EpaC patient association, explored the emotional patient journey.
Results: Among the 121 participants [70% >50 years, 64% Italian, 29% non-Italian natives with a median residence of 13 years], 80% had been receiving BLV for >12 months at the time of the survey: 79% considered their liver disease severe, 86% perceived therapy as effective, and 87% reported improvements in daily life. Thirty-three patients expected therapy to last at least three years, and 15% anticipated it would continue indefinitely. Despite BLV was reported as easy to administer, 14% occasionally missed doses, 13% had considered discontinuation, most commonly (51%) because they believed disease was under control. BLV was collected monthly by 52% of patients, which may explain the 16% reporting interference with daily activities. Treatment effectiveness emerged as a key motivational factor, with adherence stabilizing at 80% after the first six months of BLV, regardless of nationality. Qualitative interviews highlighted the need for greater public awareness of HBV/HDV.
Conclusion: Adherence to BLV remains high in Italy, supported by comprehensive patient care and personalized management.

FRI-609
Novel HBV biomarkers predict HBsAg seroclearance in patients with chronic hepatitis B infection after cessation of long term nucleos(t)ide analogue
Lung Yi Loey Mak[1], Mark Anderson[2], Rex Wan-Hin Hui[1], Tiffany Fortney[2], Karen Cheuk-Ying Ho[1], Rene Geissler[2], James Fung[1], Wai-Kay Seto[1], Gavin Cloherty[2], Man-Fung Yuen[1]. [1]*The University of Hong Kong, Pok Fu Lam, Hong Kong;* [2]*Abbott Laboratories, Abbott Diagnostics Division, Abbott Park, Illinois, United States*
Email: loeymak@gmail.com

Background and aims: We examined the profile of novel viral biomarkers among patients with chronic hepatitis B (CHB) infection who stopped long-term nucleoside analogue (NUC).
Method: This prospective study recruited patients with HBeAg-negative non-cirrhotic CHB on ≥3 years of first-line NUC with

protocolized NUC cessation & intensive monitoring every 6 weeks. NUC was resumed upon clinical relapse (CR), defined as virological relapse (VR, serum HBV DNA rise from undetectable to >2000 IU/mL) plus alanine aminotransferase (ALT) >2 times upper limit of normal. HBV biomarkers including quantitative hepatitis B surface antigen (qHBsAg) and isoforms (LHBs, MHBs, SHBs), HBV RNA, HBcAg, P-HBcAg, HBcrAg and circulating immune complexes (CICs) were measured at baseline and end-of-follow-up. Additional measurement was performed at VR and ALT normalization in some patients. The primary outcome was HBsAg seroclearance (defined as <0.05 IU/mL). Patients were followed-up for ≥1 year after NUC cessation (without CR) or ≥1 year after ALT normalization (with CR), whichever was later.

Results: Among 51 patients who completed study (median age 50.1, 62.7% male, baseline qHBsAg 298 IU/mL with 25.5% <100 IU/mL, median time on NUC 7.4 years), 28 patients (54.9%) developed CR at a median of 24 weeks (median HBV DNA: 4.5 log IU/mL, median ALT: 152 U/L). No patients developed hepatic decompensation. Over a median follow-up of 91 weeks, a total of 6 patients (3 with no CR, 3 with CR; log rank P = 0.857) developed HBsAg seroclearance at weeks 20, 24, 48, 81, 91 and 96, with an event rate of 11.7%. Shifts in qHBsAg categories were observed with or without CR, showing increase in proportion of qHBsAg <10 IU/mL over time. qHBsAg, MHBs and SHBs increased only in the CR group but remained static in no CR group. LHBs, HBV RNA, and CIC were increased unanimously during VR. Baseline SHBs (0.859; 93.3% sensitivity, 83.3% specificity for cut-off level of 3.99 $\log_{10}$ S/CO) had higher area under ROC values than baseline qHBsAg (0.815; 88.9% sensitivity, 83.3% specificity for cut-off level of 1.84 $\log_{10}$ IU/mL) to predict HBsAg seroclearance. Baseline qHBsAg (HR 0.114, 95% CI 0.020–0.647), controlled attenuation parameter (HR 1.022, 95% CI 1.001–1.044), and SHBs (HR 0.135, 95% CI 0.023–0.780) were independently associated with HBsAg seroclearance.

Conclusion: HBsAg seroclearance following NUC cessation was observed with or without CR. SHBs at NUC cessation has higher performance characteristics than qHBsAg to predict subsequent HBsAg seroclearance.

FRI-610

NTCP variants do not impact Bulevirtide antiviral activity or HDV treatment response

Savrina Manhas[1], Amos Lichtman[1], Thomas Aeschbacher[1], Christopher Richards[1], David Pan[1], Nikita Kolhatkar[1], Jason Perry[1], Ross Martin[1], Dmitry Manuilov[1], Hongmei Mo[1], Jenny Svarovskaia[1].
[1]*Gilead Sciences, Foster City, United States*
Email: savrina.manhas1@gilead.com

Background and aims: Sodium taurocholate cotransporting polypeptide (NTCP, *SLC10A1*) is a hepatocyte bile acid transporter and entry receptor for hepatitis B virus (HBV) and hepatitis D virus (HDV). Bulevirtide (BLV), a myristoylated PreS1 lipopeptide, blocks HDV entry by binding NTCP. NTCP single nucleotide polymorphisms (SNPs), such as C800T (S267F) a variant previously linked to reduced HBV susceptibility, have been reported. This study mapped PreS1–NTCP peptide-protein interactions, identified NTCP SNPs at contact residues, and evaluated their impact on NTCP expression, BLV potency, and treatment response.

Method: Non-synonymous NTCP SNPs were selected based on (1) structural proximity to the PreS1 binding site mapped with recent NTCP cryo-EM structure or (2) minor allele prevalence (MAP) >0.05% in gnomAD v4.1 (N = 1,614,324). NTCP expression was quantified in MYR301 (phase 3 study NCT03852719) participants by RNA sequencing (RNASeq; N = 24) and multiplex immunofluorescence (MIF; N = 81), with whole-exome sequencing (WES) for subsets. BLV potency was tested in primary human hepatocytes (PHHs) expressing NTCP variants. In addition, BLV treatment response for participants with the synonymous NTCP SNP G225A (rs4646285) was analysed in MYR301 and MYR204 (phase 2b study NCT03852433) participants.

Results: Three NTCP SNPs C800T, T263C, T668C resulting in S267F, I88T, and I223T substitutions, respectively, met selection criteria. Structural mapping identified 72 of 349 NTCP residues interacting with PreS1 within 5 Å, two of which had a MAP >0.05%: C800T (S267F; ≤0.17%) and T263C (I88T; ≤0.06%). BLV retained subnanomolar potency against HDV in PHHs expressing S267F variant (EC_{50}: 0.08 nM). T668C (I223T) variant was the most prevalent (≤0.21%) but did not directly interact with PreS1. I223T remained sensitive to BLV (EC_{50}: 0.11 nM). The most common SNP in MYR301 and MYR204 was a synonymous G225A (16%, 46/293). NTCP expression was similar for participants with and without G225A SNP (RNASeq: 2.41 vs 2.39 log10 copies per million; MIF: −1.82 vs −1.82 log2 intensity). Week 96 virologic response rates were also comparable: 94.1% (16/17) for G225A vs 84.4% (65/77) for G225G. HDV RNA decline, ALT normalization and combined response rates did not differ by G225 SNP.

Conclusion: NTCP polymorphisms were rare and did not impact BLV binding or antiviral activity in vitro. The synonymous SNP G225A did not impact NTCP expression or treatment response to BLV in chronic HDV.

FRI-611

National registry of patients with hepatitis D treated with bulevirtide: real-world clinical practice data in Spain

Background and aims: Bulevirtide (BLV) was approved for reimbursement in Spain in mid-2023 as the first specific treatment for chronic hepatitis D (CHD). However, data on its effectiveness and safety in real-world clinical practice in our country remain limited. The aim of this study was to evaluate the efficacy and safety of BLV in CHD patients with ≥1 year of treatment included in the Spanish Association for the Study of the Liver (AEEH) national registry.
Method: This was a multicenter, observational study including all patients with baseline viremia who received BLV for ≥1 year and had available data at baseline, week 24, and week 48 (and week 72, when available). Virological response (HDV RNA decline >2 log or undetectable), biochemical response (normal ALT), and combined response were assessed, as well as the impact of baseline viral load on treatment response.
Results: A total of 603 patients were included, of whom 125 received BLV; 60 had HDV RNA quantified in all visits. Sixty-eight percent were male, with a median age of 51 years (IQR 40–57); 60% were born outside of Spain, and 76% had liver cirrhosis. At week 48, the virological response rate was 60%, with undetectable HDV RNA in 28% of patients. At week 72, virological response increased to 63%. Overall, combined response was observed in 41% at week 24 and 47% at week 48. Among the 25 patients without virological response at week 24, 24% achieved a complete response and 28% a partial response (decline ≥1 log and <2 log) by week 48. A greater rate of HDV RNA clearance at week 48 was observed in patients with baseline viral load <10,000 IU/ml (50%) compared to >10,000 IU/ml (20%) ($p = 0.05$). Adverse events were mild (three headaches and one self-limited local erythema). During follow-up, three patients developed *de novo* hepatocellular carcinoma (HCC).
Conclusion: Data from the Spanish national registry demonstrates that BLV achieves progressive improvements in virological and biochemical responses in CHD patients under real-world clinical conditions. Its greater efficacy in cases with low baseline viral load and the increasing response rates over time support BLV as an effective and safe therapeutic option for CHD.

FRI-612
Early miRNA signatures predict virological control and response to Bulevirtide in chronic hepatitis D

Email: javier.perez@vhir.org

Background and aims: Novel therapies for Hepatitis D Virus (HDV) infection, such as Bulevirtide (BLV), highlight the urgent need for early predictive biomarkers of treatment response. MicroRNAs (miRNAs), small RNA molecules that also regulate the host response during viral infection, have emerged as promising candidates. This study aims to analyze miRNA profiles associated with virological control or response in untreated and BLV-treated patients with Chronic Hepatitis D.
Method: The miRNA profile was analyzed by microarray *(Affymetrix)* in plasma samples in an exploratory cohort of 30 anti-HDAg-positive patients: 15 with detectable and 15 with undetectable HDV-RNA. The identified miRNAs were subsequently validated by digital PCR *(QIAcuity)* in two independent longitudinal cohorts: (1) 35 untreated HDV patients (n = 99 samples) with at least two consecutive samples and 8 healthy donors; (2) 16 BLV-treated patients followed at the start of treatment, 6 and 12 months, and classified as responders or non-responders according to the presence of a combined response at 1 year (drop of >2 log in HDV-RNA and ALT normalization).
Results: In the exploratory cohort, five miRNAs (miR-122-5p, miR-192-5p, miR-194-5p, miR-23b-3p and miR-26a-5p) were significantly downregulated in patients with undetectable HDV-RNA ($p < 0.05$). This trend was confirmed in the untreated validation cohort, where patients with virological control (n = 13) or normal ALT levels (n = 10) showed lower levels of miR-122-5p, miR-192-5p and miR-194-5p compared with patients with persistent viremia (n = 12). MiR-23b-3p and miR-26a-5p were downregulated in all HDV patients compared to healthy donors. BLV responders (n = 6) exhibited an early, marked drop in all five miRNAs by month 6 of treatment. Especially miR-23b-3p and miR-26a-5p, showed the strongest association with treatment response (AUC = 0.87 and 0.82; $p = 0.016$ and 0.042, respectively).
Conclusion: A specific miRNA profile linked to virological control and treatment response has been identified. Notably, the early decline of miR-23b-3p and miR-26a-5p levels may serve as predictive biomarkers of early treatment response, offering a new tool for management of HDV infection.

Long-term efficacy and safety of tenofovir disoproxil fumarate in chronic hepatitis B: real-world experience from a North African center

Boukhraiss Rajaa[1], Mohamed Borahma[1], Fatima Zahra Chabib[1], Nawal Lagdali[1], Sabbah Selma[1], Fatima Zahra Ajana[1], Maryeme Kadiri[1].
[1]Department of Gastroenterology and Hepatology, CHU Ibn Sina, Faculty of Medicine and Pharmacy of Rabat, Mohammed V University, Rabat, Morocco
Email: dr.chabib.fatimazahra@gmail.com

Background and aims: Chronic hepatitis B (CHB) remains a major public health concern due to progression to cirrhosis and hepatocellular carcinoma. Tenofovir disoproxil fumarate (TDF) is recommended as first-line therapy for its potent antiviral activity, high genetic barrier, and antifibrotic efficacy. This study evaluated the long-term virological efficacy and safety of TDF in CHB patients.
Method: Retrospective single-center study including CHB patients treated with TDF between 2017 and January 2025, with ≥12 months follow-up. Clinical, biochemical, and virological assessments were performed at M6, M12, M24, and beyond M36 (maximum 84 months).
Results: Forty-five patients (mean age 47.1 ± 12 years; 60% male) were included. Comorbidities: diabetes 11.1%, hypertension 15.6%, metabolic syndrome 22.2%. Baseline ALT elevation: 24.4%; viral co-infection: 6.7%; HBeAg-negative: 93.3%; treatment-naïve: 84.4%. Advanced fibrosis (F3–F4) was present in 13.3%. Virological suppression at M6: 68.9%; ALT normalization: 97.8%. At M12, 100% achieved undetectable HBV DNA. At M24 (n = 40), virological rebound occurred in 7.5%, persistent ALT elevation in 2.5%, and HBeAg seroconversion in 5%. Long-term follow-up (>M36, n = 33): low-level viremia in 12.1%,

ALT abnormalities in 3%, HBeAg negativation in 3%. Fibrosis reassessment (n = 14) showed improvement in 64.3%, stability in 21.4%, progression in 14.3%. Safety profile was favorable: eGFR decrease in 2.2%,Treatment modification occurred in 6.7% of patients for osteoporosis and in 6.7% for hypophosphatemia. No HBsAg seroconversion observed.
Conclusion: Long-term TDF therapy provides durable virological suppression, favorable biochemical outcomes, and low adverse events in CHB patients. These real-world data support TDF as an effective and well-tolerated long-term therapy.

FRI-617
Peginterferon alpha-2b and nucleos(t)ide analogs combination therapy for chronic hepatitis B patients with high HBsAg level at the end of treatment (52 weeks) from ongoing CREATED excellent study
Wenhua Zhang[1], Haitao Tang[1], Qinghua Lu[2], Haifang Cao[2], Tingxia Chao[1], Fengmei Wang[1], Wenling Jia[1], Chunhui Liang[1], Feng Ren[3], Hongfei Zhang[4]. *[1]Gansu Wuwei Tumour Hospital, Wuwei, China; [2]The 4th People's Hospital of Qinghai Province, Xining, China; [3]Beijing Youan Hospital, Capital Medical University, Beijing, China; [4]Jumei Doctor Group Medical (Shenzhen) Co., Ltd, Shenzhen, China*
Email: renfeng7512@hotmail.com

Background and aims: Chronic hepatitis B (CHB) patients with HBV DNA <LLOQ, HBeAg negative and HBsAg < 1500 IU/mL were the preferred population for clinical cure (PPCC). This study aims to observe the efficacy of nucleos(t)ide analogs (NAs) combined with peginterferon alpha-2b (PegIFNα-2b) in treating CHB patients with HBsAg > 1500 IU/mL (Non-preferred population for clinical cure, NPPCC).
Method: The CREATED EXCELLENT study (ChiCTR2400081073) is a multi-center, prospective, positive-controlled study. CHB patients with NAs treated for ≥3 months and HBsAg > 1500 IU/mL were enrolled and divided into two groups. The NAs monotherapy group continued to receive their original NAs (ETV/TDF/TAF/TMF) treatment, while the PegIFNα-2b+NAs group received PegIFNα-2b (180 μg/week) in addition to NAs. The total treatment period was 52 weeks, and all participants were followed up for 24 weeks after the end of treatment (EOT).
Results: A total of 682 patients (NAs monotherapy group, n = 330; PegIFNα-2b+NAs group, n = 352) were included. At baseline, there were 170 patients with HBsAg between 1500 IU/mL and 3000 IU/mL (NAs group: 21.81%, PegIFNα-2b+NAs group: 27.84%), 133 patients with HBsAg between 3000 IU/mL and 6000 IU/mL (NAs group: 18.23%, PegIFNα-2b+NAs group: 20.68%), 90 patients with HBsAg between 6000 IU/mL and 9000 IU/mL (NAs group: 12.11%, PegIFNα-2b+NAs group: 14.24%); and 289 patients with HBsAg greater than 9000 IU/mL (NAs group: 47.91%, PegIFNα-2b+NAs group: 37.23%). The baseline average HBsAg level in the NAs group was 18767.23 ± 5623.33 IU/mL and in the PegIFNα-2b+NAs group was 17346.91 IU/mL ($P > 0.05$). After 52 weeks of treatment, the average HBsAg level of the NAs group was 16963.92 ± 5127.89 IU/mL and the PegIFNα-2b +NAs group was 3589.40 ± 1223.47 IU/mL($P < 0.001$). The stratification ratio of patients with HBsAg < 1500 IU/mL, 1500 < HBsAg < 3000 IU/mL, 3000 < HBsAg < 6000 IU/mL, 6000 < HBsAg < 9000 IU/mL and more than 9000 IU/mL were 46.51%, 14.11%, 25.66%, 4.73% and 9.32%, respectively, in the PegIFNα-2b+NAs group; there rates were 20.00%, 30.15%, 26.72%, 3.32%, and 20.22% in the NAs group, respectively. At week 52 of EOT, 2 participants in NAs group had HBsAg loss, compared with 9 participants in PegIFNα-2b+NAs group.
Conclusion: Compared with NAs monotherapy, PegIFNα-2b combined with NAs therapy for the treatment of NPPCC (HBsAg > 1500 IU/mL) rapidly reduced HBsAg levels, and increased the number of PPCC (HBsAg<1500 IU/mL), thereby providing a new treatment strategy for CHB patients with high-level HBsAg to achieve clinical cure.

FRI-618
Characteristics of circulating immune cells in pediatric patients with chronic hepatitis B undergoing antiviral therapy
Haifang Cao[1], Hong Zhang[2], Qinghua Lu[1], 玲 徐[3], Yang Zhao[3], Hongfei Zhang[4], Feng Ren[3]. *[1]The 4th People's Hospital of Qinghai Province, Xining, China; [2]Public Health Clinical Center of Chengdu, Chengdu, China; [3]Beijing Youan Hospital, Capital Medical University, Beijing, China; [4]Jumei Doctor Group Medical (Shenzhen) Co., Ltd, Shenzhen, China*
Email: zhhf302@163.com

Background and aims: Hepatitis B surface antigen (HBsAg) loss or functional cure (FC), is considered the desirable therapeutic outcome for chronic hepatitis B (CHB) patients. However, the immune pathological biomarkers and underlying mechanisms in remain unclear, especially for pediatric CHB patients. In this study we comprehensively interrogate disease-associated cell states identified within PBMCs from either pediatric CHB or FC patients to provide novel insights into putative mechanisms underlying FC.
Method: We utilized mass cytometry to characterize the circulating immune cells profiles of 89 pediatric CHB patients (aged 3~18 years) including: 36 treatment-naïve CHB patients, 25 treated patients with nucleos(t)ide analogs (NAs), and 28 patients who achieved FC treated with NAs combined with Peginterferon alpha-2b (PegIFNα-2b, Pegbing®, Xiamen Amoytop Biotech Co., Ltd.). Peripheral blood mononuclear cells (PBMCs) were isolated from blood samples and subjected to high-dimensional immune cell profiling via mass cytometry to analyze their distinct immunological cell features.
Results: Unsupervised analysis revealed a reconfigured circulating immune landscape in pediatric CHB patients who achieved FC, distinct from both treatment-naïve and NAs-treated patients without achieving FC. Specifically, PegIFNα-2b+NAs-treated pediatric CHB patients with FC exhibited significantly elevated frequencies of peripheral NKT cells and TCRγδ-positive T cells. In contrast, NAs-treated pediatric CHB patients without achieving FC showed marked increases in conventional immune subsets, including $CD4^+$ T cells, NK cells, and both memory $CD8^+$ and $CD4^+$ T cells. Furthermore, T cells from PegIFNα-2b+NAs-treated pediatric CHB patients with FC displayed a distinct chemokine receptor profile, characterized by higher expression of CCR5, which is a marker previously associated with effective anti-HBV immune responses and treatment success in pediatric cohorts.
Conclusion: Pediatric CHB patients who achieve FC exhibit unique circulating immune cell functional characteristics, namely T cell functional reconstitution and activation of natural killer T cells. This profile provides insights into the mechanisms of pediatric CHB patients with FC and could guide the development of targeted immunotherapies for pediatric CHB patients.

FRI-619
Response to bulevirtide synchronizes HDV RNA and anti-HDV kinetics
Gabriele Ricco[1], Daniela Cavallone[2], Piero Colombatto[1], Barbara Coco[1], Filippo Oliveri[1], Francesco Damone[1], Giovanni Petralli[1], Veronica Romagnoli[1], Antonio Salvati[1], Lidia Surace[1], Alessia Calì[1], Barbara Vianello[1], Ferruccio Bonino[3], Maurizia Brunetto[1,2]. *[1]Hepatology Unit, University Hospital of Pisa, Pisa, Italy; [2]Department of Clinical and Experimental Medicine, University of Pisa, Pisa, Italy; [3]Italian National Research Council, Institute of Clinical Physiology, Pisa, Italy*
Email: riccogabriele@gmail.com

Background and aims: Currently the efficacy of treatment in chronic hepatitis D (CHD) is monitored by ALT and HDV RNA. Preliminary data indicate that declining anti-HDV levels are associated with virological control after Interferon. We evaluated HDV RNA and anti-HDV kinetics in CHD patients (pts) treated with bulevirtide (BLV).
Method: BLV-treated CHD pts with baseline samples (BL) and weeks (w) 48–144 were included. HDV RNA was quantified by qPCR

(AltoStar HDV RT-PCR kit 1.5; Altona; LOD: 1.12 IU/mL). Anti-HDV was tested by CLIA (Liaison XL Murex anti HDV, DiaSorin) after 10-fold endpoint dilution and Log AU/mL were calculated multiplying the AU/mL by the dilution factor. Virological response (VR) was defined as ≥2Log HDV RNA decline or undetectability. Correlations were assessed by Spearman's test.

Results: Twenty-six CHD pts (92.3% cirrhosis; median age 48.9 yrs, M/F 11/15) received BLV 2 mg/day for a median of 120 (57–193) weeks. At BL, median HDV RNA, anti-HDV were: 5.52 (1.70/7.20) Log IU/mL, 3.83 (3.39/4.72) Log AU/mL; 15/26 (57.7%) pts tested anti-HDV positive at 1:1000 and 11/26 (42.3%) at 1:10,000 dilution. VR rates were 69.2%, 66.7%, 65% and 80% at w48, w72, w96 and w144, while ALT normalization occurred at the same time points in 92.3%, 83.3%, 90% and 100%. Overall, HDV RNA correlated with anti-HDV ($\rho = 0.646$, $p < 0.001$) and ALT ($\rho = 0.560$, $p < 0.001$). The correlation between HDV RNA and anti-HDV was absent at BL ($\rho = 0.122$, $p = 0.551$), but increased during treatment: $\rho = 0.366$ ($p = 0.066$) at w48, $\rho = 0.572$ ($p = 0.003$) at w72, $\rho = 0.448$ ($p = 0.048$) at w96 and $\rho = 0.742$ ($p = 0.014$) at w144. At the end of follow-up (EOF), 15/26 (57.7%) pts showed a VR and a significantly lower median anti-HDV levels [3.18 (2.00/3.80) Log AU/mL] compared to 11 (42.3%) non-responders [3.71 (3.03/4.24) Log AU/mL] ($p = 0.020$). In VR pts anti-HDV levels declined throughout EOF, when anti-HDV were positive in 4 (26.7%) at 1:100, 11 (73.3%) at 1:1000 dilutions. Conversely, among the 11 non-responders, anti-HDV levels were positive in 10 (90.9%) at 1:1000 and in 1 (9.1%) at 1:10,000 ($p = 0.042$).

Conclusion: HDV RNA and anti-HDV levels were significantly correlated in BLV-treated CHD pts. Anti-HDV levels declined in parallel with HDV RNA in virological responders. Further studies are warranted to determine whether a sustained reduction in anti-HDV levels could serve as a surrogate marker of immunological control and help guide safe treatment discontinuation.

FRI-620
Clinical outcomes of Bulevirtide treatment in patients with chronic hepatitis Delta in a tertiary center from Bucharest, Romania

Violeta Molagic[1,2], Isabela Staicu[1,2], Anca Saran[1,2], Nicoleta Mihai[1,2], Alina Cozma[2], Daniela Neagu[2], Adrian Marinescu[1,2], Codrin Gheorghe[2], Cătălin Tilișcan[1,2], Raluca Năstase[2], Anca Negru[1,2], Sorin Stefan Arama[1,2], Victoria Arama[1,2]. *[1]University of Medicine and Pharmacy "Carol Davila," Bucharest, Romania; [2]National Institute for Infectious Diseases "Prof. Dr. Matei Balș," Bucharest, Romania*
Email: violeta_molagic@yahoo.com

Background and aims: Hepatitis B and D viruses (HBV and HDV) lead to high liver disease burden with limited therapeutic options, despite effective HBV vaccination available in the last three decades. A recent HBV prevalence evaluation among Europe sets Romania the second highest (6.2%). The assessed HDV global prevalence was 4.5% in people with chronic HBV infection, yet there is insufficient data for an accurate estimation in Romania. Bulevirtide (BLV), an entry inhibitor, was approved in Romania in 2024 and preliminary results indicate positive effects on slowing disease progression, however routine clinical practice data is currently limited. Objective: Analysis of the clinical characteristics and treatment outcomes of patients with chronic HDV infection.

Method: We conducted a retrospective study on chronic HDV infection adult patients receiving BLV treatment who were evaluated in our department of the National Institute for Infectious Diseases "Prof. Dr. Matei Bals" between August 2024 and December 2025. Clinical, biological and treatment-related data was analysed using SPSS Statistics (version 26).

Results: We included 33 patients, with a median age of 45 years (IQR: 27) and male to female ratio of 1:1.36. Compensated cirrhosis was diagnosed in 11/33 patients (33%) and one patient had HIV co-infection. At initiation of BLV, median levels of alanine aminotransferase (ALT) were 75 U/L, aspartate aminotransferase (AST) 49 U/L, HBV-DNA 120 IU/mL, HDV-RNA 598.432 IU/mL, AST to Platelet Ratio Index (APRI) 0.78 points and Fibrosis-4 (FIB-4) Index 2.05 points. Of the 23/33 patients (70%) who completed 24 weeks of BLV therapy, biochemical response (BR) was observed in 10/23 patients (43%) and it was more frequent in patients < 40 years ($p = 0.005$). BR was associated with lower APRI (median 0.35 points, $p = 0.01$) and FIB-4 (median 1.52 points, $p = 0.02$) in 7/10 patients (70%). In addition, 10/23 patients (43%) reached $\geq 2 \log_{10}$ IU/mL HDV-RNA decline from baseline at 24 weeks (median of 721 IU/mL). Among 7/33 patients (21%) who received 48 weeks of BLV treatment, without adverse events, 4/7 patients (57%) achieved both BR and virologic response.

Conclusion: Clinical outcomes of BLV treatment for chronic HBV and HDV hepatitis show liver function improvement and viral suppression after 6 to 12 months of administration. Further studies must assess the long-term evolution and more eligible patients need to be enrolled, currently being the only approved therapeutic option available.

FRI-621
Bile acid profile modifications in patients with chronic hepatitis D receiving bulevirtide therapy

Christiane Stern[1], Aurore Desmons[2], Segolene Brichler[3], Emmanuel Gordien[3], Stéphanie Marque Juillet[1], Muriel Girard[4]. *[1]Centre Hospitalier de Versailles, Le Chesnay, France; [2]Hopital Saint Antoine, AP-HP, Paris, France; [3]Hopital Avicenne, Bobigny, France; [4]Hopital Necker Enfants Malades, Paris, France*
Email: christiane.stern@gmail.com

Background and aims: Bulevirtide (BLV) is the only approved treatment for patients with chronic hepatitis D (CHD). Due to its mode of action blocking the entry receptor Na+-taurocholate cotransporting polypeptide (NTCP), an increase in total serum bile acids (BA) is generally observed in patients receiving BLV and thought to be non-clinically significant. Nonetheless, the BA composition in those patients has not been evaluated. The aim of this study is to evaluate the BA profile in patients with CHD receiving BLV.

Method: All consecutive patients with CHD who came for a follow-up visit in our department since July 2025 were eligible for this study (ongoing recruitment). Sociodemographic data, clinical signs and treatment history were recorded. The following tests were performed in all patients: complete blood count, prothrombin time, bilirubin, ALT, AST, GGT, albumin, serum creatinine, quantitative HBsAg, HBV-DNA and HDV-RNA, abdominal ultrasound, liver and spleen elastography. The bile acid composition was evaluated in each patient after at least 6-hour fasting by liquid chromatography-tandem mass spectrometry (LC-MS/MS) assay. Bile acids profiles were analyzed according to HDV therapy (BLV *vs* none).

Results: Eleven CHD patients with bile acid profile were included. Baseline characteristics were: male gender 45%, median age 51 ± 8, African origin 36%, compensated cirrhosis 36%. Median HBsAg, HBV-DNA and HDV-RNA were 3.59 (0–4.26), TND (0–3.89) and 5.76 log (TND – 6.09), respectively. At baseline, 9 out of 10 patients with positive HBsAg were receiving HBV treatment (tenofovir = 8, entecavir = 1), 4 patients were treated with BLV and 7 patients were not receiving HDV treatment (3 naïve, 3 discontinued BLV and 1 discontinued REP 2139). Among the 4 patients on BLV, none of them had pruritus. Mean total BA - UDCA was 3.82 µmol/L (0.93–42.68). BA composition in patients receiving BLV showed low rates of free bile acids (0.03–0.07) when compared to normal levels (0.18–0.78) in patients without current HDV treatment, except in one patient without virological response on BLV therapy (0.36). Also, the primary/secondary BA ratio was increased only in patients receiving BLV therapy and in a patient with cirrhosis/CSPH.

Conclusion: BA profile seems to be modified in patients receiving BLV therapy. Unconjugated BA may be decreased in patients receiving BLV which could be used as a marker of adherence to therapy. The impact of these BA modifications on long-term should be evaluated by prospective larger studies.

Background and aims: Hepatitis B virus (HBV) related acute on chronic liver failure (ACLF) is associated with high short-term mortality. Early initiation of antivirals is the cornerstone of management. However, comparative data regarding efficacy and outcomes with tenofovir alafenamide (TAF) versus tenofovir disoproxil fumarate (TDF) is limited. The present study compared survival outcomes of TAF versus TDF in patients with HBV ACLF.

Method: In this multicentre retrospective study data from the APASL ACLF Research Consortium cohort were analysed to compare short-term survival outcomes in patients with HBV-related ACLF treated with TAF vs TDF.

Results: A total of 813 HBV-related ACLF patients were included: 600 in the TAF group (487 males, 113 females) and 213 in the TDF group (194 males, 19 females). The median age in years was 45 (17–84) in the TAF group and 43 (17–75) in the TDF group. The mean CTP score (10.9 ± 1.4 vs 9.7 ± 0.96, p = 0.00), MELD score (28.2 ± 7.2 vs 24 ± 3.7, p = 0.00) and MELD Na (30.1 ± 7.0 vs 25.8 ± 3.9, p = 0.00) were higher in the TAF group; however, the AARC score (9.8 ± 1.5 vs 9.8 ± 1.4, p = 0.23) was comparable. Kaplan–Meier survival analysis demonstrated a significant difference in the in-hospital survival between the two treatment groups, with improved survival in the TAF group compared with the TDF group (median survival 68 days [95% CI 48.6–87.4] vs. 48 days [95% CI 39.0–57.0]; 75th percentile survival 43 vs. 25 days, respectively; log-rank $\chi^2 = 5.95$, p = 0.02). On univariable Cox regression analysis, treatment with TAF was associated with lower in-hospital mortality compared with TDF (HR 0.62, 95% CI 0.42–0.92; p = 0.02); however, on multivariable analysis, only the number of organ failures at presentation independently predicted mortality (HR 1.35 per organ failure, 95% CI 1.09–1.67; p = 0.01).

Conclusion: In HBV-related ACLF, TAF was associated with improved unadjusted survival; however, the baseline number of organ failures rather than antiviral choice independently predicted short-term mortality.

Background and aims: Peginterferon alpha (PegIFNα) treatment enables patients with chronic hepatitis B (CHB) to achieve high HBsAg loss rates. However, evidence remains limited regarding the efficacy of PegIFNα retreatment. This study investigated the efficacy of PegIFNα retreatment in patients who initially responded well but did not attain functional cure.

Method: This is a long-term follow-up study (NCT06707922) of a randomized controlled phase 3 trial (NCT04846491). At the end of the phase 3 trial, nucleos(t)ide analogue (NA)-experienced patients with HBsAg decline ≥ 1 $\log_{10}$ IU/mL and HBsAg level < 100 IU/mL, as well as treatment-naïve patients with HBsAg decline ≥ 1.5 $\log_{10}$ IU/mL and HBsAg level < 1500 IU/mL were enrolled in cohort 2. All

patients initially received treatment with PegIFNα-2b (Pegbing®, Xiamen Amoytop Biotech Co., Ltd.) 180 μg/week combined with tenofovir alafenamide fumarate (TAF) for 72 weeks, after which all drugs were discontinued and patients were followed up to 5 years. PegIFNα-2b was given intermittently in cycles (8 weeks of treatment + 4 weeks of interval, repeating every 12 weeks). Here, we report the results of the 72-week analysis in cohort 2.

Results: A total of 47 NA-experienced patients and 15 treatment-naïve patients were enrolled in cohort 2. The average ages of the two populations were 42.5 and 34.5 years, and 85.1% and 66.7% were male. Among NA-experienced patients, the mean baseline HBsAg level was 13.00 IU/mL, and all were negative for HBeAg and HBV DNA. Among treatment-naïve patients, the mean baseline HBsAg level was 272.77 IU/mL, 73.3% were HBeAg negative and 100% were HBV DNA undetectable. The HBsAg loss rate in NA-experienced patients increased from 23.4% (11/47) at week 24 to 42.6% (20/47) at week 48 and further to 46.8% (22/47) at week 72, while that in treatment-naïve patients increased from 13.3% (2/15) to 26.7% (4/15) and then to 40% (6/15). All patients who achieved HBsAg loss at weeks 48 and 72 also concurrently attained HBV DNA undetectable. At week 72, HBsAg seroconversion was observed in 35.0% (14/40) of NA-experienced patients and 30.8% (4/13) of treatment-naïve patients. Among the four HBeAg-positive treatment-naïve patients, one achieved HBeAg loss and seroconversion.

Conclusion: Regardless of whether patients were NA-experienced or treatment-naïve, more than 40% still achieved HBsAg loss through PegIFNα-2b retreatment. Patients with good initial responses to PegIFNα have a high chance of pursuing functional cure by retreatment with PegIFNα.

Background and aims: Long-term nucleos(t)ide analogue therapy effectively suppresses hepatitis B virus (HBV) replication in chronic hepatitis B (CHB); however, elevated alanine aminotransferase (ALT) levels may persist. We evaluated factors associated with persistent ALT (pALT) elevation (ALT above the AASLD upper limit of normal [25 U/L females, 35 for males]) after 8 years (Y) of tenofovir-based therapy.

Method: Pooled data from patients (pts) in two Phase 3 trials GS-US-320-0108 (HBeAg negative) and GS-US-320-0110 (HBeAg positive) trials were analysed. Pts were randomised 2:1 to TAF 25 mg/or TDF 300 mg/d for up to 3Y, then given open-label TAF through Y8. ALT status (normal vs pALT) was assessed at Y8. Baseline (BL) variables were analysed as predictors of pALT using multivariate logistic regression.

Results: Of 1159 pts with Y8 ALT data, 907 (78%) had normal ALT and 252 (22%) had pALT. At BL, pts with pALT were younger (median 37 vs 42 Y), more often male (73% vs 65%), and had higher mean BMI (25.5 vs 23.9 kg/m^2; $p < 0.0001$) vs pts with normal ALT. Overweight (BMI 25 to < 30 kg/m^2) and obesity (> 30 kg/m^2) were present in 46% and 10% of pts with pALT vs 30% and 6% with normal ALT ($p < 0.0001$). Slightly more pts with pALT had BL diabetes and hyperlipidaemia (9% and 10%, respectively) vs pts with normal ALT (7% and 8%). HBV genotype (GT) distribution showed more frequent GTA (9% vs 4%) and GTD (21% vs 17%) in pts with vs without pALT ($p = 0.0009$). At Y8, median (range) ALT was 45 (26–270) U/L and 19 (3–35) U/L in the pALT and normal ALT groups. At Y8, 88% vs 97% achieved HBV DNA < 29 IU/mL, with less HBeAg loss (35% vs 50%) and seroconversion (23% vs 33%) in pALT pts. By multivariate analysis, predictors of pALT included higher BL BMI (odds ratio [OR] 1.14; $p < 0.0001$), younger age (OR 0.96 for each Y older; $p < 0.0001$), and HBV GTA (OR 2.28; $p = 0.0053$). Over 8Y, both groups had similar modest changes in lipid parameters (median total cholesterol [TC] +6 vs +5 mg/dL; LDL +12 vs +15 mg/dL; HDL −8 vs −7 mg/dL in pts with pALT vs normal ALT) and minimal change in TC/HDL ratio (0.7 vs 0.5), while triglyceride (+27 vs +10 mg/dL) and glucose (+9 vs +5 mg/dL) increases were greater in pts with pALT.

Conclusion: After 8Y of tenofovir-based therapy, approximately 20% of patients had pALT, often despite durable viral suppression. Younger age, higher BMI, and GTA were independent predictors of pALT, suggesting roles for metabolic and viral factors in ongoing hepatic inflammation during long-term treatment.

FRI-625

Characterisation of HDV RNA, HBsAg and ALT kinetics in patients treated with bulevirtide and pegylated interferon for 96 weeks in the SEE-D trial

Emmanuel Zavalis[1], Adquate Mhlanga[2], Karin Lindahl[1,3], Susanne Cederberg[1,4], Annika Olsson[1,4], Niklas Björkström[3,4,5], Heiner Wedemeyer[4,6], Pietro Lampertico[7,8], Harel Dahari[2], Soo Aleman[1,3,4]. *[1]Department of Infectious Diseases, Karolinska University Hospital, Stockholm, Sweden; [2]Program for Experimental and Theoretical Modeling, Division of Hepatology, Department of Medicine, Stritch School of Medicine, Loyola University Chicago, Maywood, United States; [3]Center for Infectious Diseases, Karolinska Institutet, Stockholm, Sweden; [4]D-SOLVE Consortium, Hannover, Germany; [5]Department of Clinical Microbiology, Karolinska University Hospital, Stockholm, Sweden; [6]Department of Gastroenterology, Hepatology, Infectious Diseases and Endocrinology, Hannover Medical School, Hannover, Germany; [7]Division of Gastroenterology and Hepatology, Foundation IRCCS Ca' Granda Ospedale Maggiore Policlinico, Milan, Italy; [8]CRC "a. M. and a. Migliavacca" Center for Liver Disease, Department of Pathophysiology and Transplantation, University of Milan, Milan, Italy*
Email: soo.aleman@regionstockholm.se

Background and aims: Combination therapy of 48 weeks with bulevirtide (BLV) and pegylated Interferon (peg-IFN) has shown higher rates of on-treatment undetectable HDV compared with BLV monotherapy in the MYR204 trial. Data from longer combination therapy is lacking.

Method: Thirty-one patients with chronic hepatitis D were enrolled at Karolinska University Hospital, Sweden, in the SEE-D clinical trial (EU no. 2023-504414-29-00). They received 96-weeks combination treatment with BLV (2 mg/day) and peg-IFN (180 μg weekly, reduced to 135 μg from Week 48), followed by solidifying BLV therapy; all received nucleos(t)ide therapy. Participants were sampled every 12 weeks and upon clinical indication for HDV RNA ([LoQ] < 50 IU/ml and [LoD] < 6 IU/mL), HBsAg ([LoD] < 0.05 IU/mL) and ALT ([ULN] 65.9 IU/ml for men and 44.9 IU/ml for women; local laboratory references). HDV kinetic patterns were evaluated visually and with

Change-Point Estimation in R to define slope and time boundaries of the initial decline phase.
Results: Twenty participants (65%) were IFN-experienced, and 18 (58%) were men. At baseline, 10/31 (32%) had fibrosis stage F3 and 14/31 (45%) had F4. Mean (SE) baseline HDV RNA, HBsAg and ALT were 4.76 ± 0.21 $\log_{10}$ IU/mL, 3.82 ± 0.06 $\log_{10}$ IU/mL, and 106 ± 14.9 U/L, respectively. All participants initially showed a rapid initial HDV decline (−0.91 ± 0.08 $\log_{10}$ IU/mL/month), followed by: i) undetectability (monophasic - MP, n = 16, 53%), ii) slower second phase of decline to undetectability (biphasic - BP, n = 11, 37%), or iii) flat incompleteesponse (FIR, n = 3, 10%) plateauing above LoQ. Transient LoD to LoQ fluctuations, indicating a plateau below detectability, occurred in three of the participants in the MP group. Two on-therapy breakthroughs were observed to >3 log10 IU/mL; one BP and one FIR. By Week 72, 24 participants (78%) had achieved HDV undetectability and in those that reached week 96, all but one achieved undetectability. ALT normalization was observed in 21 participants (68%) at Week 72 and 18 (58%) at Week 96. HBsAg decline >75% occurred in 10 participants (32%) at final follow-up, all but one (LoQ) had undetectable HDV; one loss occurred.
Conclusion: In this interim analysis, three main kinetic patterns of HDV decline were observed. Approximately one third achieved >75% HBsAg reduction at final follow-up, primarily those with undetectable HDV. HBsAg reduction may reflect a loss of HBsAg-producing cells and/or interferon-mediated inhibition of HBsAg production.

Email: hxliang@zzu.edu.cn

Background and aims: Optimizing antiviral strategies and achieving hepatitis B surface antigen (HBsAg) loss remain major challenges in the management of chronic hepatitis B (CHB). This study aimed to evaluate the effects of 48-week peginterferon alfa-2b (Peg-IFN α-2b) therapy, with or without nucleos(t)ide analogues (NAs), in patients with CHB enrolled in the VISION study.
Method: In May 2024, we launched the multicenter, prospective VISION study to assess the long-term effects of Peg-IFN α-2b with or without NAs in CHB patients. This 48-week analysis involved two treatment groups: Peg-IFN α-2b monotherapy and Peg-IFN α-2b in combination with NAs, with a primary focus on assessing effectiveness and safety. Baseline characteristics between the two groups were balanced using propensity score matching (PSM).
Results: A total of 1138 patients completed the 48-week follow-up. After PSM, 798 patients were included in the analysis, comprising 399 patients in the monotherapy group and 399 patients in the combination group. At baseline, there were no significant differences between the monotherapy and combination groups in the proportion of males (64.7% [258/399] vs. 64.2% [256/399], $p = 0.882$), mean age (43.5 ± 9.6 vs. 43.4 ± 9.4 years, $p = 0.958$), HBeAg positivity rate (19.8% [79/399] vs. 21.3% [85/399], $p = 0.599$), HBsAg levels (2.2 ± 1.3 vs. 2.3 ± 1.2 log IU/mL, $p = 0.226$), HBV DNA levels (1.9 ± 1.5 vs. 1.9 ± 1.6 log IU/mL, $p = 0.636$), and ALT levels (34.1 ± 45.9 vs. 33.8 ± 31.0 U/L, $p = 0.920$). At 48 weeks, HBsAg loss rates (30.1% [120/399] vs. 29.3% [117/399], $p = 0.816$) and ALT levels (49.0 ± 87.3 vs. 46.0 ± 40.8 U/L, $p = 0.587$) were comparable between the two groups, while HBV DNA levels were slightly higher in the monotherapy group (1.6 ± 1.4 vs. 1.2 ± 0.8 log IU/mL, $p = 0.029$). Notably, subgroup analysis showed that among patients with baseline HBsAg levels of <100, 100–<500, 500–<1500, and ≥1500 IU/mL, HBsAg loss rates were 55.9% (81/145), 27.9% (24/86), 12.3% (8/65), and 6.8% (7/103) in the monotherapy group, and 56.3% (76/135), 27.8% (27/97), 10.0% (7/70), and 7.2% (7/97) in the combination group (all $p > 0.05$). Both treatment groups were generally well tolerated, with no serious adverse events observed.
Conclusion: At 48 weeks, among patients with low baseline HBsAg and HBV DNA levels, Peg-IFN α-2b monotherapy and Peg-IFN α-2b plus NAs combination therapy demonstrated comparable HBsAg loss rates and ALT levels, with no evident short-term advantage of combination therapy. The long-term benefits of these regimens are currently under investigation.

FRI-627

HBsAg seroclearance profiles and post-treatment trajectories with refined baseline HBsAg stratification in a nationalwide cohort study: implications for functional and partial cure with individualized finite treatment

Qiran Zhang[1], Feng Sun[1], Ruirui You[1], Shanshan Zhu[1], Shulan Sui[1], Yiqi Yu[1], Jiming Zhang[1], Wenhong Zhang[1]. *[1]Huashan Hospital, Fudan University, Shanghai, China*
Email: zhangqiran@fudan.edu.cn

Background and aims: Achieving a functional cure, characterized by HBsAg seroclearance, or a partial cure with sustained low-level HBsAg, is a key goal in CHB management. Detailed data are lacking to define the likelihood of achieving and maintaining these treatment endpoints across the full spectrum of baseline HBsAg levels in real-world practice. This study aimed to provide evidence on this issue.
Method: In this nationalwide, multicenter real-world cohort study, adults with CHB who initiated or were receiving NA or IFN-based therapy were enrolled from 98 centers. All enrolled individuals were followed by prospective data collection. Cumulative HBsAg seroclearance was described across finely stratified baseline HBsAg categories and over time, separately for NA and IFN-based regimens and stratified by IFN treatment duration. For PegIFN-treated patients, post-treatment HBsAg trajectories after cessation of PegIFN were also evaluated.
Results: Among 7271 participants included, 3623 received IFN-based therapy and 3648 received NA only. With NA monotherapy, clinically meaningful HBsAg seroclearance was largely confined to patients with baseline HBsAg <20 IU/mL (22.9% for those <10 IU/mL and 6.76% for those with 10–20 IU/mL by week 168). For patients with higher baseline HBsAg levels in this cohort, HBsAg clearance occurred only as sporadic events. In contrast, HBsAg seroclearance under IFN-based therapy was observed across the full baseline HBsAg spectrum, with incidence clearly dependent on both baseline HBsAg and follow-up duration. At week 48, the cumulative HBsAg clearance rate exceeded 30% for patients with baseline HBsAg <50 IU/mL, 20% for those <100 IU/mL, and 10% for those <500 IU/mL. By week 168, the rate

surpassed 30% for those <100 IU/mL, 20% for those <1000 IU/mL, and 10% for those <3000 IU/mL. Analysis of PegIFN-treated patients after therapy cessation showed that most (73.0%) maintained stable HBsAg levels overall, while 16.4–32.4% experienced further HBsAg decline or seroclearance, particularly those with lower HBsAg at PegIFN cessation.

Conclusion: This study demonstrates that currently available antiviral agents can lead to HBsAg loss or sustained low-level HBsAg in a subset of CHB patients, with strong dependence on baseline HBsAg burden. Patients attaining very low HBsAg levels show potential for subsequent HBsAg loss during continued NA therapy. However, over half of patients did not reach these favorable states with existing regimens, highlighting the unmet need for novel agents.

FRI-628

Younger age and abnormal baseline ALT levels predict superior responses to peginterferon alpha-2b therapy in children with chronic HBV infection

Email: zhhf302@163.com

Background and aims: Chronic hepatitis B in children poses a major global public health challenge. This study aimed to evaluate the efficacy and safety of antiviral therapy in chronic HBV-infected children and to analyse factors associated with treatment response.

Method: The Sprout Project, a prospective real-world study (NCT05792761), recruited chronic HBV-infected children aged 3–18 years to receive either nucleos(t)ide analogue (NA) monotherapy or combined with peginterferon alpha-2b (PegIFNα-2b, Pegbing®, Xiamen Amoytop Biotech Co., Ltd.) for 96 weeks. The present analysis included patients who had completed 48 weeks of PegIFNα-2b treatment.

Results: A total of 668 pediatric patients were included in this analysis. The mean age was 8.32 years, comprising 282 patients aged ≥3 to ≤7 years and 386 patients aged >7 to <18 years. Males accounted for 60.3% of the cohort. The mean baseline HBsAg, HBV DNA and HBeAg levels were 3.73, 5.75 $\log_{10}$ IU/mL and 2.35 $\log_{10}$ COI, respectively. 85.0% were HBV DNA positive and 84.5% were HBeAg positive. The mean baseline ALT level was 51.11 U/L, and 41.17% of patients had abnormal baseline ALT. PegIFNα-2b combination therapy markedly reduced HBsAg levels, with a mean decline of 1.86 $\log_{10}$ IU/mL at week 48. The overall rates of HBsAg loss, HBeAg loss, and HBV DNA undetectable at week 48 were 18.7% (125/668), 16.5% (93/562), and 61.6% (341/554), respectively. Patients aged ≥3 to ≤7 years achieved a significantly greater HBsAg decline (2.22 ± 2.20 vs. 1.59 ± 1.82 $\log_{10}$ IU/mL, p = 0.001) and a higher HBsAg loss rate (24.5% vs. 14.5%, p = 0.001) at week 48 compared with those aged >7 to <18 years, while no difference was observed in HBeAg or HBV DNA response. Compared with patients with normal baseline ALT, those with abnormal baseline ALT obtained better HBsAg and HBeAg responses, including a greater HBsAg reduction (2.18 ± 2.20 vs. 1.63 ± 1.84 $\log_{10}$ IU/mL, p = 0.01), a higher HBsAg loss rate (25.8% vs. 13.7%, p < 0.001), and a higher HBeAg loss rate (25.6% vs. 9.9%, p < 0.001). The highest responses were observed in children aged ≥3 to ≤7 years with abnormal baseline ALT, with the 48-week HBsAg loss, HBeAg loss, and HBV DNA undetectable rates of 36.7%, 33.0%, and 67.3%, respectively. PegIFNα-2b combination therapy was well-tolerated throughout the study.

Conclusion: PegIFNα-based therapy for children with chronic HBV infection is safe and effective. Younger age and abnormal baseline ALT levels are identified as favorable predictors of superior treatment outcomes.

FRI-629

Interferon-α enhances HBsAg-specific B cell responses via monocyte-Tfh-B cell axis to facilitate functional cure of hepatitis B

Shihong Zhong[1], Yang Zhou[1], Libo Tang[1], Xiaofang Li[2], Jinlin Hou[1], Jianhua Li[2], Xiaoyong Zhang[1], Yongyin Li[1]. *[1]Department of Infectious Diseases, Nanfang Hospital, Southern Medical University, Guangzhou, China, Guangzhou, China; [2]Key Laboratory of Medical Molecular Virology (MOE/NHC/CAMS), Department of Pathogen Biology, School of Basic Medical Sciences, Shanghai Medical College, Fudan University, Shanghai, China, Shanghai, China*
Email: yongyinli@foxmail.com

Background and aims: Achieving a functional cure for chronic hepatitis B virus (HBV) infection remains challenging. Our recent clinical trial demonstrated pegylated interferon-α (Peg-IFNα) plus siRNA outperformed siRNA alone, implicating IFNα in immune-mediated cure (*N Engl J Med*, 2024). However, its immunological mechanisms, especially in modulating humoral immunity, remain poorly defined. We aimed to elucidate how IFNα regulates B cell responses to facilitate HBV functional cure.

Method: We longitudinally followed CHB patients receiving Peg-IFNα and stratified them by week 72 virological outcomes: HBeAg-non-seroconversion (eAg-NSC, n = 11), HBeAg-seroconversion (eAg-SC, n = 7), and HBsAg seroconversion (sAg-SC, n = 6). Three NAs-treated patients achieving HBsAg seroconversion (NAs-sAg-SC) were included for comparison. Peripheral blood was collected at baseline and week 12 for scRNA-seq and flow cytometry. IFNα's effects on immune subsets and HBV-specific responses were further assessed via in vitro cytokine stimulation and in vivo models using *Il6*$^{-/-}$, *Il21r*$^{-/-}$, *Ccr2*$^{-/-}$ chimeric, and *Cxcl13*$^{-/-}$ mice.

Results: scRNA-seq and flow cytometry showed Peg-IFNα selectively expanded Tfh and plasma cells in sAg-SC patients. In vitro IFNα stimulation of B cells had minimal effects, suggesting intermediary cell involvement. Monocytes exhibited robust IL6-related gene upregulation, and IFNα enhanced their IL6 secretion, boosting humoral immunity. Although IL-6 did not directly activate B cells, IFNα promoted IL6-mediated Tfh interactions and IL6ST-high Tfh subsets with elevated IL21 in sAg-SC patients. IL6 increased IL21 in CXCR5^{+} CD4^{+} T cells, but this was absent in *Il6*$^{-/-}$ or monocyte-deficient mice. IL21-stimulated B cells showed enriched humoral response signatures. scRNA-seq revealed heightened IL21–IL21R signaling between Tfh and GC-like/plasma B cells in IFNα-treated sAg-SC patients. Spatial analysis confirmed IFNα-driven GC formation via CXCL13-CXCR5, which was abolished in *Il6*$^{-/-}$, *Ccr2*$^{-/-}$ chimeric, and *Cxcl13*$^{-/-}$ mice.

Conclusion: IFNα orchestrates antiviral humoral immunity through a monocyte–Tfh–B cell axis, providing mechanistic insight and therapeutic targets to optimize HBV cure strategies.

Up to 36 months durability of functional cure in response to bepirovirsen therapy in B-Clear On-NA responders: results from the B-Sure study

Seng Gee Lim[1], Tarik Asselah[2], Gheorghe Diaconescu[3], Adrian Gadano[4], Sebastián Marciano[4], Giuliano Rizzardini[5], Tatiana Stepanova[6], Hyung Joon Yim[7], Man-Fung Yuen[8], Alexandra Walker[9], Jane Dong[10], Lauren Maynard[11], Isabelle Santhiapillai[11], Helene Plein[9], Yi Cui[11], Tamara Lukic[12], Raju Gowda[13], Matthijs Broer[14], Melanie Paff[15], Dickens Theodore[16], Robert Elston[11], Marjan Hezareh[9]. *[1]National University Health System, Singapore, Singapore; [2]Université de Paris-Cité & INSERM UMR1149, Department of Hepatology, AP-HP Hôpital Beaujon, Clichy, France; [3]Spitalul Clinic de Boli Infectioase si Pneumoftiziologie, Craiova, Romania; [4]Hospital Italiano de Buenos Aires, Buenos Aires, Argentina; [5]Luigi Sacco Hospital, Milan, Italy; [6]Modern Medicine Clinic, Moscow, Russian Federation; [7]Korea University Ansan Hospital, Ansan, Korea, Rep. of South; [8]Queen Mary Hospital, The University of Hong Kong, Hong Kong, China; [9]GSK, London, United Kingdom; [10]GSK, Shanghai, China; [11]GSK, Stevenage, United Kingdom; [12]GSK, Dubai, United Arab Emirates; [13]GSK, Philadelphia, United States; [14]GSK, Amersfoort, Netherlands; [15]GSK, Collegeville, United States; [16]GSK, Durham, United States*
Email: mdclimsg@nus.edu.sg

Background and aims: Bepirovirsen (BPV) is an unconjugated antisense oligonucleotide in Phase 3 development for the treatment of chronic hepatitis B virus (HBV) infection. In the Phase 2b study B-Clear (NCT04449029), a subset of participants (pts) on nucleos(t)ide analogues (NAs) achieved a virological response at the end of BPV treatment, which was sustained for 24 weeks. Pts who had a complete (CR) or partial (PR) response at the end of the B-Clear (parent) study were eligible for the B-Sure long-term durability study (NCT04954859; ongoing). Here we present up to 45 months of follow-up data on the durability of response for B-Clear On-NA CRs and PRs enrolled in B-Sure.
Method: CR was defined as hepatitis B surface antigen (HBsAg) < 0.05 IU/mL and HBV DNA < lower limit of quantification (LLOQ; < 20 IU/mL), and PR as 0.05 ≤ HBsAg < 100 IU/mL and HBV DNA < LLOQ, both for 24 weeks off BPV in B-Clear. If eligible, pts discontinued NA 3 months (mo) into B-Sure (≥ 9 mo from their last BPV dose) and were followed further to determine achievement of functional cure (FC; sustained HBsAg < 0.05 IU/mL and HBV DNA < LLOQ at 24 weeks off all HBV treatment) and durability of response off all HBV therapy. Adverse events (AEs) were recorded at each visit.
Results: In total, 44 pts (14 CRs, 26 PRs and 4 non-responders) were enrolled into B-Sure. Of the 14 CRs, 10 (71%) discontinued NAs 3 mo after rollover into B-Sure; 8/10 (80%) maintained a CR to 6 mo post–NA cessation, thus achieving FC; 8/8 (100%) have maintained 24 mo FC, 7/7 (100%) 30 mo FC and 1/1 (100%) 36 mo FC (follow-up ongoing). Of the 26 PRs, 22 (85%) discontinued NAs 3 mo after rollover into B-Sure. 2/22 (9%) achieved delayed FC at 6 post–NA cessation and have maintained FC for 30 mo. 5/22 (23%) maintained PR status at 6 mo post–NA cessation and 1/22 (5%) at 36 mo post–NA cessation; all 4 losses of PR beyond 6 mo post–NA cessation were due to HBV DNA reversion. Among 22 PRs who discontinued NAs, 13 (59%) had restarted NA therapy by 18 mo post–NA cessation. Of all pts who discontinued NAs, 4 had alanine aminotransferase (ALT) ≥ 2x upper limit of normal (ULN) and 1 had ALT > 5x ULN; 1 of those did not restart NA. Post–NA cessation, no pts reported AEs of severe ALT flare. There was no indication that prior use of BPV had any latent adverse effects.
Conclusion: FC is achieved after BPV and discontinuation of all HBV treatments and durable for up to 36 months in B-Clear CRs enrolled in B-Sure, with no long-term safety signals reported.

Email: soo.aleman@ki.se

Background and aims: Bulevirtide (BLV), a first-in-class entry inhibitor, is approved as a 2 mg dose in the European Economic Area and other areas for the treatment of patients with chronic hepatitis delta. BLV 2 or 10 mg monotherapy has been shown to be generally safe and well tolerated in multiple clinical trials. Here, we present an integrated safety analysis of BLV 10 mg monotherapy across participant subgroups at week 96 for the Phase 3 MYR301 (NCT03852719) and Phase 2 MYR204 (NCT03852433) studies.
Method: This integrated analysis evaluated safety by baseline (BL) characteristics and demographics in participants treated with BLV 10 mg administered as two 5-mg injections subcutaneously once daily for 96 weeks. Assessments included treatment-emergent adverse events (TEAEs), Grade ≥ 3 TEAEs, serious AEs (SAEs), and TEAEs considered related to BLV; AEs were coded according to Medical Dictionary for Regulatory Activities Version 27.1. Safety parameters were analysed across BL subgroups: age (< 45, ≥ 45 years), sex (male, female), race (White, other), body mass index (< 25 kg/m^2, ≥ 25 kg/m^2), cirrhosis status (presence, absence), concomitant hepatitis B virus treatment (yes, no), alanine aminotransferase levels (≤ 1.5 × upper limit of normal [ULN], > 1.5 × ULN), and renal function (≥ 60 to < 90 mL/min/1.73 m^2, ≥ 90 mL/min/1.73 m^2).
Results: A total of 150 participants treated with BLV 10 mg were included in this analysis. BL characteristics and demographics were well balanced across the groups. Overall, the safety profile was consistent across all subgroups, and analyses of safety events by preferred term within each subgroup showed similar results. Despite a higher incidence of some cytopenias (such as platelets, lymphocytes, leucocytes, and neutrophils) likely due to background incidence, the safety profile of BLV 10 mg was similar in those with and without cirrhosis. Of note, only 1 participant with cirrhosis at BL had an on-treatment liver-related AE (Grade 1 ascites). In addition,

there was 1 study discontinuation due to an AE (myalgia [nonserious]). No SAEs related to BLV were reported in any subgroup, and no consistent differences in other safety outcomes were observed across subgroups.
Conclusion: Long-term treatment with BLV 10 mg monotherapy was safe and well tolerated. Overall, the safety profile remained consistent across all subgroups, including participants with cirrhosis, supporting its use in people with compensated liver disease.

Email: cscoffin@ucalgary.ca

Background and aims: Bepirovirsen (BPV) is an unconjugated antisense oligonucleotide in Phase 3 development for chronic hepatitis B virus (HBV) infection. In the Phase 2b study B-Together (NCT04676724), a subset of participants (pts) on nucleos(t)ide analogs (NAs) achieved a virological response following 12 or 24 weeks of BPV and 24 weeks of pegylated interferon α-2a (Peg-IFN) sequential therapy, which was sustained for 24 weeks following the end of Peg-IFN treatment. Pts with a complete response (CR) or partial response (PR) at the end of B-Together were eligible for the B-Sure long-term durability study (NCT04954859; ongoing). Here we present up to 33 months of follow-up data on the durability of response for B-Together complete responders (CRs) and partial responders (PRs) enrolled in B-Sure.
Method: CR was defined as both hepatitis B surface antigen (HBsAg) < 0.05 IU/mL and HBV DNA < lower limit of quantification (LLOQ; < 20 IU/mL), and PR as 0.05 ≤ HBsAg < 100 IU/mL and HBV DNA < LLOQ, both for 24 weeks off BPV + Peg-IFN sequential therapy in B-Together. If eligible, pts discontinued NA treatment 3 months (mo) into B-Sure (≥ 9 mo from the end of BPV + Peg-IFN sequential therapy) and were followed to determine the achievement and durability of functional cure (FC; sustained HBsAg < 0.05 IU/mL and HBV DNA < LLOQ at 24 weeks off all HBV treatment). Adverse events (AEs) were recorded at each visit.
Results: In total, 23 On-NA pts (13 CRs, 8 PRs and 2 non-responders) from B-Together were enrolled into B-Sure. Of the CRs, 12/13 discontinued NAs 3 mo into B-Sure; 9/12 maintained CR to 6 mo post–NA cessation, thus achieving FC. Of these, 7/7 (100%) have maintained 18 mo FC and 4/4 (100%) who reached the 33 mo B-Sure visit have maintained 24 mo FC (follow-up ongoing); no CRs restarted NAs during B-Sure. Of the PRs, 3/8 discontinued NAs 3 months into B-Sure; 1 PR achieved delayed FC at 18 mo post–NA cessation and has maintained 12 mo FC; 1 has maintained PR up to 24 mo post–NA cessation; 1 lost PR due to virological relapse and restarted NA treatment. Of all pts who discontinued NAs, none had alanine aminotransferase (ALT) ≥ 2x upper limit of normal. Post–NA cessation, no pt reported AEs of severe ALT flare. There was no indication that prior use of BPV had any latent adverse effects.
Conclusion: FC is achieved after discontinuation of all HBV treatments and is durable for up to 24 mo in CRs in response to sequential BPV + Peg-IFN therapy, and no long-term safety signals were reported.
Funding: GSK (206882).

WED-578
Transcriptomic profiling reveals distinct immune signatures in chronic hepatitis B and identifies blood transcriptional modules associated with hepatitis B e antigen loss following therapeutic vaccination with GS-2829 and GS-6779
David Pan[1], Edward J. Gane[2], Yao-Chun (Holden) Hsu[3], Rachel Wen-Juei Jeng[4,5], Christopher Richards[1], Sarah Arterburn[1], Ricardo Ramirez[1], Meghan Holdorf[1], Simon Fletcher[1], Jenny Stanton[1], Frida Abramov[1], Mario Cortese[1]. *[1]Gilead Sciences, Inc., Foster City, United States; [2]University of Auckland, Auckland, New Zealand; [3]Department of Medical Research, E-Da Hospital, School of Medicine, I-Shou University, Kaohsiung, Taiwan; [4]Department of Gastroenterology and Hepatology, Chang Gung Memorial Hospital, Linkou, Taiwan; [5]College of Medicine, Chang Gung University, Taoyuan, Taiwan*
Email: mario.cortese@gilead.com

Background and aims: Therapeutic vaccination aims to generate or boost preexisting hepatitis B virus (HBV)-specific immunity in chronic hepatitis B (CHB). Arenaviral vector vaccines, GS-2829 and GS-6779, encoding multiple HBV antigens, induced HBV-specific T-cell responses and hepatitis B e antigen (HBeAg) loss in a subset of Phase 1b study participants. Whole-blood RNA sequencing was performed to compare transcriptional responses between healthy participants (HP) and patients with CHB, and to elucidate vaccine-induced immune mechanisms associated with HBeAg loss.
Method: Transcriptomic analysis was performed on a subset of 22 study participants (4 HP; 18 CHB). The CHB cohort included 10 HBeAg-positive patients at baseline, of whom 5 achieved HBeAg loss after vaccination. Samples were collected at baseline (day [D]1) and during vaccination (on the day of [D57 and D58], and 2 weeks after the 3rd and 4th immunisations [D71 and D99]). Differential expression and gene set enrichment analysis (|normalised enrichment score| ≥2; false discovery rate <0.05) using blood transcriptional modules (BTMs) were conducted.
Results: HP displayed strong and durable enrichment of several T-cell–associated BTMs at all postvaccination time points compared to baseline. Patients with CHB had previously showed reduced HBV-specific T-cell response via ex vivo IFN-γ ELISpot compared to HP, consistent with more sporadic enrichment in T-cell BTMs. Additionally, natural killer cell–associated BTMs were more enriched in HP. Conversely, patients with CHB exhibited stronger and more persistent activation of myeloid and innate modules, which were downregulated in HP. Loss of HBeAg was associated with consistent upregulation of *STAT4*, *CNBP*, and *KLRC1* genes, suggesting engagement of the IL-12 or interferon pathways. Those who remained HBeAg positive exhibited downregulation of these immune genes and upregulation of epigenetic regulators (*FASN*, *DOT1L*) known to be associated with CHB and hepatocellular carcinoma. Importantly, *STAT4* and *KLRC1* were significantly differentially expressed ($p < 0.01$) on D85 in HBeAg loss vs no-loss patients, and showed a positive association with HBeAg decline ($R = 0.4$ and $R = 0.32$, respectively).
Conclusion: Therapeutic vaccination with GS-2829 and GS-6779 elicited distinct peripheral immune signatures in HP and patients with CHB. Several genes were differentially expressed in HBeAg loss

vs no-loss groups following vaccination. These findings could provide insights for future functional cure regimens.

Email: edgane@adhb.govt.nz

Background and aims: Treatment for chronic hepatitis D virus (HDV) infection, the most severe form of viral hepatitis affecting 12–72 million patients worldwide, is limited. Bulevirtide (BLV), an inhibitor of the sodium-taurocholate co-transporting polypeptide (NTCP), has been approved for the treatment of HDV infection in some countries. BLV inhibition of NTCP results in bile acid (BA) elevations, reduced HDV RNA and serum ALT. Orally administered NTCP inhibitors may provide similar safety and efficacy with improved dosing convenience compared to daily subcutaneous BLV injections. ABI-6250-101 (NCT06740474) is a randomized, blinded study assessing the safety, pharmacokinetics, and pharmacodynamics (PD) of a potentially first in class, oral NTCP inhibitor ABI-6250 (6250) in healthy subjects.
Method: Two single-dose cohorts of 5 mg and 25 mg, and 3 multiple-dose cohorts of 0.05 mg, 0.2 mg and 1 mg 6250 once-daily (QD) for 10 days are complete. In each cohort 8 subjects were randomized 3:1 to 6250 or placebo (PBO). Safety was assessed by physical examination, adverse events (AEs) and lab parameters. PD was assessed by changes in plasma BAs (on-target) and coproporphyrin-1 (CP-1; off-target). 6250 plasma concentrations were measured by LCMS.
Results: Demographics were similar across cohorts. 6250 C_{max} and AUC increased with dose with $t_{1/2}$ of ~4–5 days. Dose dependent BA elevations (non-pruritic), were observed at doses above 0.05 mg with 63.4-fold increase at 25 mg and 3.5-fold increase at 0.2 mg single doses. Two-fold CP-1 elevations were observed at 25 mg but not in any other cohort. Treatment-emergent (TE)AEs were reported in 20/30 and 4/10 6250 and PBO recipients respectively; all were Grade 1/2. No serious AEs were reported. Lab abnormalities were observed in 18/30 and 7/10 6250 and PBO recipients respectively; all were Grade 1/2 except for an unrelated, self-limited creatine kinase increase in a 5 mg recipient. Self-limited, asymptomatic ALT elevations were observed at all dose levels and PBO. Grade 1 ALT elevations were observed in similar proportions across multiple dosing groups; 16.7% at 1 mg, 0.2 mg, and PBO, and 0% at 0.05mg. One subject in the 1mg dose group discontinued treatment due to a Grade 1 ALT elevation.
Conclusion: Overall, 6250 was well tolerated when administered as single doses up to 25 mg, and up to 1 mg QD for 10 days. Dose dependent elevations in plasma BAs were observed. Planning for a longer duration Phase 2 study in subjects with chronic HDV infection is ongoing.

Email: rachel.jeng@gmail.com

Background and aims: Hepatitis B e antigen (HBeAg) loss is a key milestone towards functional cure in chronic hepatitis B (CHB). In prior studies, only 6%–8% of virally suppressed patients (pts) on tenofovir achieved HBeAg loss at 1 year (Y). In a Phase 1b study, 45% of HBeAg-positive (HBeAg+) pts treated with high-dose arenavirus-vectored therapeutic vaccines GS-2829 and GS-6779 achieved HBeAg loss. This analysis characterised HBeAg+ pts and identified virologic and immunologic patterns seen with HBeAg loss.
Method: Changes in HBeAg, hepatitis B core-related antigen (HBcrAg), and HBV-specific T-cell responses (*ex vivo* IFN-γ ELISpot) were assessed in HBeAg+ pts enrolled in a Phase 1b study by on-treatment HBeAg status through up to posttreatment week (W) 24.
Results: Of 13 HBeAg+ pts, 11 received 2 or 3 high-dose GS-2829 + GS-6779 cycles; 2 received placebo (PBO). At baseline (BL), the 13 pts had a median age of 45 Y, 69% were male, all were Asian, and median (range) hepatitis B surface antigen (HBsAg) of 710 (1.37, 3725) IU/mL. HBeAg loss/seroconversion occurred in 5/11 (45%) pts by day 85 (end of 2nd cycle); of these, 1 lost anti-HBe but remained HBeAg-, and another had HBeAg seroreversion but remained anti-HBe+, while neither PBO pt lost HBeAg. BL characteristics in treated pts were largely similar between pts with vs without HBeAg loss. Pts with HBeAg loss primarily had genotype B infection (4/5 [80%] vs 1/6 [17%]), shorter nucleos(t)ide analogue therapy duration (median 144 vs 271 W) and lower median (range) HBeAg levels (0.37 [0.14, 2.71] vs 4.05 [0.25, 13.31] IU/mL). All treated pts showed declines in HBeAg and HBcrAg; notably, 6 of 11 (55%) had HBeAg declines ≥ 0.5 $\log_{10}$ IU/mL, including 3 with HBeAg loss, while no PBO pt had such decline. HBeAg loss pts exhibited stronger hepatitis B core antigen (HBcAg)-specific T-cell responses, while those without HBeAg loss had more robust polymerase (pol)-specific T-cell responses. HBeAg+ pts with BL HBsAg < 800 IU/mL had more pronounced HBcAg-specific T-cell responses vs those with ≥ 800 IU/mL; no difference was seen between BL HBsAg groups in pol-specific response.
Conclusion: High-dose GS-2829 + GS-6779 induced a substantial rate of HBeAg loss with characteristic immunologic changes. The emergence of HBcAg-specific T-cell responses in pts with HBeAg loss and/or reduction suggests potential links between antigen clearance and immune restoration. These findings support further evaluation of GS-2829 + GS-6779 as part of finite cure for CHB.

WED-581

SOLSTICE week 48 subgroup analysis: Impact of BMI on ALT normalization after successful viral control in participants with chronic hepatitis delta virus infection treated with tobevibart plus elebsiran

Alina Jucov[1], Tarik Asselah[2], Anca Streinu-Cercel[3], Edward J. Gane[4], Heiner Wedemeyer[5], Pietro Lampertico[6,7], Patrick Kennedy[8], Michael A. Chattergoon[9], Bria Bullard[9], Cheng Huang[9], Rima Acosta[9], Sophie Chow[9], Carey Hwang[9], Cara Pilowa[9], Todd Correll[9],

Email: alina.jucov@arensia-em.com

Background and aims: Hepatitis delta virus (HDV) infection is the most severe form of viral hepatitis with limited treatment options. The ongoing phase 2 SOLSTICE study is investigating the antiviral activity and safety of the monoclonal antibody tobevibart alone and in combination with the small interfering RNA elebsiran in participants with chronic HDV infection, with or without compensated cirrhosis, on NRTI therapy (NCT05461170). ALT normalization is used to assess resolution of inflammation during antiviral treatment, but is non-specific, multifactorial, and may be influenced by factors beyond HDV viremia in infected persons. Here we sought to examine additional factors impacting ALT normalization.
Method: A subgroup analysis of ALT normalization was performed based on baseline participant and disease characteristics after 48 weeks of therapy with tobevibart 300 mg plus elebsiran 200 mg subcutaneously (SC) every 4 weeks (tobevibart+elebsiran Q4W; N = 32).
Results: After 48 weeks, HDV RNA decreased by ≥2 $\log_{10}$ from baseline in 97% (31/32) of participants receiving tobevibart+elebsiran Q4W and HDV RNA target not detected (TND) was achieved by 66% (21/32) of participants. Most participants receiving tobevibart +elebsiran Q4W had reductions in ALT values compared to baseline, with ALT normalization observed in 56% (18/32) of participants at week 48. In the full cohort, there was a trend towards lower baseline BMI in those who achieved ALT normalization at week 48. Of the 21 participants receiving tobevibart+elebsiran Q4W who achieved HDV RNA TND at week 48, median baseline ALT was 2.2x ULN, 2.0x ULN, and 1.3x ULN in BMI subgroups <25, 25–29.9, and ≥30, respectively. Among those achieving TND, ALT normalization was achieved by 80% (4/5), 64% (7/11), and 20% (1/5) in BMI subgroups <25, 25–29.9, and ≥30, respectively. Across the BMI subgroups, treatment-emergent adverse events (TEAEs) were primarily Grade 1–2 and transient in nature. No treatment-related serious adverse events occurred.
Conclusion: At 48 weeks, participants receiving tobevibart+elebsiran Q4W therapy achieved high rates of HDV RNA TND. ALT normalization at week 48 was more frequently observed in participants with lower baseline BMI, which suggests that elevated BMI could be independently contributing to elevated ALT even in participants achieving HDV RNA TND receiving tobevibart+elebsiran therapy.

Email: alexander.x.koenig@gsk.com

Background and aims: Bepirovirsen (BPV) is a Ph 3 ASO for chronic hepatitis B (CHB) that targets all HBV mRNAs including pgRNA. The ASO binding site overlaps HBx and HBV polymerase (Pol) protein-coding regions. In the Ph 2 B-Clear trial, treatment-emergent single nucleotide polymorphisms (SNPs) occurred in 6% (3/49) of On-NA and 3% (5/143) of Not-on-NA participants. This study aimed to 1) confirm HBx inhibition by BPV, 2) verify BPV binding site conservation in public database sequences, 3) assess impact of SNPs on HBx/Pol function/viral fitness, and 4) test SNPs for BPV susceptibility.
Method: The BPV binding site was analyzed for SNPs in 9,139 HBV consensus genomic sequences of the public database HBVdb. Thirteen SNPs identified from B-Clear and HBVdb with nonsynonymous mutations in HBx/Pol were cloned into HBV GtD plasmid, variant virus produced, and phenotyped in HepG2 cells and PHH. HBV variants were assessed for HBx function to degrade Smc5 and Smc6 (host Smc5/6 complex markers) and Pol activity (HBV DNA qPCR). Clinically identified variants with WT comparable fitness were tested for BPV susceptibility in PHH over 22 days. HBsAg, HBeAg, HBV DNA, HBcAg, and Smc5/6 were quantified by ELISA, qPCR, high-content imaging, and automated capillary electrophoresis immunoassay.
Results: BPV inhibited all viral markers, including HBx, HBsAg, HBeAg, HBcAg and HBV DNA. In line with the B-Clear sequencing results, SNPs in the BPV binding site were infrequent across genotypes in HBVdb (97.6% conserved). Among 13 evaluated SNPs, G1A, C7A, G8A, C9T, A13C, A13G, C15T showed reduced fitness compared to WT. G1A (low fitness SNP) translates to HBx A70T hydrophobic-to-polar aa substitution, resulting in abolished HBx function, whereas C2T (WT comparable fitness, HBx A70V; hydrophobic-to-hydrophobic aa) retained HBx function and antigen expression, suggesting a critical role of hydrophobic residues in the zinc-binding motif for HBx function. C7A (Pol F834L) reduced Pol-dependent replication, while C2T (Pol H833Y) did not. All variants tested (G8A, C9A, T10A, T10G, C15T, C20T) remained susceptible to BPV, with max. 4.1-fold HBsAg EC50 increase for C9A.
Conclusion: The BPV binding site is conserved and functionally critical, suggesting that potential escape mutations would likely incur a high fitness cost. BPV maintained antiviral activity against tested variants; furthermore, its restoration of the antiviral Smc5/6 host defense, potentially leading to HBV cccDNA silencing, also supports its therapeutic potential for CHB.

WED-586
Population pharmacokinetics of pevifoscorvir sodium (ALG-000184) in healthy participants and participants with chronic hepatitis B in support of phase 2 dose selection

Kha Le[1], Paul Ko[2], Russ Wada[2], Min Wu[1,1,1], Stanley Wang[1], Edward J. Gane[3], Man-Fung Yuen[4], Kosh Agarwal[5], Jinlin Hou[6], Hong Ren[7], Yanhua Ding[8], Alina Jucov[9], Xieer Liang[6], Jia Xu[8], Alexei Haceatrean[9], Kusum Gupta[1], Doug Clark[1], Lawrence Blatt[1], Tse-I Lin[1], Sushmita Chanda[1]. [1]*Aligos Therapeutics, South San Francisco, United States;* [2]*QuanTx Consulting, Mountain View, United States;* [3]*University of Auckland, Auckland, New Zealand;* [4]*The University of Hong Kong, Hong Kong, Hong Kong;* [5]*Kings College Hospital, London, United Kingdom;* [6]*Nanfang Hospital, Southern Medical University, Guangzhou, China;* [7]*The Second Affiliated Hospital of ChongQing Medical University, ChongQing, China;* [8]*The First Hospital of Jilin University, Changchun, China;* [9]*Arensia Exploratory Medicine, Chișinău, Moldova*
Email: kle@aligos.com

Background and aims: Pevifoscorvir sodium is a prodrug of ALG-001075, a potent capsid assembly modulator-empty that inhibits viral replication and cccDNA establishment in vitro for chronic

hepatitis B (CHB). The population pharmacokinetic (PopPK) analysis is aimed to identify key covariates influencing ALG-001075 pharmacokinetics and facilitate safe and effective dosing.
Method: The dataset consisted of 3158 quantifiable samples collected from 162 participants in a multi-part Phase 1 clinical study, including both healthy volunteers (HV) and participants with CHB. The study had five parts with doses ranging from 10 to 500 mg administered daily, twice daily or as single dose for up to 96 weeks. A nonlinear mixed-effects modelling approach was used to develop the PopPK model. Covariates tested included body weight (WT), age, sex, race (Asian vs. non-Asian), Chinese origin (Chinese vs. non-Chinese), albumin, ALP, AST, ALT, bilirubin, creatinine clearance, population (CHB vs. HV), and HBeAg status (positive vs. negative). A full covariate model included all significant covariates identified in a univariate forward search ($p < 0.05$) using the likelihood ratio test. Stepwise backward elimination process ($p < 0.01$) resulted in the final model. The final model was qualified using a prediction-corrected visual predictive check (pcVPC) method.
Results: A two-compartment model with first order absorption rate, dose-dependent zero order absorption duration and lag time best described the pevifoscorvir sodium PK. Significant covariates included WT on central and peripheral clearances (CL,Q) and volumes (V2,V3), non-Asian race on CL and V2, and CHB on CL. Simulated steady-state exposures in Asians were approximately 50–60% higher than those in non-Asians. Simulated exposures in the heaviest participants were ~20–30% lower than those in the lightest participants. A pcVPC showed that the model adequately captured the central tendency and range of the data in all participants. Overall, the magnitude of the covariate effects (<60%) is not likely to be clinically meaningful, given the observed relatively narrow range of change in HBV DNA for doses ranging 10–300 mg QD and good tolerability over this wide dose range.
Conclusion: The PK of ALG 001075 in HV and CHB participants was well described by the popPK model. The significant covariates were WT on CL/Q and V2/V3, non-Asian race on CL and V2, and CHB on CL. No dose adjustment was required based on liver disease severity or demographics, supporting fixed dosing in this population.

WED-587

Up to 36 months durability of functional cure in response to bepirovirsen therapy in B-Clear Not-on-NA responders: results from the B-Sure study

Email: mdclimsg@nus.edu.sg

Background and aims: Bepirovirsen is an unconjugated antisense oligonucleotide in Phase 3 clinical trials for the treatment of chronic hepatitis B virus (HBV) infection. In the B-Clear Phase 2b study (NCT04449029), a subset of participants (pts) achieved a virological response at the end of a 24-week bepirovirsen treatment period, which was sustained for 24 weeks post treatment completion. This occurred in pts on and not on background nucleos(t)ide analogue (NA) therapy (On-NA and Not-on-NA, respectively). Pts who achieved a complete (CR) or partial (PR) response at the end of the B-Clear (parent) study were eligible for this long-term durability study (B-Sure; NCT04954859; ongoing). Here we present up to 39 months of follow-up data on the achievement and durability of functional cure (FC) in B-Clear Not-on-NA complete responders (CRs) and partial responders (PRs) who entered B-Sure.
Method: CR was defined as HBsAg < 0.05 IU/mL and HBV DNA < LLOQ (< 20 IU/mL), and PR as 0.05 ≤ HBsAg < 100 IU/mL and HBV DNA < LLOQ, both for 24 weeks off bepirovirsen in the B-Clear study. Pts maintaining a CR at Month 3 of B-Sure (i.e., at least 9 months off bepirovirsen) were considered to have achieved FC (sustained HBsAg < 0.05 IU/mL and HBV DNA < LLOQ at 24 weeks off all HBV treatment). Adverse events were recorded at each visit.
Results: Overall, 17 B-Clear Not-on-NA pts (11 CRs, 5 PRs and 1 non-responder) were enrolled into B-Sure; mean age was 44.1 years, and 9/17 (53%) had HBsAg ≤ 1000 IU/mL at B-Clear baseline. For CRs, 8/11 (73%) pts maintained a CR at 3 months of B-Sure follow-up, thus achieving FC; FC has been maintained for 18 months by 8/8 (100%), for 24 months by 7/7 (100%), for 30 months by 7/7 (100%), and for 36 months by 4/4 (100%) who reached 39 months of follow-up. The 3 CRs who did not achieve FC had HBsAg reversion by 3 months of B-Sure; 1 subsequently experienced HBsAg loss (Month 15), achieving FC at Month 21, but then had HBsAg reversion at Month 33. For PRs, 1/5 has maintained a PR through 39 months of B-Sure follow-up; all losses of PR were due to HBV DNA reversion. 3 PRs started NA treatment after B-Sure enrolment. Of all pts, 1 had alanine aminotransferase (ALT) ≥ 2x upper limit of normal (ULN) and 1 had ALT > 5x ULN. There was no indication that prior use of bepirovirsen had any latent adverse effects.
Conclusion: These data provide evidence that FC is achieved and durable for up to 36 months following the end of bepirovirsen treatment, with no new safety signals reported.
Funding: GSK (206882).

WED-588

Sustained reduction of HBV antigen levels at ≥6 months follow-up in HBeAg-positive participants with chronic hepatitis B infection after 96 weeks of 300 mg pevifoscorvir sodium monotherapy

Lung Yi Loey Mak[1], Andreas Jekle[2,2,2], Mark Anderson[3], Sushmita Chanda[2], Lillian Adame[2], Tiffany Fortney[3], Heleen Roose[4], Lawrence Blatt[2], Rene Geissler[3], Min Wu[2,2,5], Kha Le[2], Gavin Cloherty[3], Tse-I Lin[4], Man-Fung Yuen[1]. *[1]The University of Hong Kong, Pok Fu Lam, Hong Kong; [2]Aligos Therapeutics, South San Francisco, United States; [3]Abbott Laboratories, Abbott Diagnostics Division, Abbott Park, Illinois, United States; [4]Aligos Belgium, Leuven, Belgium; [5]Aligos Therapeutics, San Bruno, United States*
Email: loeymak@gmail.com

Background and aims: Pevifoscorvir sodium (pevy, ALG-000184) is a prodrug of ALG-001075, a novel Type E Capsid Assembly Modulator (CAM-E). In the Phase 1 study ALG-000184-201 (NCT04536337), pevy has demonstrated potent on-treatment suppression of HBV DNA, RNA, and viral antigens in participants with chronic hepatitis B virus infection who received oral, once daily 300 mg pevy for 96 weeks. After the end of the pevy treatment (EOT), these antiviral effects were sustained during an 8-week follow-up (FU) period on

entecavir (ETV). Here, we report the sustained antiviral effect during long-term follow-up (LFU) of 24–48 weeks on ETV.
Method: 9 of 10 HBeAg-positive participants of Part 4 Cohort B were evaluated for HBV antigen changes during ≥24 weeks of ETV-only FU after the end of 300 mg pevy for 96 weeks. qHBsAg and qHBeAg were measured by Roche Elecsys HBsAg II assay on a cobas analyzer (LLOD 0.05 IU/mL) and Elecsys HBeAg quant (LLOD 0.10 IU/mL). HBV RNA was measured by Research Use Only (RUO) RealTime HBV RNA v2.0 (LLOQ 0.49 Log U/mL, 10 copies/mL) (Abbott Diagnostics). HBcAg, P-HBcAg, and HBsAg isoforms were measured with a prototype RUO assays (Abbott Diagnostics) and expressed as signal/cut-off ratio (S/CO).
Results: Median HBsAg levels declined by 1.07 $\log_{10}$ IU/mL during pevy treatment. This reduction was sustained during LFU. The median HBsAg levels were 3.38 $\log_{10}$ IU/mL at EOT and 3.30 $\log_{10}$ IU/mL at LFU, which were below the median baseline level of 4.31 $\log_{10}$ IU/mL. Similarly, reductions in HBeAg observed during pevy treatment were sustained during LFU. HBV RNA and P-HBcAg strongly decreased during pevy treatment, followed by a partial increase during LFU as expected by the mechanisms of pevy and ETV, respectively. HBV DNA remained <10 IU/mL in 5/9 participants at LFU, with minor increases to 11.1, 26.8, 40.2, and 364 IU/mL for the other 4 participants. The median decline of total HBs, MHBs and LHBs at the end pevy monotherapy were 0.40, 1.03, and 1.38 $\log_{10}$ S/CO, respectively, suggesting pevy acting on all HBsAg isoforms. Larger reductions in LHBs than total HBs indicate that pevy acts on cccDNA-derived HBsAg and that remaining HBsAg is mostly derived from integrated DNA.
Conclusion: Potent on-treatment effects on viral antigens were observed after 96 weeks of 300 mg oral monotherapy with pevy, indicating cccDNA pool reduction. These effects were sustained during ≥24 weeks of ETV FU HBeAg-positive participants with chronic hepatitis B virus infection.

Turkish real-world effectiveness and safety of bulevirtide in chronic hepatitis delta: a multicentric experience with long-term follow up

Muge Ozari Gulnar[1], Mustafa Celen[2], Mehmet Akif Yağlı[3], Özgür Aktaş[4], Gökhan Kabaçam[5], Mujdat Zeybel[1], Yılmaz Çakaloğlu[6], Murat Akyildiz[1], Sabahattin Kaymakoğlu[3], Cihan Yurdaydin[1]. *[1]Koç University Hospital, Department of Gastroenterology, İstanbul, Türkiye; [2]Dicle University Hospital, Department of Infectious Diseases, Diyarbakır, Türkiye; [3]İstanbul University Hospital, Department of Gastroenterology, İstanbul, Türkiye; [4]Koç University School of Medicine, İstanbul, Türkiye; [5]Güven Hospital, Department of Gastroenterology, Ankara, Türkiye; [6]Amerikan Hospital, Department of Gastroenterology, İstanbul, Türkiye*
Email: muge.ozari@gmail.com

Background and aims: Bulevirtide (BLV), was approved in Europe in 2020 for treating compensated CHD. It is available also in Russia and Australia. BLV is not licenced in Turkey, a CHD endemic country. We present first real-world data on BLV use in CHD In Turkey. This study evaluated daily 2mgBLV therapy in CHD patients for up to 36-months, with emphasis on virologic and biohemical response (VR, BR) and viral breakthrough (VBr).
Method: 33 patients with CHD who initiated BLV therapy between 2020–2023 were analyzed. All patients had baseline detectable HDRNA and elevated ALT. Five patients had decompansated cirrhosis all other patients had compensated liver disease. Seven patients used the European label Hepcludex, and remaining 26 patients received Myrcludex from Russia. Primary outcomes were VR (defined as undetectability or > 2 log decrease in HDVRNA) and BR (defined as ALT normalization) at end of on-treatment follow-up (FU). VBr was defined as an increase of HDV RNA > 1log from nadir or HDV RNA becoming detectable after undetectability. Statistical analyses included t and Mann-Whitney U tests for continuous and Fisher's exact and Chi-squared tests for categorical variables.
Results: Mean (±SD) baseline ALT was 99.6 (± 66.7) U/L and HDVRNA was 4.94 (± 1.11 log) IU/mL. At 12 months, VR was achieved in 74.1% (20/27) of evaluable patients, and BR was 70.4% (19/27). Response rates were sustained through 24 months reaching 61.1% (11/18) with VR and 64.7% (11/17) with BR. VBr occurred in 4 of 26 patients on the Russian BLV (15.4%). Patients with VBr had higher baseline INR (1.22 ± 0.03 vs 1.04 ± 0.14, p = 0.033) and a trend toward higher baseline HDVRNA (5.82 ± 0.81 vs 4.82 ± 1.10 log. IU/mL, p = 0.091). Two patients with VBr had no on-treatment FU HDVRNA testing. Remaining 2 patients continued therapy and had persistent viremia throughout FU. Mean time to VBr was 18.5 ± 3.87 months (range: 15–24 months). Following VBr, 3 patients experienced ALT elevations. Seven patients (21%) discontinued BLV treatment (21.2%) at median 19 months (range 12–27). Decompensated patients (n = 5, 15.2%) demonstrated similar VR rates compared to patients with compensated liver disease, suggesting efficacy across the disease severity spectrum. BLV was well tolerated.
Conclusion: In this real-world Turkish cohort, BLV demonstrated VR in 74% of patients at 12 months on-treatment and, maintained VR in the majority throughout 36 months. An unexpected high VBr rate was observed with the Russian BLV. Patients denied non-compliance.

Multitargeting ASO-based constructs as a new promising silencing strategy in HBV infection in vitro

Arnau Puig Lopez[1], Ariadna Vila Planas[2], Javier Pérez Garreta[3,4,5], Ariadna Rando-Segura[1,4], Maria Buti[3,4,5], Montserrat Terrazas Martinez[2], Roser Ferrer[6,7,8], Maria Francesca Cortese[1,9]. *[1]Department of Microbiology, Liver Unit, Vall d'Hebron Institut de Recerca (VHIR), Vall d'Hebron Barcelona Hospital Campus, Barcelona, Spain; [2]Department of Inorganic and Organic Chemistry, Organic Chemistry Section, Institute of Biomedicine, University of Barcelona (IBUB), Barcelona, Spain; [3]Department of Hepatology, Vall d'Hebron Hospital Universitari, Vall d'Hebron Barcelona Hospital Campus, Barcelona, Spain; [4]Instituto de Salud Carlos III, Centro de Investigación Biomédica en Red de Enfermedades Hepáticas y Digestivas (CIBERehd), Madrid, Spain; [5]Universitat Autònoma de Barcelona (UAB), Barcelona, Spain; [6]Clinical Biochemistry Department, Vall d'Hebron University Hospital, Barcelona, Spain; [7]Clinical Biochemistry, Drug Delivery & Therapy (CB-DDT) Research Group, Vall d'Hebron Research Institute (VHIR), Barcelona, Spain; [8]Bioquimica i Biologia Molecular Department, Universitat Autònoma de Barcelona (UAB), Barcelona, Spain; [9]Instituto de Salud Carlos III, Centro de Investigación Biomédica en Red de Enfermedades Hepáticas y Digestivas (CIBERehd), Barcelona, Spain*
Email: arnau.puig@vhir.org

Background and aims: Persistent transcriptional activity of hepatitis B virus (HBV) covalently closed circular DNA remains a major obstacle to functional cure. Targeted silencing of viral transcripts is therefore an attractive strategy to suppress viral replication. We developed a novel class of stimuli-responsive construct specifically designed for the simultaneous intracellular release of two Locked-Nucleic Acid ASO (LNA-ASO) targeting hyper-conserved regions of HBV.
Method: The construct was composed of two biostable LNA-ASOs linked together by a linker that is specifically cleaved upon exposure to specific endoneous intracellular enzymes. The antiviral activity of the individual ASOs and the dual construct was evaluated in vitro in HBV-infected HepG2-hNTCP through transient transfection. Treated cells were collected at 72 hours post transfection and the intracellular pregenomic RNA (pgRNA) was quantified by qPCR. A scrambled ASO was used as a control.
Results: Both LNA-ASOs efficiently silenced intracellular pgRNA HBV expression with IC50 values of 24.2 nM and 22.7 nM, respectively (IC90 >100 nM for the LNA-ASO1 and 82.2 nM for the LNA-ASO2). To ensure a robust silencing of the HBV pgRNA, both ASOs were tested at

a concentration twice the IC50 reaching a median [IQR] inhibition versus the scrambled ASO of respectively 79.2% [67.3;89.3] and 75.6% [60.2;83.7]. Since both molecules were active against HBV infection, a multitargeting ASO-based construct was designed. Native gel analysis showed that the newly synthesized construct efficiently carried both LNA-ASOs. Moreover, both molecules were efficiently released under emulated intracellular enzymatic conditions. To ensure that once released the LNA-ASOs remained functional, HBV-infected cells were treated with serial dilutions of the construct resulting in potent pgRNA inhibition, with an estimated IC50 of 2.8 nM, and a sustained inhibition at low nanomolar concentrations (IC90 = 3.5 nM).

Conclusion: This newly designed construct may serve as potent inhibitor of viral expression and shows potential as a therapeutic strategy for the multitargeted silencing of HBV. By enabling simultaneous targeting of conserved viral regions, this strategy has clear therapeutic potential and supports further development toward translational and preclinical evaluation in HBV infection. Email: gherlanus@gmail.com

Background and aims: Bulevirtide (BLV) 2 mg is approved in Europe for treatment of patients (pts) with chronic hepatitis delta. BLV monotherapy was shown to be generally safe and well tolerated. This subgroup efficacy analysis evaluated virologic response (VR) and biochemical response (BR) to the investigational BLV 10 mg dose at weeks 48 and 96 for the MYR301 (Phase 3; NCT03852719) and MYR204 (Phase 2; NCT03852433) studies.

Method: In a pooled analysis, VR (undetectable hepatitis delta virus [HDV] RNA or ≥ 2 $\log_{10}$ IU/mL decline from baseline [BL]), BR (alanine aminotransferase [ALT] normalisation), and combined response (CR; VR + BR) rates were assessed at weeks 48 and 96 across demographic and disease characteristic subgroups of pts treated with BLV 10 mg/day. The following subgroups were assessed: age (years; < 45, ≥ 45), sex (male, female), race (White, other), BL ALT (≤ 1.5 × upper limit of normal [ULN], > 1.5 × ULN), BL HDV RNA (< median, ≥ median), cirrhosis (yes, no), and concomitant hepatitis B virus (HBV) treatment (yes, no).

Results: Overall, 150 pts were included. At BL, mean (SD) age was 41 (8.2) years, 63% were male and 84% White, mean (SD) ALT was 108 (84.8) U/L, median (quartile [Q]1, Q3) HDV RNA was 5.5 (4.37, 6.21) $\log_{10}$ IU/mL, 43% had cirrhosis, and 55% had received concomitant HBV treatment. At BL, 30% were ≥ 45 years old, 73% had ALT > 1.5 × ULN, 98% had HDV genotype 1, and 1% had HDV genotype 5. At week 96, CR rates (%, [95% CI]) were: age < 45 vs ≥ 45, 52 (42–62) vs 56 (40–70); male vs female, 52 (42–63) vs 55 (42–69); White vs other race, 52 (43–61) vs 58 (37–78); BL ALT ≤ vs > 1.5 × ULN, 56 (40–72) vs 52 (43–62); BL HDV RNA < vs ≥ median, 57 (45–69) vs 49 (38–61); cirrhosis, yes vs no, 49 (37–62) vs 56 (45–67); concomitant HBV treatment, yes vs no, 59 (48–70) vs 46 (34–59). VR and BR rates were also comparable across subgroups. Undetectable HDV RNA rates were higher in pts with BL viral loads < median (53 [41–65] vs 20 [12–31]) at week 96. At week 48, efficacy was also comparable across subgroups.

Conclusion: Overall, the efficacy of treatment with BLV 10 mg was consistent across subgroups with different demographics and disease characteristics, supporting the use of BLV for treatment of patients with HDV and compensated liver disease. Pts with lower viral load at BL were more likely to achieve viral suppression.

Background and aims: Lonafarnib (LNF) boosted with ritonavir (LNF/RTV) is the only oral therapeutic under development for the treatment of chronic hepatitis D (CHD). LNF has a dual mechanism of action, inhibiting the host farnesyltransferase to disrupt HDV virion assembly, and promoting immune response in infected hepatocytes. LNF has been studied in over 2400 subjects across several clinical programs.

Method: Oral LNF/RTV with or without peginterferon Alfa-2a (Peg) was evaluated in D-LIVR, the largest phase 3 randomized placebo-controlled HDV trial to date (n = 407). The primary endpoint was a composite score of ≥ 2 log HDV RNA reduction and ALT normalization compared to baseline at 48-weeks on-treatment. This study presents extended analyses of the durability, breadth, and kinetics of treatment response in the D-LIVR study including time-to-response Kaplan Meier estimation.

Results: Both LNF-based regimens met the primary composite endpoint compared to placebo (LNF/RTV: p = 0.004, LNF/RTV+Peg: p < 0.0001) along with significant improvement in virologic and biochemical response seperately. Significant therapeutic benefit was also demonstrated in histological improvement at week 48 (LNF/RTV +Peg vs placebo, p = 0.01). Treatment effects on composite score vs placebo were durable at 24 weeks off treatment (LNF/RTV: p < 0.0001, LNF/RTV+Peg: p < 0.0001). Time-to-event analysis identified additional responders who achieved composite response at any time during the study. These "any-time responders" included 41.0% (LNF/RTV) and 57% (LNF/RTV+Peg) of treated patients compared to 1.9% in the placebo arm. Additionally, LNF-based therapies elicited treatment responses markedly faster than Peg monotherapy. LNF/RTV+Peg patients demonstrated ≥ 2 log HDV RNA reduction at a median time of 8.3 weeks (95% CI: 8.1–12.1) compared to 28.3 weeks (95% CI: 16.3–48.1) for Peg monotherapy using Kaplan Meier estimates.
Conclusion: LNF/RTV is a first-in-class CHD therapy with efficacy and safety in patients with CHD and substantial benefit after treatment cessation. The addition of Peg further increases response rates with a favorable safety profile and rapid treatment response kinetics. LNF/RTV represents a valuable addition to the CHD therapeutic armamentarium and because it is the only drug targeting virion assembly and the only oral CHD therapeutic under development, it may represent a backbone for combination treatments.

WED-595

Antiviral effect and safety of terbinafine in chronic hepatitis B: results of a phase 1b study

Diederick van Doorn[1], Robin Erken[1], Martine Peters-Bakker[1], Karel van Dort[1], Sophie Willemse[2], Hendrik Reesink[3], Ulrich Beuers[1], Neeltje Kootstra[1], R. Bart Takkenberg[1]. *[1]Amsterdam UMC, Amsterdam, Netherlands; [2]Cairns Hospital and Hinterland Health Services, Cairns, Australia; [3]Center of Human Drug Research, Leiden, Netherlands*
Email: d.j.vandoorn@amsterdamumc.nl

Background and aims: Terbinafine, an antifungal agent, has been identified as a specific inhibitor of hepatitis B virus X protein (HBx) which is a key regulator of viral transcription and replication. However, due to its potential hepatotoxicity, terbinafine is prescribed with caution in people with (chronic) liver disease. We investigated the antiviral effect and safety of terbinafine as monotherapy or in addition to long-term tenofovir disoproxil (TDF) in patients with chronic hepatitis B in a phase 1b study.
Method: In this randomized, double-blind, placebo-controlled trial, 32 patients with chronic hepatitis B and stable disease without cirrhosis were enrolled between 2021 and 2025. Two groups of hepatitis B patients were included in the study: patients with untreated chronic hepatitis B with a low viral load (Group A, n = 16) and patients with chronic hepatitis B on stable TDF therapy with suppressed HBV DNA (Group B, n = 16). Within each group, patients were randomized 2.2 to 1 for terbinafine or placebo (11 terbinafine and 5 placebo per group). Treatment duration was 10 weeks (4 weeks 250 mg daily, 2 weeks wash-out, 4 weeks 500 mg daily), followed by post-treatment follow-up of 12 weeks. Primary endpoints were: >0.32 log10 IU/mL decline of serum HBsAg levels, and >0.86 log10 IU/mL decline in serum HBV DNA in Group A at week 10. Secondary endpoints included safety and tolerability.
Results: Thirty-two patients were included and randomized. Baseline virological characteristics were comparable between both treatment arms. After 10 weeks, terbinafine treatment resulted in a modest, but non-significant decline in HBsAg (0.06 log10 IU/ml, p = 0.10), whilst placebo showed no effect (0.02, p = 0.85). Mixed-model analysis showed no effect of terbinafine treatment, time, or interaction effect. In Group A, HBV DNA declined by 0.27 log10 IU/mL in the terbinafine arm and 0.72 log10 IU/mL in the placebo arm. Terbinafine was well tolerated in all exposed participants, with no significant differences in adverse events as compared to placebo, particularly no relevant changes in liver biochemistry occurred.
Conclusion: Despite terbinafine being well tolerated and showing a favorable safety profile, this phase 1b study showed that terbinafine did not significantly affect serum HBsAg or HBV DNA levels when compared to placebo in patients with chronic hepatitis B with low viral load or virological suppression on nucleoside analogues.

Suppressing HBsAg by hepatitis B immunoglobulins does not lead to functional cure and has no impact on NK cell, T cell and B cell phenotypes in patients with chronic hepatitis B

Katja Deterding[1], Po-Chun Chen[1,2], Julia Kahlhöfer[1,3], Lisa Sandmann[1,2,4], Kerstin Port[1], Anke R.M. Kraft[1,2,5], Anika Grosshennig[6], Norman Woller[1,2], Ringlstetter Rieke[6], Markus Cornberg[1,2,3,4,5], Heiner Wedemeyer[1,2,4]. *[1]Department of Gastroenterology, Hepatology, Infectious Diseases and Endocrinology, Hannover Medical School, Hannover, Germany; [2]German Center for Infection Research (DZIF), Partner Site Hannover-Braunschweig, Braunschweig, Germany; [3]German Center for Infection Research (DZIF), HepNet Study House of the German Liver Foundation, Hannover, Germany; [4]Cluster of Excellence RESIST (EXC 2155), Hannover Medical School, Hannover, Germany; [5]Centre for Individualised Infection Medicine (CiiM), a Joint Venture Between the Helmholtz Centre for Infection Research (HZI) and Hannover Medical School (MHH), Hannover, Germany; [6]Institute for Biostatistics, Hannover Medical School, Hannover, Germany*
Email: wedemeyer.heiner@mh-hannover.de

Background and aims: Suppressing HBsAg has been suggested as a strategy to restore immune responses in chronic hepatitis B (CHB). Hepatitis B-specific immunoglobulins (HBIG) prevent reinfection after transplantation. This study aimed to investigate (i) whether suppressing HBsAg levels by HBIG therapy alters phenotypes and function of immune cells in patients with CHB and low baseline HBsAg levels, and (ii), if HBIG therapy for 12 weeks can lead to long-term changes in HBsAg levels or even functional cure.
Method: Nine HBV infected adults (median age 61 y [35–72], 67% male) were enrolled in an investigator-initiated, open-label, single arm phase II pilot-study (Cohort A (n = 4), patients treated with tenofovir, and Cohort B (n = 5), untreated patients with HBV-DNA < 2000 IU/mL). All participants were HBeAg-negative and had HBsAg <100 IU/mL. The intervention was a 12-week HBIG regimen: 10,000 IU Hepatect® i.v. at baseline, followed by 500 IU Zutectra® s.c. on days 1 to 6, a second iv infusion of 10,000 IU Hepatect® on day 7, and then 500 IU Zutectra® s.c. every other day (day 9 to 84). High resolution immune phenotyping of NK cells, T cells and B cells by spectral flow cytometry (>70 markers) was performed before, during and after treatment and also in control patients with high HBsAg levels of >3000 IU/ml.
Results: Median HBsAg at baseline was 52.2 IU/mL (4.0–73.0). Patients not receiving TDF (n = 5) had a median HBV-DNA of 305 IU/mL (100–1100). HBsAg became undetectable in all patients immediately after iv HBIG but remained negative throughout 12 weeks of s.c. HBIG in only two patients. At week 12, eight out of nine patients had HBsAg levels <10 IU/ml. High resolution immune phenotyping did not reveal substantial differences in NK cell, T cell and B cell profiles between study patients and controls. Of note, UMAP clustering of distinct cell types in each individual patient revealed some heterogeneity of NK cell populations between patients which, however, remained largely unchanged throughout and after HBIG therapy. Similarly, T cell and B cell profiles showed no major alterations. At week 24 of follow-up, all patients were again HBsAg positive, with individual HBsAg levels similar to baseline. One serious adverse event occurred during follow-up, unrelated to study medication.
Conclusion: In patients with CHB and low HBsAg levels, HBIG-mediated HBsAg suppression was not associated with detectable changes in NK-, T-, or B-cell phenotypes HBIG therapy for 12 weeks has no apparent impact long-term HBsAg setpoints.

WED-597

Safety, pharmacokinetics, pharmacodynamics, and antiviral activity of cavrotolimod, alone and in combination with low-dose nivolumab, for the treatment of chronic hepatitis B

Grace Lai-Hung Wong[1], Alina Jucov[2], Marta Dobryanska[3], Edward J. Gane[4], Stuart Roberts[5], Simone Strasser[6], Eternity Labio[7], Jacinta Holmes[8], Bobby Asem[9], Jerome Deval[9], Susanna K. Tan[9], Paul B. Eckburg[9], Hassan Javanbakht[9], Leesun Kim[9], Loghman Salimzadeh[10], Adam Gehring[10], Nancy Shulman[9], Man-Fung Yuen[11]. *[1]Department of Medicine and Therapeutics, The Chinese University of Hong Kong, Hong Kong, China; [2]Arensia Exploratory Medicine GmbH, Chisinau, Moldova, and Nicolae Testemitanu State University of Medicine and Pharmacy, Chişinău, Moldova; [3]Medical Center of LLC Arensia Exploratory Medicine, Kyiv, Ukraine; [4]University of Auckland, Auckland, New Zealand; [5]Alfred Hospital & School for Translational Medicine, Monash University, Melbourne, Australia; [6]AW Morrow Gastroenterology and Liver Centre, Royal Prince Alfred Hospital, Sydney, Australia; [7]Liver Unit, Makati Medical Center, Metro Manila, Philippines; [8]St Vincent's Hospital Melbourne, Melbourne, Australia; [9]Bluejay Therapeutics, Inc., Redwood City, United States; [10]Schwartz-Reisman Liver Research Centre, University Health Network, Toronto, Canada, and Toronto Centre for Liver Disease, University Health Network, Toronto, Canada; [11]Department of Medicine, Queen Mary Hospital, The University of Hong Kong, Hong Kong, China*
Email: mfyuen@hku.hk

Background and aims: Restoration of HBV-specific immune responses is central to achieving functional cure for chronic hepatitis B (CHB). Cavrotolimod is a novel spherical nucleic acid Toll-Like Receptor 9 agonist oligonucleotide designed to activate innate and adaptive immunity. Study BJT-008-001 is an ongoing Ph1b/2 study evaluating cavrotolimod ± nivolumab ± brelovitug (mAb against HBsAg) in subjects with CHB. Herein, Phase 1b results are presented.
Method: Part 1 (n = 20) was a randomized, double-blind, placebo-controlled study of cavrotolimod (2–6 mg SC Q1–4W) × 4 weeks, and Part 2 (n = 7) was an open-label study of cavrotolimod 3 mg SC Q2W × 4 weeks + low-dose nivolumab on Day 1. Safety (treatment emergent adverse events [TEAEs], labs, physical exams), pharmacokinetics (PK), and pharmacodynamics (PD) were assessed.
Results: In Parts 1 & 2, 169 TEAEs were observed in 25/27 (93%) participants. Most TEAEs were Grade 1 (68%) or 2 (31%) severity, and most were deemed related to study drug (93%). The most common TEAEs were injection site reactions (ISRs, 51%) and flu-like illness (20%). No related serious, severe, or immune-related TEAEs were observed. Cavrotolimod was measurable in plasma within 2–4 hours of dosing in most subjects. Day 1 exposure (Cmax, AUC) increased linearly with weekly doses from 2 to 6 mg, whereas Day 29 exposure increased in a greater than dose proportional fashion. Coadministration of nivolumab had no significant effect on cavrotolimod PK. One subject achieved HBsAg clearance (baseline 8 IU/mL) accompanied by an ALT increase, and another developed anti-HBs without HBsAg clearance; however, no other meaningful HBsAg changes were observed. Cavrotolimod induced transient, dose-dependent increases in serum cytokines, including CXCL10, IFN-g, IL-15 and IL-12p40. Global CD4 and CD8 T cells were also transiently activated, and improved activation of HBV-specific T-cell responses was observed.
Conclusion: Multiple doses of cavrotolimod × 4 weeks ± 1 dose nivolumab were generally well tolerated in CHB subjects. Most subjects experienced mild-to-moderate ISRs that were not treatment-limiting. Cavrotolimod elicited a potent immune response with strong cytokine/chemokine production and augmented HBV-specific T cell responses. Cavrotolimod may evolve as an important part of combination therapy in achieving functional cure of CHB.

WED-601-YI

Intermittent versus continuous interferon-alpha 2b plus tenofovir alafenamide therapy results in fewer adverse events with similar HBsAg reduction in treatment-naïve HBeAg-negative CHB patients: a multiregional randomized controlled trial in China

Weien Yu[1], Tiantian Hu[1], Haoru Xie[1], Shenyan Zhang[1], Tingting Gao[1], Yuxian Huang[2], Xinxin Zhang[3], Lihong Qu[4], Yuanwang Qiu[5], Xiaoping Wu[6], Huajiang Shen[7], Xueping Yu[8], Daokun Yang[9], Haoxiang Zhu[1], Jiming Zhang[1]. *[1]Department of Infectious Diseases, Shanghai Key Laboratory of Infectious Diseases and Biosafety Emergency Response, National Medical Center for Infectious Diseases, Huashan Hospital, Fudan University, Shanghai, China, Shanghai, China; [2]Department of Infectious Diseases, Shanghai Key Laboratory of Infectious Diseases and Biosafety Emergency Response, National Medical Center for Infectious Diseases, Huashan Hospital, Fudan University, Shanghai, China, Shanghai Public Health Clinical Center affiliated to Fudan University, Shanghai, China; [3]Department of Infectious Diseases, Research Laboratory of Clinical Virology, Ruijin Hospital, Shanghai Jiao Tong University School of Medicine, Shanghai, China; [4]Department of Infectious Diseases, School of Medicine, Shanghai East Hospital, Tongji University, Shanghai, China; [5]Department of Infectious Diseases, Affiliated Wuxi Fifth Hospital of Jiangnan University, Wuxi, China; [6]Department of Infectious Diseases, the First Affiliated Hospital of Nanchang University, Nanchang, China; [7]Department of Infection, Affiliated Hospital of Shaoxing University (The Shaoxing Municipal Hospital), Shaoxing, China; [8]Key Laboratory of Screening and Control of Infectious Diseases (Quanzhou Medical College), Fujian Provincial University, Quanzhou, China; [9]Department of Infectious Diseases, The First Affiliated Hospital of Xinxiang Medical University, Xinxiang, China*
Email: ywe18930740242@163.com

Background and aims: Interferon-alpha (IFN-alpha) is an effective therapy for achieving hepatitis B surface antigen (HBsAg) loss in patients with chronic hepatitis B (CHB), but its clinical use is limited by adverse effects and poor tolerability. This study evaluated whether an intermittent IFN-alpha dosing strategy could achieve comparable HBsAg reduction with improved safety.
Method: This multiregional, open-label, randomized controlled trial was conducted in China. Treatment-naïve, HBeAg-negative CHB patients were randomly assigned to a continuous or intermittent treatment group. The continuous group received IFN-alpha 2b plus tenofovir alafenamide fumarate (TAF) for 48 weeks. The intermittent group received the same regimen, with IFN-alpha 2b paused for 4 weeks after every 8 doses while TAF was continued, for a total duration of 72 weeks. Follow-up assessments were performed every three months until 6 months after treatment cessation.
Results: Between August 25, 2022, and November 30, 2024, 210 patients were enrolled across nine hospitals (105 per group). Both treatment strategies showed comparable HBsAg reduction, with no significant difference in decline from baseline to end of treatment between the continuous and intermittent groups (495.7 vs. 731.1 IU/mL, $p = 0.32$). Functional cure rates were similar between groups (4.76% vs. 6.15%, $p > 0.99$) and lower than those reported in nucleos(t)ide analogue–experienced populations. Treatment group was not associated with log HBsAg reduction at Week 36, whereas baseline log HBsAg ($p = 0.011$) and age ($p = 0.049$) were independently associated. Importantly, the intermittent group demonstrated a superior hematologic safety profile during treatment. At Weeks 12, 24, and 36, significantly fewer patients in the intermittent group experienced very low or low absolute neutrophil counts (ANC) and platelet counts (PLT), with a higher proportion maintaining values within the normal range (all $p < 0.05$ for ANC; all $p < 0.001$ for PLT), corresponding to fewer episodes of grade 3–4 neutropenia and thrombocytopenia. These safety advantages were confined to the active treatment phase and were no longer observed after treatment completion.

Conclusion: In treatment-naïve, HBeAg-negative CHB patients, intermittent IFN-alpha therapy was non-inferior to continuous treatment for HBsAg reduction and functional cure, with significantly better hematologic safety.

WED-602

Pevifoscorvir sodium demonstrated profound antiviral activity in untreated HBeAg+ subjects, regardless of baseline ALT level

Man-Fung Yuen[1], Kosh Agarwal[2], Alina Jucov[3], Alexei Haceatrean[3], Min Wu[4,4], Kha Le[4], Jen Rito[4], Lawrence Blatt[4], Sushmita Chanda[4], Tse-I Lin[4], Edward J. Gane[5]. *[1]Department of Medicine, School of Clinical Medicine, The University of Hong Kong, Hong Kong, China, Hongkong, China; [2]King's College Hospital, Institute of Liver Studies, London, United Kingdom, London, United Kingdom; [3]ARENSIA Exploratory Medicine, Republican Clinical Hospital and Nicolae Testemitanu State University of Medicine and Pharmacy, Chișinău, Moldova, Chișinău, Moldova; [4]Aligos Therapeutics, South San Francisco, United States; [5]Faculty of Medicine, University of Auckland, Auckland, New Zealand, Auckland, New Zealand*
Email: mwu@aligos.com

Background and aims: Pevifoscorvir sodium (PEVY, ALG-000184) is a prodrug of ALG-001075, a capsid assembly modulator-empty (CAM-E). The Study ALG-000184–201 (NCT04536337) showed favorable safety and potent antiviral activity of 300 mg PEVY monotherapy × 96 weeks in untreated chronic HBV infected subjects. An ad hoc analysis stratified by baseline (BL) ALT (<1.2 × upper limit of normal [ULN] vs ≥1.2 × ULN; ULN = 30 U/L[female], 40 U/L[male]) assessed whether BL ALT levels impact safety or antiviral activity.
Method: Ten untreated HBeAg+ subjects received open-label 300 mg PEVY monotherapy × 96 weeks. The analysis compared safety data (treatment-emergent adverse events (TEAEs), ALT flare events, lab abnormality, electrography and physical examination findings) and antiviral activity (changes from BL in HBV DNA, RNA, HBsAg, HBeAg and HBcrAg) over 96 weeks between low-ALT group (BL ALT <1.2xULN, n = 5) and high-ALT group (BL ALT ≥ 1.2xULN, n = 5).
Results: Mean BL ALT were 35 U/L in low-ALT group and 86 U/L in high-ALT group. Mean BL disease characteristics were comparable between low- and high-ALT groups: HBV DNA 7.8 and 8.2 $\log_{10}$ IU/mL; HBV RNA 5.2 and 5.3 $\log_{10}$ copies/mL; HBsAg 4.4 and 4.2 $\log_{10}$ IU/mL; HBeAg 2.7 and 2.6 PEI $\log_{10}$ U/mL; HBcrAg 8.2 and 8.4 $\log_{10}$ U/mL, respectively. Steady state plasma ALG-001075 was not statistically different between groups. Following 96 weeks of 300 mg PEVY monotherapy, both groups showed profound decline in HBV markers. HBV DNA < LLOQ (10 U/mL) was achieved in 2 of 5 subjects in low-ALT group and 4 of 5 subjects in high-ALT group by Week 48, and in all subjects by Week 96. At Week 48 and Week 96, mean reductions were as follows: HBV DNA 6.6 vs 7.2 and 6.8 vs 7.2 $\log_{10}$ IU/mL; HBV RNA 4.2 vs 4.4 and 4.2 vs 4.4 $\log_{10}$ copies/mL; HBsAg 0.8 vs 0.6 and 1.0 vs 0.7 $\log_{10}$ U/mL; HBeAg 1.2 vs 2.0 and 1.3 vs 2.2 $\log_{10}$ PEI U/mL; HBcrAg 1.2 vs 1.9 and 1.8 vs 2.5 $\log_{10}$ U/mL, for low- vs high-ALT group, respectively. ALT flares occurred in two subjects in each group (peak ALT 4.4–14.6 × ULN) and resolved during dosing without dose modification, interruption or discontinuation; no clinically meaningful changes in liver synthesis or excretion function were observed. All other TEAEs were mild to moderate and balanced between ALT strata.
Conclusion: In untreated HBeAg+ subjects, 300 mg PEVY monotherapy for 96 weeks demonstrated favorable safety and potent antiviral activity in both BL low- and high-ALT groups. Moreover, HBeAg and HBcrAg reductions seemed greater in subjects with higher BL ALT.

WED-603

Lonafarnib as finite treatment for chronic hepatitis D: Long-term effect on hard endpoints

Cihan Yurdaydin[1], Christopher Koh[2], Muge Ozari Gulnar[1], Olga Metin[3], Özgür Aktaş[4], Esra Tunç[5], Selin Özer[4], Onur Keskin[6], Mesut Gumussoy[7], Emin Bodakçi[8], Xheni Deda[9], Sevda Aghayeva[10], Genco Gencdal[1], Mujdat Zeybel[1], Ramazan Idilman[7], Mithat Bozdayi[5], Ingrid Choong[11], Naraanbatar Dashdorj[12], Ofir Harari[13], Naranjargal Dashdorj[12], Edward Mills[14], Theo Heller[15], Jeffrey Glenn[16]. *[1]Koç University Hospital, Department of Gastroenterology, İstanbul, Türkiye; [2]Liver Diseases Branch, National Institute of Diabetes and Digestive and Kidney Diseases, National Institutes of Health, Bethesda, Maryland, United States; [3]Prof. Dr. Cemil Taşcıoğlu City Hospital, Department of Gastroenterology, İstanbul, Türkiye; [4]Koç University School of Medicine, İstanbul, Türkiye; [5]Ankara University Hospital, Hepatology Institute, Ankara, Türkiye; [6]Hacettepe University Hospital, Department of Gastroenterology, Ankara, Türkiye; [7]Ankara University Hospital, Department of Gastroenterology, Ankara, Türkiye; [8]Gaziantep City Hospital, Department of Gastroenterology, Gaziantep, Türkiye; [9]Division of Gastroenterology and Hepatology, Department of Medicine, University of Missouri School of Medicine, Columbia, MO, United States; [10]Azerbaijan Medical University, Baku, Azerbaijan; [11]Eiger BioPharmaceuticals, Inc., California, United States; [12]The Liver Center, Mongolia and Onom Foundation, Ulaanbaatar, Mongolia; [13]Redwood AI, Vancouver, BC, Canada; [14]Department of Health Research Methods, Evidence, and Impact, McMaster University, Hamilton, Ontario, Canada; [15]Translational Hepatology Section, Liver Diseases Branch, National Institute of Diabetes and Digestive and Kidney Diseases, National Institutes of Health, Bethesda, Md., United States; [16]Departments of Medicine (Division of Gastroenterology and Hepatology) and Microbiology and Immunology, Stanford University School of Medicine, Stanford, California, United States*
Email: cyurdaydin@ku.edu.tr

Background and aims: Hepatitis delta virus (HDV) infection leads to the most severe form of viral hepatitis. New treatment options are urgently needed. The farnesyl transferase inhibitor lonafarnib (LNF) may be an option for finite treatment as it possesses a dual mode of action: it interferes with virion assembly (Glenn et al Science 1992) and also has immunomodulatory properties (Lempp et al, Nat Commun 2019). The aim of this study was to assess if finite treatment with a LNF-based regimen is able to prevent hard endpoints such as complications of liver disease and death from liver disease on long-term follow-up (LTFU).
Method: All patients subject to this study had received LNF-based treatment in two phase 2 (LOWR 1 and 2) and one phase 2 (LIFT) studies in Ankara (TR) and NIH (USA), respectively, and one phase 3 (DLIVR) study in Istanbul (TR). A total of 122 patients were available for follow up. Start date used for LTFU and survival analysis was EOT date of LNF-based treatment. End of follow-up (EOFU) was set to either the last date of data collection (December 2025), or the date of liver-related event, the start date of a new potential treatment against HDV or loss to follow-up. Short-term viral response (STVR) was defined as undetectable HDV RNA or as[3] 2 log decline of HDV RNA compared to baseline and ST biochemical response (STBR) as ALT normalization at off treatment month 6. BR and VR were the co-primary endpoints. Cumulative probabilities of any event occurrence were estimated by the Kaplan-Meier method and compared with the log-rank test.
Results: STVR+STBR was achieved in 14 patients. On LTFU, none of these patients developed a clinical event in up to over 10 years of follow up, whereas out of 98 patients without STVR+STBR, 26 (26.5%) developed an event (p = 0.045 by the log rank test, Fig). The 10 year

event-free survival rate for all LNF-treated patients was superior to untreated or interferon-treated patients from historical control cohorts with comparable prevalences of baseline cirrhosis.
Conclusion: Achieving a 2 log drop in HDV RNA from baseline and normal ALT at 6 months after stopping any finite lonafarnib-based treatment regimen is associated with long-term event-free survival (i.e. no liver decompensation, liver cancer, liver transplant, or death in up to 10 over years of follow up). Event-free survival is also improved for all LNF-treated patients.

WED-604
Comparative effectiveness of sodium-glucose cotransporter-2 inhibitors, glucagon-like peptide-1 receptor agonists and dipeptidyl peptidase-4 inhibitors on risk of liver and non-liver outcomes in patients with viral hepatitis and type 2 diabetes
Xinrong Zhang[1], Scott Barnet[2], Ramsey C. Cheung[2], Mindie Nguyen[2].
[1]Division of Gastroenterology and Hepatology, School of Medicine, Stanford University Medical Center, Palo Alto, California, United States, Guangdong Provincial Key Laboratory of Food, Nutrition and Health, and Department of Epidemiology, School of Public Health, Sun Yat-sen University, Guangzhou, China; [2]Division of Gastroenterology and Hepatology, School of Medicine, Stanford University Medical Center, Palo Alto, California, United States
Email: mindiehn@stanford.edu

Background and aims: With the epidemic of metabolic diseases, type 2 diabetes (T2D) and viral hepatitis frequently coexist and worsen liver and non-liver outcomes synergistically, but effective pharmacological therapies are limited. Sodium-glucose cotransporter-2 inhibitors (SGLT-2i) are a novel class of anti-diabetic drugs that confer substantial cardiovascular and renal protection beyond their glucose-lowering effects. Therefore, we aimed to examine hepatic and extrahepatic effectiveness of SGLT-2i through head-to-head comparisons with dipeptidyl peptidase-4 inhibitors (DPP-4i) or glucagon-like peptide-1 receptor agonists (GLP-1RA) among patients with viral hepatitis and T2D in the United States (U.S.).
Method: Patients with T2D and viral hepatitis initiating SGLT-2i or comparator drugs (DPP-4i or GLP-1RA) were included (2007–2022) in the nationwide U.S. Merative™ Marketscan® Research Databases. Primary outcomes included (1) hepatocellular carcinoma (HCC) and cirrhosis, and (2) cardiovascular disease (CVD), chronic kidney disease (CKD), and non-liver cancer. Cox regression models were conducted to estimate hazard ratio (HR) and 95% confidence interval (CI).
Results: After 1:1 propensity score matching, we included 2,244 patients who initiated SGLT-2i and DPP-4i (mean age 57.5 years, 31.6% female), and 2,506 patients initiating SGLT-2i and GLP-1RA (mean age 57.8 years, 35.8% female). Compared with DPP-4i, SGLT-2i use was associated with significantly reduced risks of any liver-related outcomes (HR 0.74, 95% CI 0.54–0.99, p = 0.049), CVD (HR 0.68, 95% CI 0.47–0.98, p = 0.038), CKD (HR 0.69, 95% CI 0.49–0.97, p = 0.030), and a non-significant trend towards lower rates of HCC (HR 0.79, 95% CI 0.40–1.57, p = 0.497), cirrhosis (HR 0.76, 95% CI 0.56–1.03, p = 0.074) and non-liver cancer (HR 0.66, 95% CI 0.42–1.04, p = 0.072). In contrast, there was no significant difference in the risks of liver and non-liver outcomes when comparing SGLT-2i to GLP-1RA (all p > 0.05). These sensitivity analyses yielded results consistent with those of the main analyses when we repeated the analysis using inverse probability of treatment weighting for the balance of patient characteristics (HR: 0.54–0.97) and when we conducted a 6-month landmark analysis (HR: 0.44–0.88).
Conclusion: In this nationwide U.S. cohort study, SGLT-2i was associated with lower risks of liver and non-liver complications compared with DPP-4i, while demonstrating similar effectiveness to GLP-1RA among patients with viral hepatitis and T2D.

Viral hepatitis C – Clinical aspects including follow up after SVR

Email: g_shiha@hotmail.com

Background and aims: Direct-acting antivirals (DAAs) have transformed hepatitis C virus (HCV) care, yet hepatocellular carcinoma (HCC) risk persists after sustained virological response (SVR). Current guidelines mandate uniform 6-monthly surveillance in patients with advanced fibrosis/cirrhosis, despite wide heterogeneity in post-SVR HCC risk. Modelling studies suggest personalised surveillance may improve efficiency, but real-world evidence is lacking. We evaluated the efficacy and cost effectiveness of a personalised surveillance strategy guided by the General Evaluation Score (GES) compared with standard surveillance.
Method: In this prospective, real-world comparative cohort study, 955 patients with advanced fibrosis/cirrhosis post-SVR were enrolled across two tertiary hepatology centres: 463 received standard 6-monthly ultrasound and AFP surveillance and 492 underwent GES-guided personalised surveillance, with intervals of 2–3 months (high risk), 6 months (intermediate), and 12 months (low). Outcomes included early-stage HCC detection (BCLC 0–A), surveillance utilisation, costs, and incremental cost-effectiveness. Analyses followed CHEERS 2022 guidelines.
Results: Sixty HCC cases were identified: 25 (5.4%) under standard surveillance and 35 (7.1%) with GES-guided surveillance. Early-stage tumours were detected in 52% (13/25) of standard-surveillance cases versus 80% (28/35) in the GES cohort, representing a 2.3-fold improvement. Despite intensified monitoring of high-risk patients, total surveillance visits were slightly lower with GES (3.01 vs 3.23 visits/patient). The cost per early-stage HCC detected decreased by 54%. Real-world ICER analysis showed that GES-guided surveillance was a dominant strategy, detecting more early-stage HCCs at lower overall cost. The ICER was –533 EGP per early detected HCC.
Conclusion: Personalised HCC surveillance provides real-world evidence supporting the economic superiority of risk-stratified surveillance after SVR and may help pave the way for integrating personalised pathways into future surveillance guidelines.

Sex-specific patterns of cardiometabolic and renal complications by ethnicity among people with hepatitis C in British Columbia, Canada: a population-based study

Dahn Jeong[1,2], Stanley Wong[2], Héctor Alexander Velásquez García[1,2], Alnoor Ramji[1,3], Eric Yoshida[1,4], Jean Damascene Makuza[1], Prince Adu[1], Bushra Mahmood[1,2], Richard Morrow[1,2], Sofia Bartlett[1,2], Amee Manges[1,2], Mohammad Ehsanul Karim[1,3], Amanda Yu[2], Georgine Cua[1], Sara Qureshi[1], Mel Krajden[1,2], Naveed Janjua[1,2].
[1]University of British Columbia, Vancouver, Canada; [2]BC Centre for Disease Control, Vancouver, Canada; [3]Saint Paul's Hospital, Vancouver, Canada; [4]Vancouver General Hospital, Vancouver, Canada
Email: dahn.jeong@bccdc.ca

Background and aims: Chronic hepatitis C (HCV) infection increases the risk of extrahepatic manifestations (EHMs) such as type 2 diabetes (T2DM), and chronic kidney disease (CKD). Ethnic disparities in HCV-related outcomes have been documented, with Asian populations experiencing disproportionate disease burden. However, sex-specific patterns of EHMs across ethnic groups remain poorly understood. We aimed to assess sex-specific patterns of EHMs by ethnicity among people with chronic HCV and to examine whether disparities persist after HCV treatment.
Method: We used data from the British Columbia Hepatitis Testers Cohort (BC-HTC), including all individuals diagnosed with HCV from 1990 to 2015, linked to administrative health data. The study sample comprised 41,874 individuals with confirmed HCV. EHMs (CKD, T2DM, major adverse cardiac events [MACE], and neurocognitive disorders [NCD]) were identified through ICD-9/10 codes from hospitalization and physician billings. We computed sex-stratified incidence rates (IRs) by ethnicity (East Asian, South Asian, Other) across four groups: untreated, pre-treatment, post-treatment, and spontaneously cleared. Multivariable cause-specific hazard models estimated sex-stratified risks adjusting for sociodemographic and clinical factors.
Results: South Asian females had markedly higher EHM burden than all other groups. In the untreated group, incidence of T2DM and CKD was 22.7 and 27.9 per 1000 person-years (PY), compared with 9.3 and 18.5 for South Asian males and 5.4 and 13.1 for females of other ethnicities. Adjusted models showed untreated South Asian females had over 3-fold higher risk of T2DM (adjusted cause-specific hazard ratio [aHR] 3.53, 95%CI 2.07–5.43) than females of other ethnicities. Among treated individuals, the risk of T2DM was over 5-fold higher before treatment (aHR 5.13, 95%CI 3.89–6.75) but attenuated after treatment (aHR 3.11, 95%CI 2.05–4.71).
Conclusion: South Asian women with chronic HCV experience disproportionately high metabolic and renal disease burden, exceeding that of women in other ethnic groups. HCV treatment appears to attenuate but not eliminate these disparities, highlighting its role in advancing health equity. Intersecting social and structural determinants including sex, ethnicity, and barriers to healthcare likely contribute to disproportionate burden. Targeted, culturally-safe screening and treatment initiatives are urgently needed to reduce inequities in HCV-related outcomes.

WED-605-YI

From cure to complexity: post-SVR liver and metabolic trajectories in diabetic patients

Clelia Asero[1], Maria Stella Franzè[1], Teresa Maltese[1], Alberto La Spada[2], Daniele Lombardo[3], Claudia Grisanti[1], Giuseppina Russo[4], Annalisa Giandalia[5], Concetta Pitrone[6], Roberto Filomia[6], Gaia Caccamo[6], Carlo Saitta[1], Anna Licata[7], Teresa Pollicino[3], Irene Cacciola[1]. *[1]Università Degli Studi Di Messina, Department of Clinical and Experimental Medicine, University of Messina, Messina, Italy; Division of Medicine and Hepatology, University Hospital of Messina, Messina, Italy, Messina, Italy; [2]Università Degli Studi Di Messina, Department of Clinical and Experimental Medicine, University of Messina, Messina, Italy; Unit of Nephrology and Dialysis, University Hospital of Messina, Messina, Italy, Messina, Italy; [3]Università Degli Studi Di Messina, Department of Clinical and Experimental Medicine, University of Messina, Messina, Italy; Division of Advanced Diagnostic Laboratories, University Hospital of Messina, Messina, Italy, Messina, Italy; [4]Università Degli Studi Di Messina, Department of Clinical and Experimental Medicine, University of Messina, Messina, Italy, Messina, Italy; [5]Università Degli Studi Di Messina, Department of Human Pathology of Adulthood and Childhood "G. Barresi," University of Messina, Messina, Italy, Messina, Italy; [6]Azienda Ospedaliera Universitaria di Messina G Martino, Messina, Italy; [7]Università Degli Studi Di Palermo, Internal Medicine and Hepatology, PROMISE, University Hospital of Palermo, Palermo, Italy, Palermo, Italy*
Email: clelia.asero@gmail.com

Background and aims: The long-term effects of hepatitis C virus (HCV) cure on hepatic and metabolic outcomes in patients with type 2 diabetes (T2D) remains insufficiently defined. This study aimed to evaluate T2D-related vascular complications, liver disease progression, and overall survival over nine years of follow-up, also exploring genetic variability contribution.
Method: Consecutive T2D patients with HCV-related chronic liver disease or cirrhosis treated with direct-acting antivirals (DAAs) between 2015 and 2018 at the University Hospital of Messina were prospectively followed until September 2024. Demographic, biochemical, and clinical data were collected at baseline and throughout follow-up. Regression models were applied to identify predictors of metabolic and hepatic outcomes. Genetic variants – *PNPLA3* rs738409, *TM6SF2* rs58542926, and rs641738 at the *MBOAT7/TMC4* locus – were genotyped.
Results: A total of 183 patients (52% males, median age 67 years, 56% cirrhotic), were followed for a median of 48 months (range 24–84). Despite significant improvements observed in glycated haemoglobin ($p = 0.006$), liver-stiffness ($p < 0.001$), gamma-globulins ($p < 0.001$), and aminotransferases ($p < 0.001$), only 27.3% of patients maintained long-term clinical stability. Liver disease progression – defined as liver decompensation and/or hepatocellular carcinoma development – occurred in 20.8% of patients and was related to the MBOAT7 variant ($p = 0.025$), baseline cirrhosis ($p = 0.021$) and previous decompensation episodes ($p = 0.07$). Macrovascular and microvascular complications developed in 50.8% and 33.9% of patients, respectively, mainly within two years after sustained virological response, without significant associations with baseline features. In multivariate models, a higher triglycerides-glucose index ($p = 0.038$) predicted the composite endpoint of general progression (which included liver disease progression and/or T2D vascular complication onset), while elevated LDL cholesterol levels ($p = 0.048$) were independently related to mortality, suggesting the high impact of insulin-resistance on patients' prognosis.
Conclusion: Although DAAs lead to metabolic and hepatic improvements, long-term prognosis in T2D patients remains strongly influenced by baseline liver disease severity, insulin resistance, and genetic background, highlighting the need for early antiviral treatment and optimized metabolic control in this high-risk population.

WED-608

High efficacy of direct-acting antivirals and significant fibrosis regression in childhood cancer survivors with chronic hepatitis C: a retrospective study

Almagul Jumabayeva[1], Aliya Balabek[2], Jamilya Kaibullayeva[1,1], Balzhan Nugmanova[1], Aizhan Muratbekova[2], Yevgeniya Bondar[1].
[1]National Research Institute of Cardiology and Internal Medicine, Almaty, Kazakhstan; [2]State Municipal Enterprise under the Right of Economic Management City Polyclinic No. 5, Almaty, Kazakhstan
Email: almagulejumabayeva@gmail.com

Background and aims: Children who are survivors of cancer represent a unique cohort with a historically high prevalence of chronic hepatitis C (HCV). Data regarding the long-term impact of

direct-acting antivirals (DAAs) on liver stiffness in this specific pediatric population are limited. We aimed to evaluate the efficacy and safety of DAA therapy and to analyze the dynamics of liver fibrosis using transient elastography (TE) in children with HCV and onco-hematological comorbidities.

Method: This retrospective study analyzed data from 82 patients (mean age 10.2 ± 4.1 years) with chronic HCV treated at a single center between 2019 and 2024. The majority of patients had a history of hematological malignancies (34.1%) and solid tumors (15.9%). Patients received Sofosbuvir/Ledipasvir (67.1%) or Sofosbuvir/Velpatasvir (28.0%) according to weight-based dosing. Medical records were reviewed to extract Liver stiffness measurements (LSM) by TE (FibroScan) performed at baseline and after achieving sustained virologic response (SVR). Fibrosis stages were categorized according to METAVIR (F0–F4). Statistical analysis was performed using Wilcoxon signed-rank and McNemar tests.

Results: Sustained virologic response (SVR12/24) was achieved in 100% of patients who completed follow-up. Treatment was well tolerated with no serious adverse events, including in patients receiving concomitant maintenance chemotherapy. A significant normalization of transaminases was observed ($p < 0.001$). Paired analysis of elastography demonstrated a significant reduction in median LSM from 6.1 kPa (IQR 5.3–6.6) at baseline to 5.1 kPa (IQR 4.4–5.6) post-SVR ($p < 0.001$). The proportion of patients with no evidence of fibrosis (F0) increased significantly from 34.1% at baseline to 84.0% after treatment ($p < 0.001$). Conversely, the prevalence of F1 fibrosis decreased from 52.4% to 13.6%, and F2 from 13.4% to 2.5%. No patients showed progression of fibrosis score.

Conclusion: DAA therapy is effective and safe in children with a history of malignancy, showing no negative interaction with maintenance chemotherapy. Viral eradication is associated with rapid and significant regression of liver stiffness measurements, suggesting a high potential for reversibility of early fibrotic changes in the pediatric liver. These findings support a "test and treat" strategy for childhood cancer survivors to prevent long-term hepatic morbidity.

Navigating hepatitis C (HCV) treatment decision-making during pregnancy: a qualitative study

Tamara Barnett[1,2], Cheryl Dale[3,4], Jordan J. Feld[4], Curtis Cooper[5], Brian Conway[6], Alnoor Ramji[7], Jennifer Flemming[8], Chris Fraser[2], Carla Coffin[9], Karen Doucette[10], Naveed Janjua[11], Gisela Macphail[12], Sofia Bartlett[11], Andrew Mendlowitz[4], Valerie Martel-laferriere[13], Karen Campbell[1], Mia Biondi[1,3,4]. *[1]York University, School of Nursing, Toronto, Canada; [2]Cool Aid Community Health Centre, Victoria, Canada; [3]Arthur Labatt School of Nursing, Western University, London, Canada; [4]Viral Hepatitis Care Network (VIRCAN), Toronto Centre for Liver Disease, Toronto, Canada; [5]Ottawa Hospital Research Institute, Ottawa, Canada; [6]Vancouver Infectious Disease Centre, Vancouver, Canada; [7]Division of Gastroenterology, Department of Medicine, St Paul's Hospital, Vancouver, Canada; [8]Departments of Medicine and Public Health Sciences, Queen's University, Kingston, Canada; [9]Cumming School of Medicine, Snyder Institute, University of Calgary, Calgary, Canada; [10]Department of Medicine, Division of Infectious Diseases, Edmonton, Canada; [11]British Columbia Centre for Disease Control, Vancouver, Canada; [12]CUPS Liver Clinic, Calgary, Canada; [13]Department of Microbiology, Infectious Disease and Immunology, University of Montreal, Montreal, Canada*
Email: tamarab@yorku.ca

Background and aims: American and European guidelines now recommend considering treatment in pregnancy on a case-by-case basis. While some clinicians have begun offering HCV treatment in pregnancy, factors influencing treatment decisions are poorly understood. This study aims to understand pregnant individuals' perspectives on HCV treatment decisions.

Method: As a part of an observational clinical study, pregnant individuals aged ≥ 18 years with detectable HCV RNA were recruited from seven sites in Ontario or British Columbia from December 2024 to December 2025 after discussing HCV treatment during pregnancy with their clinician. All participants, regardless of treatment choice, were interviewed virtually prior to labour and delivery. 28 demographic questions were followed by an interview which focused on participants' experiences and perspectives on living with HCV prior to (if applicable) and/or during prenatal care, competing life priorities, understanding of vertical transmission, and factors influencing their decisions. Interpretive description with thematic analysis was used to identify clinically relevant patterns and meanings.

Results: Of the seven participants (age 25–35 years), six opted to receive treatment. Participants had varied immigration, housing, and carceral experience, as well as levels of education. Only one case was a new diagnosis in the current pregnancy, speaking to the number of individuals untreated preconception. Key themes included initial shock and concern regarding diagnosis, family influence on decisions, turning to online resources for additional information, and motivations tied to maternal identity and external judgment. Facilitators of treatment included parental responsibility, motivation to protect their infant, positive healthcare relationships and structured support environments. Barriers to treatment during pregnancy included stigma, confusion from inconsistent provider messaging, competing priorities, and psychosocial stressors. Participants felt there was 'no correct choice' between preventing vertical transmission and potential treatment risks.

Conclusion: These preliminary findings from a qualitative study highlight factors influencing HCV treatment acceptance in pregnancy, including maternal identity, provider relationships, family perspectives, and patient-facing online resources. The findings emphasize the need for consistent provider and public-facing guidance within stigma-free, family-centered models of care.

Cumulative metformin exposure and risk of hepatocellular carcinoma after hepatitis C cure in a multicentre cohort

Henar Calvo Sánchez[1,2,3], Lorena Jara[4], Raquel Encijo Heredia[2,3], Irene Villarino[1], Ruben Alvarado[4], Marta Quiñones[4], Maria Luisa Gutiérrez[4], Joaquin Miquel[1,2], Miguel Torralba[2,3,5], Myriam Catalá[6,7], José Gómez[6,7], Oscar Barquero-Pérez[8], Sonia Albertos Rubio[9], Conrado Fernández- Rodríguez[4], Juan Ramón Larrubia[1,2,3]. *[1]Service of Gastroenterology, University Hospital of Guadalajara, Guadalajara, Spain; [2]Translational Research Group on Cellular Immunology (GITIC), Instituto de Investigación Sanitaria de Castilla La Mancha (IDISCAM), Guadalajara, Spain; [3]Department of Medicine and Medical Specialties, University of Alcalá, Alcalá de Henares, Spain; [4]Service of Gastroenterology, University Hospital Fundación Alcorcón, Alcorcón, Spain; [5]Service of Internal Medicine, University Hospital of Guadalajara, Guadalajara, Spain; [6]Department of Biology and Geology, Physics and Inorganic Chemistry, ESCET, Rey Juan Carlos University, Móstoles, Spain; [7]Institute for Global Change Research (IICG-URJC), Rey Juan Carlos University, Móstoles, Spain; [8]Department of Signal Theory and Communications and Telematic Systems and Computing, Rey Juan Carlos University, Fuenlabrada, Spain; [9]Gastroenterology Service, Alto Penedés–Garraf Sanitary Complex, Barcelona, Spain*
Email: henarcs@hotmail.com

Background and aims: Although sustained virological response after direct-acting antivirals markedly reduces hepatocellular carcinoma risk, a clinically relevant residual risk persists, particularly in patients with advanced fibrosis or clinically significant portal hypertension. Metformin has been proposed as a chemopreventive agent in type 2 diabetes mellitus, but evidence after hepatitis C cure remains inconsistent and methodologically limited. We aimed to evaluate

whether cumulative metformin exposure is independently associated with reduced hepatocellular carcinoma risk.
Method: We analysed a multicentre cohort of 1531 patients with chronic hepatitis C who achieved sustained virological response, with a median follow-up of 75.5 months. Metformin exposure was modelled as a time-updated cumulative variable within a start–stop Cox proportional hazards framework to avoid immortal-time bias. Stabilised inverse probability of treatment and censoring weights were applied to address confounding by indication and informative censoring. Models were stratified by sex and adjusted for type 2 diabetes mellitus, clinically significant portal hypertension, FIB-4 category, and smoking status. Random survival forests with SHapley additive explanations were used for complementary validation.
Results: During follow-up, 50 patients developed hepatocellular carcinoma. Incidence increased with fibrosis severity, reaching 1.76 cases per 100 person-years in patients with FIB-4 greater than 3.25. In the weighted Cox model, independent predictors of hepatocellular carcinoma were type 2 diabetes mellitus (hazard ratio 2.45), clinically significant portal hypertension (hazard ratio 6.60), advanced fibrosis (hazard ratio 10.23), and smoking (hazard ratio 2.82). Cumulative metformin exposure was independently associated with reduced risk (hazard ratio 0.46 per year; 95% confidence interval 0.28–0.77; p = 0.003). Proportional hazards assumptions were satisfied. Machine learning analyses consistently supported a protective contribution of metformin, particularly in high-risk subgroups.
Conclusion: Cumulative metformin exposure is independently associated with a sustained reduction in hepatocellular carcinoma risk after hepatitis C cure, particularly among patients with type 2 diabetes mellitus and advanced fibrosis. These findings support metformin as a potential chemopreventive strategy in high-risk post-cure populations.

WED-611
Multidisciplinary program for on-site screening and treatment of hepatitis C in patients with severe mental illness attended in mental health centers: the MENTAL-C study

Nuria Cañete Hidalgo[1], Cristóbal Díez-Aja[1], Maria Teresa Salvador[1], Herminia Manteca[1], José Ignacio Castro[1], Antonio Sergio Murcia[1], Elena Colominas[1], Esther Garrido[1], Diego Lázaro[1], Xavi Bessa[1], Montserrat Garcia-Retortillo[1]. [1]*Hospital Del Mar, Barcelona, Spain*
Email: ncanete@hmar.cat

Background and aims: Individuals with severe mental illness (SMI) are considered a vulnerable population with potential increased risk of hepatitis C virus (HCV) infection. Previous international studies report higher prevalence compared to the general population, while recent national data suggest similar rates. This study aimed to perform opportunistic screening for HCV, HBV, and HIV in patients with SMI and to implement a coordinated treatment pathway within Mental Health Centers (MHCs).
Method: This was a non-randomized, single-center interventional study. Professionals from three MHCs offered screening for HCV, HBV, and HIV to all patients diagnosed with SMI according to DSM-V criteria. Routine blood tests were used to include serologies. The Hepatology Unit held telematic meetings with MHC teams to decide treatment and coordinate medication delivery. Each MHC administered therapy and monitored adherence and response.
Results: Of 236 patients, 233 (98.7%) accepted screening. Seven patients were anti-HCV positive (3%), and five were HCV RNA positive (2.1%). Two treated patients were previously lost to follow-up and were successfully managed through the program. All five patients with active HCV infection achieved sustained virological response (SVR) with full adherence. HBsAg was positive in 2/233 patients (0.8%), and no HIV-positive cases were detected.
Conclusion: The prevalence of HCV infection in patients with SMI was higher than in the general population, supporting systematic screening. Opportunistic screening in MHCs showed high acceptability. Coordination between Hepatology Units and MHCs enables high-quality, patient-centered care.

WED-612
Serum laminin-γ2 monomer as a noninvasive marker for predictinghepatocellular carcinoma after direct-acting antiviral-induced cure ofhepatitis C virus infection

Yu Ping Chang[1]. [1]*National Taiwan University Hospital, Hsin-Chu Branch, BioMedical Park Hospital, Zhubei City, Taiwan*
Email: melsachangchang@gmail.com

Background and aims: The clinical utility of serum laminin-γ2 monomer (LG2m) in predicting hepatocellular carcinoma (HCC) occurrence after direct-acting antiviral (DAA)-induced hepatitis C virus (HCV) clearance remains to be established.
Method: A total of 978 patients who underwent pretreatment serum LG2m assessment were enrolled. All patients received biannual liver imaging and alpha-fetoprotein (AFP) evaluations to detect HCC occurrence from the time of HCV cure to the last follow-up. The HCC-free probability was compared between patients with LG2m < 30 pg/mL and ≥ 30 pg/mL using the log-rank test. Univariable and multivariable Cox proportional hazards models were constructed for LG2m, fibrosis index based on four parameters (FIB-4), AFP, protein induced by vitamin K absence or antagonist-II (PIVKA-II), and albumin-bilirubin (ALBI) grade, with model selection guided by the Akaike information criterion (AIC). Results are expressed as hazard ratios (HRs) with 95% confidence intervals (CIs).
Results: The HCC-free probability was significantly higher in patients with LG2m < 30 pg/mL compared with those with LG2m ≥ 30 pg/mL (p < 0.0001). In univariable Cox analysis, LG2m (cHR: 2.79, 95% CI: 2.39–3.26; p < 0.001) outperformed FIB-4, AFP, PIVKA-II, and ALBI grade, showing the lowest AIC value (1129.259). In the multivariable Cox model, LG2m (aHR: 1.84, 95% CI: 1.48–2.29; p < 0.001), age (aHR: 1.07, 95% CI: 1.04–1.09; p < 0.001), male sex (aHR: 2.40, 95% CI: 1.56–3.68; p < 0.001), and F4 fibrosis (aHR: 42.0, 95% CI: 5.73–308; p < 0.001; vs. F0) were independent predictors of HCC occurrence.
Conclusion: Serum LG2m outperforms FIB-4, AFP, PIVKA-II, and ALBI grade in predicting HCC occurrence and serves as a reliable noninvasive biomarker for patients.
achieving HCV cure with DAA therapy.

WED-613
Serum Golgi protein 73 as a noninvasive marker of hepatic fibrosis in chronic hepatitis C virus infection

Yun-Chu Chen[1], Yu Ping Chang[2], Ji-Yuh Lee[3], Chi-Yi Chen[4], Wei-Yu Kao[5], Chih-Lin Lin[6], Sheng-Shun Yang[7], Yu-Lueng Shih[8], Cheng-Yuan Peng[9], Fu-Jen Lee[10], Ming-Chang Tsai[11], Shang-Chin Huang[12], Tung-Hung Su[1], Tai-Chung Tseng[1], Chun-Jen Liu[1], Pei-Jer Chen[1], Jia-Horng Kao[1], Chen-Hua Liu[1]. Email: ycc103311151@gmail.com

Background and aims: The clinical utility of serum Golgi protein 73 (GP73) for evaluating hepatic fibrosis for hepatitis C virus (HCV) infection remains uncertain.
Method: We retrospectively enrolled 978 patients who underwent measurement of serum GP73, aspartate-to-platelet ratio index (APRI), and fibrosis index based on four parameters (FIB-4). Hepatic fibrosis was staged using vibration-controlled transient elastography

(VCTE) with cutoff values of ≤ 7.0, 7.1–9.4, 9.5–12.4, and ≥ 12.5 kPa corresponding to F0-F1, F2, F3, and F4. Median GP73, APRI, and FIB-4 levels across fibrosis stages were compared using Kruskal-Wallis test. Areas under the receiver operating characteristic curves (AUROCs) were calculated and compared using c-statistics, and optimal GP73 cutoff values were determined by maximal Youden index. Multivariable linear regression was performed to identify factors affecting GP73 levels.

Results: Median GP73, APRI, and FIB-4 levels increased with advancing fibrosis stage ($p < 0.001$). Serum GP73 outperformed APRI in discriminating ≥ F2 (AUROC 0.86 vs. 0.79, $p < 0.0001$), ≥ F3 (0.88 vs. 0.81, $p = 0.0003$), and F4 (0.90 vs. 0.84, $p = 0.0017$). GP73 showed superior performance to FIB-4 for ≥ F2 (0.86 vs. 0.82, $p = 0.005$) and comparable performance for ≥ F3 (0.88 vs. 0.87, $p = 0.63$) and F4 (0.90 vs. 0.89, $p = 0.72$). Optimal GP73 cutoff values were 122, 159, and 174 ng/mL for ≥ F2, ≥ F3, and F4. Hepatic fibrosis stage was the major determinant of GP73 levels.

Conclusion: Serum GP73 is a reliable and accurate noninvasive biomarker for staging hepatic fibrosis for HCV.

WED-617-YI

Hepatic and extrahepatic malignancies in hepatitis C virus-infected patients with cirrhosis treated with direct-acting antivirals in long-term observation

Krystyna Dobrowolska[1], Jakub Janczura[1], Michał Brzdęk[2], Robert Flisiak[3], Kinga Brzdęk[4], Dorota Zarębska-Michaluk[5].
[1]Collegium Medicum, Jan Kochanowski University, Kielce, Poland; [2]Department of Gastroenterology, Medical University of Lodz, Łódź, Poland; [3]Department of Infectious Diseases and Hepatology, Medical University of Białystok, Białystok, Poland; [4]Department of Rheumatology and Connective Tissue Diseases, Nicolaus Copernicus Memorial Hospital, Łódź, Poland; [5]Department of Infectious Diseases and Allergology, Jan Kochanowski University, Kielce, Poland
Email: krystyna.dobrowolska98@gmail.com

Background and aims: Patients with chronic hepatitis C virus (HCV) infection and cirrhosis are at risk of developing hepatocellular carcinoma (HCC) and malignancies outside the liver. The aim of this study was to evaluate long-term survival rates among patients with cirrhosis and to assess the development of hepatic and extrahepatic malignancies after direct-acting antiviral (DAA) therapy.

Method: We analyzed retrospective data collected from all 323 consecutive patients with liver cirrhosis infected with HCV out of a total of 1395 patients treated with DAAs between 2015 and 2025 at a single hepatology center, who were under long-term follow-up for a median of 6 years.

Results: The population analyzed was dominated by men (57%), and at the start of treatment three-quarters were people over 50 years of age. More than 95% of patients had at least one comorbid condition, with the most common being steatotic liver disease (69%). Before DAA treatment, HCC was diagnosed in 21 patients (6.5%), and non-liver cancer was diagnosed in 23 individuals (7.1%). No patient had a history of liver transplantation. Clinical symptoms of hepatic decompensation were present at baseline in 46 patients (14.2%). The effectiveness of DAA therapy was 95.4%, which is significantly lower than the 99.1% observed in a population of 1072 patients without cirrhosis ($p < 0.001$). During the long-term follow-up period of 6(3–7) years [median(IQR)], there were 34 (10.5%) new diagnoses of HCC (2 patients with DAA treatment failure), and 24 (7.4%) newly diagnosed non-liver neoplasms (only DAA responders). During long-term follow-up, 136 patients (42.1%) died; in 48 cases (35.3%), death was directly caused by malignant neoplasms, including 31 cases of HCC (12 diagnosed before DAA and 19 de novo cases) and 17 cases of non-liver malignancies (7 diagnosed before DAA and 10 de novo cases). The probability of survival was significantly lower among patients with cirrhosis compared to non-cirrhotic persons ($chi^2 = 220$, $df = 1$, $p < 0.001$).

Conclusion: During long-term observation of a population of cirrhotic patients infected with HCV, about 10% developed de novo HCC and 7% developed non-liver malignancies. Approximately 42% of patients died, with neoplasm being the direct cause of death in one third of them. The probability of survival in the long-term observation was significantly lower among patients with cirrhosis compared to non-cirrhotic persons.

WED-618

Evaluation of clinical performance and utility of the combined HCV antigen-antibody assay (HCV Duo)

Kazumi Yamasaki[1], Tatsuya Fujino[1], Tomoyuki Suehiro[1], Yuki Kugiyama[1], Tomohito Kojima[1], Yasuhide Motoyoshi[1], Shinya Nagaoka[1], Atsumasa Komori[1], Hiroshi Yatsuhashi[1]. *[1]NHO Nagasaki Medical Center, Omura, Japan*
Email: yatsuhahashihiroshi@gmail.com

Background and aims: HCV Duo is the first diagnostic reagent in Japan capable of simultaneously detecting HCV antibodies (Duo-Ab) and HCV core antigens (Duo-Ag) in a single measurement. This study aimed to evaluate the sensitivity and specificity of Duo-Ab and Duo-Ag, assess their concordance with a conventional HCV antibody assay (CLIA: Company A), and clarify the clinical utility of HCV Duo.

Method: We analyzed 628 patients (HCV RNA positive: 507; negative: 121) who first visited our liver clinic between January 2010 and December 2021 and had previously tested positive using the Company A antibody assay. HCV Duo was performed using electrochemiluminescence immunoassay (ECLIA) for the simultaneous qualitative detection of Duo-Ab and Duo-Ag, with a cutoff index (COI) 1.0 defined as positive. The overall result was determined by the higher COI value between Duo-Ab and Duo-Ag. Discrepant cases between the two antibody assays were further investigated using Line Immunoassay (LIA) and HCV RNA results. Duo-Ag positivity rates were also analyzed by HCV RNA viral load.

Results: Among the 628 cases, 591 (94.1%) were overall positive for HCV Duo. The breakdown was: 393 (62.6%) Duo-Ag(+)/Duo-Ab(+), 1 (0.1%) Duo-Ag(+)/Duo-Ab(−), and 197 (31.4%) Duo-Ag(−)/Duo-Ab(+). Discrepancy between Duo-Ab and Company A antibody was observed in 38 cases (6.0%). LIA testing of these cases showed 27 negative, 10 indeterminate, and 1 uninterpretable; no cases were LIA-positive. The sensitivity of Duo-Ag for HCV RNA-positive cases (n = 507) was 78% (394/507), and the specificity for RNA-negative cases (n = 121) was 100%. Duo-Ag positivity rates increased in a viral load-dependent manner: 9% for 2.0 Log IU/mL, 16% for 3.0–3.9, 35% for 4.0–4.9, 75% for 5.0–5.9, 95% for 6.0–6.9, and 100% for 7.0 Log IU/mL.

Conclusion: HCV Duo enables rapid evaluation of HCV infection status at the first visit by simultaneously measuring Duo-Ab and Duo-Ag, contributing to improved diagnostic efficiency and reduced patient burden. Our results demonstrate that Duo-Ab has high specificity (consistent with LIA) and Duo-Ag provides high sensitivity in cases with high viral loads. While HCV RNA confirmation remains essential for cases with low viral loads, HCV Duo offers significant clinical utility as a single-step diagnostic approach for HCV infection.

WED-619

Survival benefits of SVR across different BCLC stages in HCV patients: results from the England national HCV registry

Maria Guerra Veloz[1], Rathiga Rudra[2], Daniel Clayton-Chubb[3], Simon Hume[3], Renita George[1], Sarah Selemani[1], Paul Ross[1], Janet Dearden[2], Aileen Marshall[3], Peter Sandwith[2], Kosh Agarwal[1], Matthew Foxton[4], Douglas Macdonald[3]. *[1]King's College Hospital, Institute of Liver Studies, London, United Kingdom; [2]Department of Hepatology, Barts Health NHS Trust, London, United Kingdom; [3]Royal Free Hospital, London, United Kingdom; [4]Chelsea & Westminster NHS Foundation Trust, London, United Kingdom*
Email: maria.guerraveloz@nhs.net

Background and aims: The usefulness and optimal timing of direct acting antiviral (DAA) therapy initiation in patients with

hepatocellular carcinoma (HCC) across the different BCLC stages remains undefined. Since 2015, NHS England has approved DAA therapies for all viraemic patients, including those with HCC. The aim of this study is to assess the long-term benefits (overall survival, OS) of DAA therapies in those with HCC across the different stages.
Method: This retrospective multicentre study included BCLC 0/A/B/C patients with HCV related HCC who started DAA therapies and had an outcome reported (SVR or non-SVR). The data was extracted from the National Hepatitis C Registry in Greater London and cross-referenced with the multidisciplinary HCC team records in each centre between 2015 and 2025.
Results: 168 HCV RNA-positive patients were included. The BCLC stage was 0/A 69.6% (117), B 17.9% (30) and C 12.5% (21). The majority had compensated cirrhosis (71.6%) with normal liver function (Child Pugh A (85.8%) and ALBI grade 1 (73.3%)). 24% received more than one DAA therapy. The median time from DAA therapy initiation to HCC diagnosis was 4 (IQR 1–11) months. SVR rate was 85.1% (143/168). SVR rate based on BCLC stage was 88.9 vs 69 vs 90% in BCLC 0/A, B and C respectively.47% (79) received curative treatments for their HCC (resection, transplant, ablation or chemoembolisation followed by adjunctive ablation). The median number of anti-cancer treatments provided was 2 (IQR 1–4). The median OS for BCLC patients who achieved SVR was 93 (95% CI 83–104) months (Stage 0/A), 63 (95% CI 40–87) months (Stage B), and 40 (95% CI 23–58) months (Stage C). (Log Rank $p < 0.001$). In contrast, OS for BCLC patients who did not achieve SVR was 39 (95% CI 23–55) months (Stage 0/A), 29 (95% CI 20–39) months (Stage B), and 13 (95% CI 5–20) months (Stage C). (Log Rank $p < 0.001$). The improvement in OS was also noted across different cancer treatments (curative intent with SVR (109 months) vs curative intent with non-SVR (43 months). In the multivariate Cox regression model, [adjusted by sex, age, BCLC stage, liver function (ALBI grade)], not achieving SVR (HR 3.4, 95% CI 1.9–6.2, $p < 0.001$) and non-receiving curative HCC treatments (HR 3.07, $p < 0.001$) were the major risk factors associated with mortality.
Conclusion: SVR post DAA therapies led to an improvement in the OS irrespective of BCLC stage at presentation. Therefore, we believe that DAA therapies should be initiated together with anti-cancer treatments.

WED-620
Obesity as a population-wide risk factor for liver disease progression: results from the German hepatitis C-registry (DHC-R) and the UK biobank

Katharina Luise Hupa-Breier[1], Thriveni Raju[2], Peter Buggisch[3], Hartwig Klinker[4], Stefan Mauss[5], Albrecht Stoehr[3], Renate Heyne[6], Karl-Georg Simon[7], Thomas Berg[8], Katja Deterding[1], Andreas Geier[9], Heiner Wedemeyer[1,10], Carolin V. Schneider[2], Monika Rau[9].

Email: hupa.katharina@mh-hannover.de

Background and aims: Obesity and alcohol consumption are established risk factors for liver disease, but their individual and combined effects in patients with chronic hepatitis C virus infection (cHCV) remain insufficiently defined, particularly regarding potential supra-additive interactions. We aimed to assess the impact of obesity and alcohol consumption on liver disease progression in cHCV patients after sustained virologic response (SVR) and to externally validate these findings in a large population-based cohort.
Method: Patients from the German Hepatitis C-Registry achieving SVR were stratified by obesity (BMI ≥25 vs. <25) and alcohol consumption (none vs. any). The primary endpoint was progression to cirrhosis; secondary endpoint was disease-related mortality. External validation was performed in the UK Biobank, analysing predictors of liver disease progression, (first ICD-code K74.6 diagnosis) in individuals with risk for liver disease (FIB-4 ≥1.3).
Results: In the German cHCV-cohort (n = 5967), 51.7% were overweight/obese and 18.3% reported active alcohol consumption. Obesity without alcohol consumption was associated with a significantly higher risk of cirrhosis progression compared with lean patients who consumed alcohol. In multivariate models, obesity and type 2 diabetes mellitus (T2DM) were the strongest independent predictors of disease progression (OR for BMI >35: 2.833 [1.682–4.771]; OR for T2DM: 1.489 [1.004–2.208]), with similar patterns observed for mortality-related outcomes. External validation in the UK Biobank (n = 200,633) confirmed obesity as the dominant risk factor for cirrhosis progression (OR 2.70, 95% CI 2.33–3.13 vs. lean) in the general population. Compared with lean non-drinkers, odds of cirrhosis were increased in lean former drinkers (OR 2.34), obese drinkers (OR 2.29), obese non-drinkers (OR 2.91), and were highest in obese former drinkers (OR 7.77). No supra-additive interaction between obesity and alcohol consumption was observed in both cohorts.
Conclusion: Across two large and complementary cohorts, obesity rather than alcohol consumption is the predominant risk factors for liver disease progression. Importantly, the UK Biobank analysis shows that the adverse impact of obesity extends beyond the cHCV population and represents a universal risk factor for progressive liver disease. These findings underscore the need for targeted weight management strategies both in patients cured of HCV and in the general population.

WED-621
The oral cholate challenge test detects early hepatic improvement with ledipasvir/sofosbuvir in liver transplant recipients and patients with advanced cirrhosis

Michael McRae[1], Joanne Imperial[2], Greg Everson[2]. [1]*Custom DX Solutions LLC, Houston, Texas, United States;* [2]*HepQuant, LLC, Denver, Colorado, United States*
Email: michael.mcrae@hepquant.com

Background and aims: Restoring hepatic function after SVR is a key objective in the management of advanced HCV. In the SOLAR-1 trial, liver transplant (LTx) recipients with fibrosis or cirrhosis and patients with end-stage liver disease (ESLD) received ledipasvir/sofosbuvir plus ribavirin. In a sub-study of SOLAR-1, hepatic function was measured using the HepQuant SHUNT test (results reported at EASL 2015). Here, we focus on results using only the oral cholate dose (HepQuant DuO).
Method: 31 subjects were enrolled in the sub-study, 2 did not achieve SVR, and 1 decompensated from spontaneous bacterial peritonitis, leaving 28 patients with SVR. The Test was performed at baseline and at weeks 4, 24, and 48 in three groups: non-cirrhotic LTx recipients (n = 10), cirrhotic LTx recipients (n = 10), and pre-LTx ESLD patients (n = 8). HepQuant DuO involves an oral dose of deuterium-labelled (d4) cholate, blood draws at 20 and 60 minutes, and measurement of d4-cholate by LC-MS/MS. The Disease Severity Index (DSI) was calculated, which ranges from 0 (healthy) to 50 (severe dysfunction). Change from baseline in DSI was evaluated after 4, 24, and 48 weeks.
Results: At baseline, DSI was 20.4 ± 4.6 in non-cirrhotic LTx recipients, 26.7 ± 5.9 in cirrhotic LTx recipients, and 38.3 ± 2.4 in ESLD patients. By week 4, DSI declined significantly in non-cirrhotic LTx recipients (−4.6 ± 3.9, $p < 0.01$), showed a non-significant reduction in cirrhotic LTx recipients (−1.2 ± 2.5, $p = 0.20$), and remained

unchanged in ESLD patients (+0.3 ± 2.7, p = 0.77). By week 24, DSI remained significantly reduced in non-cirrhotic LTx recipients (−3.8 ± 3.4, p = 0.02), trended downward in cirrhotic LTx recipients (−2.1 ± 3.6, p = 0.10), and did not change in ESLD patients (0.0 ± 2.7, p = 0.97). By week 48, DSI remained significantly reduced in non-cirrhotic LTx recipients (−2.8 ± 3.7, p = 0.045); the downward trend was not sustained in cirrhotic LTx recipients (−0.7 ± 4.2, p = 0.62); and, DSI remained unchanged in ESLD patients (+1.8 ± 3.4, p = 0.21).
Conclusion: The favorable early improvements in function in noncirrhotic patients implies a dynamic reversibility of the changes to the hepatic microcirculation with resolution of the necroinflammation. Slower improvement or lack of early improvement in function in advanced disease suggest that longer follow-up may be required to demonstrate recovery. These findings underscore DSI's sensitivity in detecting early functional responses to antiviral therapy across a spectrum of stages of fibrosis and clinical severity.

WED-623
Persistence of cryoglobulinemia after SVR in asymptomatic HCV patients identifies a population at risk for immune and lymphoproliferative disorders

Email: annalinda.zignego@unifi.it

Background and aims: Serum cryoglobulins are detectable in 40–60% of patients with chronic HCV infection, but only a minority develop clinically overt cryoglobulinemic vasculitis (CV). Although the impact of antiviral therapy (AVT) on CV is well established, the long-term clinical significance of asymptomatic cryoglobulinemia, representing most cases and often considered an epiphenomenon, remains unclear. We aimed to evaluate the long-term outcome of asymptomatic cryoglobulinemia after sustained virological response (SVR) and its implications for post-treatment follow-up (FU).
Method: Within the Italian PITER network, we conducted a multicenter study assessing the long-term evolution of asymptomatic cryoglobulinemia after SVR. Patients were classified according to post-AVT cryoglobulin status: persistent positivity (Group A) or negativization (Group B). Group A was further subdivided into persistent (A1) or transient (A2) cryoglobulinemia.
Results: Among more than 100 enrolled patients, 65 had complete, largely prospectively collected long-term FU data (mean FU 76.6 ± 29.9 months; range 10–176). After AVT, 38 patients were classified as Group A (23 in subgroup A1 and 15 in A2), and 27 as Group B. No patient developed de novo CV. However, nonspecific symptoms, including fatigue, arthralgia, peripheral neuropathy, sicca syndrome, and Raynaud's phenomenon, were significantly more frequent in Group A (18/38, 47.4%) than in Group B (4/27, 14.8%) ($p < 0.05$). Autoimmune and lymphoproliferative disorders, including monoclonal gammopathy of undetermined significance, lymphadenopathy, autoantibody positivity, and B-cell lymphomas, were also significantly more prevalent in Group A (21/38, 55.3%) ($p < 0.05$) in both univariate and multivariate logistic regression analyses. This difference remained statistically significant only for patients in subgroup A1 compared with Group B. Three lymphomas occurred in Group A, including one diffuse large B-cell lymphoma diagnosed more than four years after SVR.
Conclusion: Persistent cryoglobulinemia after HCV eradication identifies a clinically distinct condition associated with immune-mediated and lymphoproliferative disorders, even in the absence of overt vasculitis. Asymptomatic HCV patients should be screened for cryoglobulins after AVT, and those with persistent positivity should undergo regular FU, similar to that recommended for patients with CV and persistent cryoglobulinemia after SVR (EASL position paper on clinical follow-up after HCV cure. J Hepatol. 2024).

WED-624
Association of a liver steatosis–related polygenic risk score with hepatocellular carcinoma risk after hepatitis C virus eradication

Yu-Sheng Lin[1], Ying-Cheng Lin[1,2], Yun-Yu Chen[2,3,4,5], Yi-Ming Chen[4,6,7], I-Chieh Chen[4], Hsin-Ju Tsai[1,2], Chia-Chang Chen[1,2], Shou-Wu Lee[1,2,8], Hwai-I Yang[9,10,11,12], Teng-Yu Lee[1,8]. *[1]Division of Gastroenterology and Hepatology, Department of Internal Medicine, Taichung Veterans General Hospital, Taichung, Taiwan; [2]Department of Post-Baccalaureate Medicine, College of Medicine, Chung Hsing University, Taichung, Taiwan; [3]Cardiovascular Center, Taichung Veterans General Hospital, Taichung, Taiwan; [4]Department of Medical Research, Taichung Veterans General Hospital, Taichung, Taiwan; [5]Heart Rhythm Center and Division of Cardiology, Department of Medicine, Taipei Veterans General Hospital, Taipei, Taiwan; [6]Division of Allergy, Immunology and Rheumatology, Department of Internal Medicine, Taichung, Taiwan; [7]Institute of Biomedical Science and Rong Hsing Research Center for Translational Medicine, National Chung Hsing University, Taichung, Taiwan; [8]School of Medicine, Chung Shan Medical University, Taichung, Taiwan; [9]Genomics Research Center, Academia Sinica, Taipei, Taiwan; [10]Institute of Clinical Medicine, National Yang Ming Chiao Tung University, Taipei, Taiwan; [11]Graduate Institute of Medicine, College of Medicine, Kaohsiung Medical University, Kaohsiung, Taiwan; [12]Biomedical Translation Research Center, Academia Sinica, Taipei, Taiwan*
Email: tony19920215@hotmail.com

Background and aims: Genetic predisposition to hepatic steatosis may increase hepatocellular carcinoma (HCC) risk after hepatitis C virus (HCV) eradication in cirrhotic patients; however, its impact on broader patient populations remains unexplored. We aimed to evaluate the association of steatosis-polygenic risk score (PRS) with HCC following direct-acting antiviral (DAA) therapy.
Method: This retrospective cohort study utilized data from the Taiwan Precision Medicine Initiative, including adults treated with DAAs for HCV. Patients with treatment failure, hepatitis B virus co-infection, significant alcohol use, or HCC diagnosis prior to sustained virological response at 24 weeks were excluded. All participants underwent genotyping, with PRS-5 being used to quantify genetic risk. We evaluated the association between PRS-5 and the risk of incident HCC using restricted cubic spline analysis with Cox proportional hazards models.
Results: The cohort included 420 patients (median age 67.0 years; 46.9% male). The 5-year cumulative incidence of HCC in PRS-5 ≥ 0.66 group was higher than PRS-5 < 0.66 group (23.97%, 95% confidence interval (CI) 7.15–40.79% vs. 8.89%, 95% CI 5.56–12.23%; $P = 0.014$). In multivariable regression, PRS-5 ≥ 0.66 (aSHR 3.59, 95% CI 1.69–7.63; $p < 0.001$), body weight index >24 kg/m^2 (aSHR 2.68, 95% CI 1.24–5.78; $p = 0.012$), and Fibrosis-4 index >3.25 (aSHR 4.58, 95% CI 2.20–9.53; $p < 0.001$) were independently associated with HCC occurrence. Subgroup analysis supported the predictive value of PRS-5 in almost all patient subgroups, including Fibrosis-4 index < 3.25 and non-cirrhosis.
Conclusion: PRS-5 is independently associated with increased HCC risk after HCV eradication, supporting its role in personalized HCC surveillance strategies.

WED-625

The association of liver stiffness measurement with liver-related complications in chronic hepatitis C infection: a retrospective study in Thailand

Pemika Manassevee[1], Sarita Ratana-Amornpinm[1]. [1]*Ramathibodi Hospital, Bangkok, Thailand*
Email: m.pemika57@gmail.com

Background and aims: Despite the success of direct-acting antivirals (DAAs), chronic hepatitis C (CHC) patients remain at risk for liver-related complications after viral clearance. This study aimed to evaluate the association between LSM and liver-related complications in CHC patients and to identify an optimal LSM threshold for risk stratification.
Method: We retrospectively reviewed 267 CHC patients treated between 2010 and 2025. Patients were followed for a median of 6.2 years. Liver-related complications were defined as ascites, variceal bleeding, hepatic encephalopathy, or hepatocellular carcinoma. VCTE was performed using FibroScan® by experienced operators. Logistic regression was used to identify independent predictors of complications. Receiver operating characteristic (ROC) analysis was performed to determine the optimal LSM cutoff using Youden's index. Complication-free survival was assessed using Kaplan–Meier analysis.
Results: During follow-up, 34 patients (12.7%) developed liver-related complications. Patients with complications were older and had significantly higher baseline LSM values. An LSM ≥ 12 kPa was strongly associated with complications (adjusted OR 8.56, 95% CI = 2.73–26.92; $p < 0.001$). In contrast, achieving a sustained virological response at 12 weeks (SVR12) was a protective predictor (OR = 0.24, 95% CI = 0.08–0.70, $p = 0.009$). Additional independent predictors included age ≥60 years (OR 3.49; $p = 0.014$), body mass index (BMI) (OR 1.14; $p = 0.022$), and platelet count (OR 0.99; $p = 0.001$). ROC analysis identified an optimal LSM cutoff of 12.1 kPa, with an area under the curve of 0.832, sensitivity of 82.4%, and specificity of 77.3%. Kaplan–Meier analysis demonstrated significantly reduced complication-free survival in patients with LSM ≥ 12 kPa (log-rank $p < 0.0001$).
Conclusion: LSM ≥ 12 kPa is a strong and independent predictor of liver-related complications in patients with chronic HCV infection. These findings support the role of transient elastography not only for fibrosis staging but also for risk stratification beyond HCC surveillance.

WED-626-YI

Hepatocellular carcinoma surveillance among chronic hepatitis C patients after successful sustained virologic response: a systematic review and meta-analysis of economic evaluation studies

Soe Thiha Maung[1,2], Peerada Valyasevi[2], Roongruedee Chaiteerakij[2]. [1]*Ma Har Myaing Hospital, Yangon, Myanmar;* [2]*Faculty of Medicine, Chulalongkorn University, Bangkok, Thailand*
Email: dr.sthm92@gmail.com

Background and aims: Although sustained virologic response (SVR) significantly reduces the risk of hepatocellular carcinoma (HCC) in chronic hepatitis C (CHC) patients, the residual risk, especially among those with advanced fibrosis or cirrhosis, necessitates consideration of ongoing surveillance. Current guidelines offer inconsistent recommendations. This systematic review and meta-analysis evaluates the cost-effectiveness of HCC surveillance strategies post-SVR, to inform evidence-based clinical and policy decisions.
Method: A systematic search was performed in PubMed, Embase, Scopus, Google Scholar, and the Cochrane Library to identify economic evaluations of HCC surveillance strategies in CHC patients post-SVR. Studies reporting cost-effectiveness outcomes. Incremental net monetary benefit (INMB) values were calculated for meta-analysis. Study quality was assessed using the ECOBIAS checklist. Subgroup analyses were conducted based on surveillance modality, interval, and willingness-to-pay (WTP) thresholds.
Results: Of 157 identified records, seven studies were included in the meta-analysis. All studies were conducted in American regions. Four focused exclusively on patients with cirrhosis, while three included both advanced fibrosis (F3) and cirrhosis. Most applied Markov models from a healthcare payer perspective. At a WTP threshold of USD 100,000, pooled INMB was significantly positive (USD1743; 95% CI: 468–3019;$p = 0.007$), particularly among cirrhosis-only populations. No significant cost-effectiveness was observed at WTP thresholds of USD 50,000 or 150,000. Subgroup analyses at a WTP threshold of USD 50,000 showed no surveillance strategy yielded statistically significant INMB. Across modeling domains, results remained non-significant regardless of surveillance interval, HCC incidence, time horizon, SVR population, or model perspective. Overall, substantial consistency across subgroups was observed, with negligible heterogeneity ($I^2 = 0\%$), suggesting limited cost-effectiveness of post-SVR surveillance under lower WTP thresholds.
Conclusion: Current international guidelines show divergence in post-SVR HCC surveillance recommendations for CHC patients with advanced fibrosis. HCC surveillance post-SVR may be cost-effective at higher WTP thresholds, especially in cirrhotic patients on U.S. setting. Given the economic and epidemiological differences, region-specific economic evaluations are urgently needed to guide appropriate surveillance policies and resource allocation across diverse healthcare systems.

WED-627

Micro-elimination of HCV in state-infected cohort – 40 years' experience

David O Sullivan[1], Rionach Cawley[1], Pauline Dillon[1], Laura Stobie[1], Eimear Carolan[1], Attracta Ruxton[1], Monica Blount[1], Dee Noone[1], John Ryan[1]. [1]*Hepatology Unit, Beaumont Hospital, Dublin, Ireland*
Email: davidosullivan805@gmail.com

Background and aims: Hepatitis C virus (HCV) remains a leading cause of cirrhosis, hepatocellular carcinoma, and liver-related mortality worldwide. In Ireland, a group of individuals were infected with HCV from contaminated blood products, mostly in the late 1970s. This provides a defined population in which to assess disease natural history and outcomes. Our aim was to review long-term outcomes in this cohort at our institution.
Method: We retrospectively reviewed 168 patients over a 40-year period. Demographics, source of infection, genotype, fibrosis stage, treatment regime, and outcomes were analysed.
Results: Of 168 patients, 16 were male and 152 were female. 98 (58%) cleared the virus without treatment, while 70 (42%) developed chronic HCV infection. Of these, presumed sources of infection included anti-D immunoglobulin (n = 59), blood transfusion (n = 8), vertical transmission (n = 2), and needle stick injury (n = 1). The predominant genotype was 1b (n = 42, 60%). 7 developed advanced fibrosis/cirrhosis, 1 developed liver cancer, and 0 underwent liver transplantation. 3 patients died of liver-related complications since completing treatment, while no patients died of liver-related disease prior to treatment. The mean time from diagnosis (first clinic visit) to liver related outcome (cirrhosis/HCC/death) was 14.0 years (median 16.5 years, range 4.4–18.2 years). By 2024, all patients in this cohort achieved viral cure (SVR). Of the 70 patients treated, median age was 66.2 years (35.7–85.5 years). Successful treatment regimens were with direct acting antivirals (n = 43), protease inhibitor-based triple therapy (n = 2), pegylated interferon/ribavirin (n = 22), and not recorded (n = 3). 1 patient received more than one treatment regimen to achieve SVR.
Conclusion: HCV infection from contaminated blood products led to significant morbidity and mortality in a subgroup of otherwise well women who had just given birth. Over four decades, micro-elimination of HCV has been achieved within this state-infected cohort. These data demonstrate transformative impacts of DAA's and

importantly, these findings align closely with Ireland's commitment to the WHO 2030 elimination targets.

WED-628

Improving machine learning prediction of hepatitis C virus infection by incorporating social determinants of health from clinical notes via natural language processing and contextual-level data

Jungjun Bae[1], Suk-Chan Jang[1], Pilar Hernandez-Con[1], Chanakan Jenjai[1], Ashley Stultz[1], Shunhua Yan[1], Daniel Paredes Pardo[1], Yonghui Wu[1], Wei-Hsuan Lo-Ciganic[2], Khoa Nguyen[1], Faheem Guirgis[1], Christine Gage[1], Robert Cook[1], Ramzi Salloum[1], David R. Nelson[1], Haesuk Park[1]. *[1]University of Florida, Gainesville, United States; [2]University of Pittsburgh, Pittsburgh, United States*
Email: hpark@cop.ufl.edu

Background and aims: We developed and validated machine learning algorithms to identify undiagnosed hepatitis C virus (HCV) infection and compared the performance of models using structured electronic health record (EHR) data alone versus models incorporating social determinants of health (SDoH) derived from clinical notes and contextual-level data.
Method: We conducted prognostic modeling using EHR data from the University of Florida Health System. The study cohort included individuals aged ^{3}18 years screened for HCV in emergency department or inpatient settings between 2016 and 2024. Individuals with a prior HCV diagnosis or treatment were excluded. Three Gradient Boosting Machine learning models were evaluated. Model 1 included 275 structured predictors from a six-month baseline, encompassing sociodemographic and clinical characteristics. Model 2 added 57 contextual-level SDoH based on residential zip codes using regional data (e.g., Social Vulnerability Index). Model 3 further added 13 person-level SDoH predictors (e.g., homelessness, injection drug use) extracted from clinical notes using natural language processing (NLP) and evaluated over one-year, two-year, and full observation periods. Model performance was assessed using C statistics, sensitivity, specificity, and risk stratification by deciles of predicted risk scores.
Results: Among 45,623 individuals screened, 7.5% had laboratory-confirmed HCV infection. Training (75%) and validation (25%) samples were comparable (mean age 48 ± 17 years; 47% male; 60% White; 34% Medicaid beneficiaries). Model 1 using structured EHR data demonstrated excellent discrimination (C statistic 0.867; 95% CI, 0.858–0.876). Model 2 incorporating contextual-level SDoH showed a modest, non-significant improvement (C statistic 0.874; 95% CI: 0.864–0.883). Model 3 incorporating NLP-derived person-level SDoH using a two-year baseline significantly improved discrimination (C statistic 0.894; 95% CI, 0.886–0.903). Using the Youden index, Model 3 achieved 82.1% sensitivity and 80.9% specificity, corresponding to one HCV-positive case detected per four tests. Risk stratification identified 87.1% of HCV-positive individuals within the top three deciles of predicted risk scores.
Conclusion: Incorporating both person- and contextual-level SDoH beyond structured EHR data significantly improved HCV prediction, highlighting the importance of integrating SDoH into screening strategies in emergency department and inpatient settings.

WED-629-YI

Prevalence of advanced liver fibrosis and cirrhosis among patients with hepatitis C in a UK prison

Jennifer Plunkett[1], Jessica Pinto[1], Claire St John[2], Amy Teague[1], Claire Smith[1], Douglas Macdonald[3], William Rosenberg[3], Paul Trembling[3]. *[1]Royal Free London NHS Foundation Trust, London, United Kingdom; [2]North Central London ODN, London, United Kingdom; [3]Institute of Liver and Digestive Health, University College London, London, United Kingdom*
Email: j.plunkett1@nhs.net

Background and aims: Hepatitis C virus (HCV) infection is a major health challenge in prison populations. Prevalence of liver fibrosis severity in this setting is not well described, with most studies relying on indirect fibrosis markers, e.g. Fib4. To our knowledge there are no studies describing the burden of advanced fibrosis or cirrhosis in individuals diagnosed with HCV within UK prisons. We aimed to estimate the prevalence of advanced (Metavir ≥F3) fibrosis or cirrhosis amongst those approved for HCV treatment through our outreach prison service.
Method: Demographics, HCV genotype, fibrosis stage and treatment regimens were extracted from our HCV database. Fibrosis was assessed using Fibroscan, Enhanced Liver Fibrosis (ELF) test and/or FIB4. Published fibrosis thresholds were used: >10 kPa or ELF >9.8 for ≥F3 fibrosis, and >13 kPa or ELF >11.3 for cirrhosis. FIB4 <1.45 ruled out ≥F3 fibrosis. Results were compared with the general HCV population in our service assessed by FibroScan.
Results: Between 2015 and 2025, 176 patients were approved for HCV treatment; 161 (91%) had fibrosis assessment. Thirty (17%) underwent FibroScan, 124 (70%) had ELF testing and seven (4%) had FIB-4 calculated. Mean FibroScan liver stiffness measurement (LSM) was 7.4 kPa (SD 4.9); five (17%) had ≥F3 fibrosis and three (10%) had cirrhosis. Mean ELF score was 9.4 (SD 1.1), 45 (36%) had ≥F3 fibrosis and six (5%) had cirrhosis. All FIB-4 scores were <1.45. Overall, 50 (31%) had ≥F3 fibrosis and 9 (6%) had cirrhosis. Although mean LSM in our general HCV cohort was higher (9.6 kPa, SD 9.7) than the prison cohort, this was not significant (p = 0.19). A larger proportion of the prison cohort had a ≥F3 fibrosis than our general cohort (31% vs 24%, p = 0.04) and a smaller proportion had cirrhosis (6% vs 16%, p < 0.001) when using any method of fibrosis assessment. HCV genotype was available in 151 (86%); genotypes 1 (49%) and 3 (41%) were most common. Pangenotypic regimens were approved for 104 (59%).
Conclusion: Almost one third of this prison cohort had ≥F3 fibrosis and would benefit from HCC surveillance; 6% had cirrhosis and may be at risk of liver-related events. Despite widespread genotype availability and few meeting criteria for cirrhosis, the majority were approved for pangenotypic treatment. These findings indicate that the prevalence of advanced fibrosis in the prison population is high and, given the importance of identifying patients requiring HCC surveillance, supports routine evaluation of liver fibrosis.

WED-633

The dynamic of fibrosis scores (FibroTest, APRI and FIB-4) over a 10 year period in HCV cirrhotic patients after sustained virological response with direct-acting antivirals therapy

Anca Saran[1], Violeta Molagic[1], Alina Orfanu[1], Nicoleta Mihai[1], Cătălin Tilișcan[1], Laurentiu Stratan[1], Aida Adamescu[1], Isabela Staicu[1], Sorin Stefan Arama[1], Victoria Arama[1]. *[1]Carol Davila University Of Medicine And Pharmacy, National Institute for Infectious Diseases "Prof. Dr. Matei Bals", Bucharest, Romania*
Email: anca_leustean@yahoo.com

Background and aims: Direct Acting Antivirals (DAA) have been used in Romania since 2015, following National Protocols for treatment. Initially, liver fibrosis assessment was performed using FibroMax; however, the current National Protocol for HCV treatment now includes APRI and FIB-4 scores alongside FibroMax for evaluating the degree of fibrosis.
Method: This prospective study was conducted from 2015 to 2025 at "Matei Balş" National Institute for Infectious Diseases. It aims to evaluate the dynamics of various liver tests, beyond FibroMax, to identify simpler methods for assessing fibrosis in patients treated with DAA who have achieved Sustained Virologic Response (SVR). We used FibroTest, the AST to Platelet Ratio Index (APRI), and the Fibrosis-4 score (FIB-4) at baseline, 6 months post-treatment, 1 year post-treatment, and annually thereafter.
Results: A total of 125 patients with HCV compensated cirrhosis were assessed at baseline. At the start of treatment, the median FibroTest value was 0.84, the median APRI score was 1.27, and the median FIB-4

score was 3.8. Both APRI and FIB-4 scores correlated with liver fibrosis as graded by FibroTest (p = 0.001 for APRI and p < 0.001 for FIB-4). At 6 months post-end of treatment (EOT), 107 patients were analyzed using FibroTest, APRI, and FIB-4. The median FibroTest value was 0.69, the median APRI - 0.45, and the median FIB-4–2.12. Statistically significant correlations were found between both fibrosis scores and FibroTest (p = 0.03 for APRI and p < 0.001 for FIB-4). At 1-year post-EOT, 76 patients were evaluated, with a median FibroTest score of 0.71, a median APRI of 0.42, and a median FIB-4 of 1.96; only FIB-4 showed statistical correlation with FibroTest (p = 0.034). At the 2-year post-EOT assessment, 43 patients had a median FibroTest value of 0.69, APRI of 0.43, and FIB-4 of 2.03, showing significant correlation with FibroTest (p = 0.03 for APRI, p = 0.012 for FIB-4). At the 7 years post-EOT evaluation, 27 patients had a median APRI value of 0.38 and FIB-4 of 2.02, with a significant correlation between APRI and FibroTest (p = 0.003), while FIB-4 no longer showed a correlation (p = 0.1). The decrease in patient numbers from baseline to the end of follow-up was attributed to the pandemic when many patients were lost to follow-up.

Conclusion: APRI and FIB-4 are effective, non-invasive markers of liver stiffness that are highly correlated with FibroTest, demonstrating accuracy in diagnosing cirrhosis, and may serve as valuable tools for monitoring liver fibrosis after EOT.

WED-634-YI

HCV screening and prevalence among children with neonatal abstinence syndrome and their mothers - underserved at-risk populations in the era of HCV elimination

Caroline Schwarz[1], Andreas Weiss[1], Michael Langthaler[1], Marc Tebruegge[1], Enisa Gutic[1], David Bauer[1], Lukas Burghart[1], Sebastian Baier-Grabner[1], Astrid Käfer[1], David Endress[1], Isabella Heissenberger-Mass[1], Thomas Reiberger[2], Christoph Wohlmuth[1], Angela Zacharasiewicz[1], Michael Gschwantler[1,3]. *[1]Klinik Ottakring, Vienna, Austria; [2]Medical University of Vienna, Vienna, Austria; [3]Sigmund Freud University, Vienna, Austria*
Email: schwarz.caroline1990@gmail.com

Background and aims: Hepatitis C virus (HCV) screening is recommended for pregnant women and for children of HCV-viremic mothers. Yet, the Austrian prenatal health program only includes screening for human immunodeficiency (HIV) and hepatitis B virus (HBV) in pregnant women. HCV prevalence is high among people who inject drugs. We retrospectively assessed HCV testing and prevalence among children with neonatal abstinence syndrome (NAS; indicating prenatal maternal substance use) and their mothers at a tertiary care center in Vienna.

Method: Children hospitalized for NAS 01/2014–01/2025 and their mothers were included. Pregnancy and delivery as well as demographic and virologic parameters were investigated.

Results: We included 243 children, with five sets of twins (122 [50.2%] male; 110 [45.3%] delivered by caesarean section; median gestational age 39 weeks). Among the corresponding 238 mothers, median age was 30 years, 4.7% were HIV-infected and 1.7% were HBV-infected; 208 (87.4%) were on opioid agonist therapy during pregnancy. Overall, 227 (95.4%) of mothers were tested for HCV: 218/227 underwent HCV-serology, 116 (53.2%) of whom were anti-HCV+. HCV PCR was performed in 110/116, identifying viremia in 47 (42.7%). Additionally, 9 women received HCV PCR without prior HCV-serology, 6 (66.7%) of whom were HCV-RNA+. Overall, 53/119 (44.5%) mothers tested for HCV-RNA had confirmed viremia. Forty-two (79.2%) children of the 53 HCV-viremic mothers underwent HCV testing, and 4 (9.5%) were found to have vertical HCV acquisition. Additionally, 1 of 7 (14.3%) children whose mothers were anti-HCV+ but did not undergo PCR testing had HCV viremia. Vertical HCV transmission appears likely in this case, as HCV PCR was repeatedly positive from the neonatal period until three years of age. To date, 3 of the 5 HCV-viremic children have received antiviral therapy with a pediatric formulation of glecaprevir/pibrentasvir, with two having achieved confirmed sustained virologic response.

Conclusion: HCV screening is well-established in pregnant women with substance use in our setting, yet almost 10% of mothers did not undergo (confirmatory) PCR testing. Despite the substantial observed vertical transmission rate of about 10%, outpatient testing of HCV-exposed children was often pending. Universal, rather than targeted, HCV reflex testing of pregnant women would aid to detect HCV-infected individuals early on a national level, potentially improving the outcomes of mothers and their offspring.

WED-635

Clinical impact of antiviral therapy in elderly patients with HCV-related chronic liver disease: preliminary results of a prospective single-center cohort study

Salvatore Stefano Sciarrone[1], Federica Villa[1], Lucia Fini[1], Milena Di Leo[1], Alessandra Losco[1], Davide Viganò[1], Stefania Zatelli[1], Gianmarco Bulighin[2], Piermaria Battezati[3], Luca De Luca[1]. *[1]Gastroentrology-Endoscopy Unit, Department of Surgery, Asst Santi Paolo E Carlo-Milan University, Milan, Italy; [2]Unit of Gastroenterology, Department of Medecine, San Bonifacio Hospital, AULSS 9 Scaligera, Verona, Italy; [3]Internal Medecine and Hepatology Unit, Department of Medecine, ASST Santi Paolo e Carlo-University of Milan, Milano, Italy*
Email: salvo.sciarrone@gmail.com

Background and aims: Hepatitis C virus (HCV) infection affects an estimated 130–170 million people worldwide, including about 1 million in Italy. Neurocognitive and psychiatric manifestations - such as depression, anxiety, and fatigue - have been reported in up to 50% of patients with chronic HCV infection, possibly related to direct viral neurotoxicity. To evaluate the efficacy of direct-acting antiviral (DAA) therapy in HCV-RNA-positive patients aged 80 years or older and its impact on liver disease and neurocognitive status.

Method: Fifty patients aged 80 years or older, eligible for DAA treatment and followed at the hepatology outpatient clinic of the Girolamo Fracastoro Hospital (San Bonifacio, Verona, Italy), underwent liver disease assessment with FibroScan and biochemical tests. Neurocognitive status was evaluated using the Mini-Mental State Examination (MMSE) and the Beck Depression Inventory-II total score (BDI-II total) at baseline and 1 month after the end of therapy.

Results: All patients received Sofosbuvir/Velpatasvir (70%) or Glecaprevir/Pibrentasvir (30%) and achieved a sustained virologic response at 12 weeks (SVR12). Baseline laboratory abnormalities were mild, with median values of AST 80 IU/L, ALT 67 IU/L, GGT 50 IU/L, ALP 33 IU/L, and bilirubin 1.2 mg/dL. The mean MMSE score increased from 23.02 at baseline to 25.54 one month after the end of therapy (P = 0.05), while the mean BDI-II total score decreased from 26.22 to 20.76 (P = 0.01). On multivariable analysis, SVR was the only factor significantly associated with improvement in neurocognitive status (OR 0.03, 95% CI 0.24–0.60; p < 0.001), whereas male sex (OR 0.81, 95% CI 0.42–1.50), GGT (OR 1.05, 95% CI 0.49–2.23), and ALP (OR 0.98, 95% CI 0.40–2.36) were not significant.

Conclusion: These preliminary data suggest that HCV eradication with DAAs is highly effective in very elderly patients and is associated with significant improvement in neurocognitive status. Extending screening and treatment to this age group could provide meaningful clinical and socioeconomic benefits.

WED-636

Intrahepatic cholestasis of pregnancy and preterm birth in pregnant individuals with chronic hepatitis C: findings from ostrich, a multicenter north american cohort

Marcela Smid[1], Jasmin Charles[1], Amanda Allshouse[1], Salman Yakub[1], Kara Rood[2], John Cafardi[3], Tatyana Kushner[4], Mia Biondi[5], Jordan J. Feld[6], Mark Yudin[7], Genevieve Eastbrook[8], Sarah Osmundson[9], Todd Davies[10], Cathleen Letterio[11], Kyung min Kwon[11], Sharon Hillier[12], Catherine Chappell[12]. *[1]University of Utah Health, Salt Lake City, United States; [2]The Ohio State University,*

Columbus, United States; [3]University of Cincinnati, Cincinnati, United States; [4]Icahn School of Medicine, New York, United States; [5]York University, Toronto, Canada; [6]University Health Network, Toronto, Canada; [7]Unity Health Toronto, Toronto, Canada; [8]London Health Sciences Centre Lhsc, London, Canada; [9]Vanderbilt University, Nashville, United States; [10]Marshall University, Huntington, United States; [11]Gilead Sciences, Foster City, United States; [12]Upmc Magee Womens, Franklin, United States
Email: Marcela.Smid@hsc.utah.edu

Background and aims: Intrahepatic cholestasis of pregnancy (ICP) is associated with adverse perinatal outcomes, yet its epidemiology among pregnant individuals with chronic hepatitis C virus (HCV) is poorly characterized. We aimed to describe the frequency, recurrence, and clinical features of ICP in this population.
Method: We conducted a retrospective cohort study of singleton pregnancies ≥20 weeks' gestation with detectable HCV RNA delivered between 2016 and 2023 across five North American sites. ICP was identified by clinical diagnosis and bile acid levels ≥10 μmol/L. Demographic, obstetric, and HCV characteristics, including highest viral load (VL) during pregnancy, were compared by ICP status using descriptive and bivariable analyses; multivariable modeling was not performed due to small event counts. Associations between peak bile acid levels and preterm birth (<37 weeks' gestation) were evaluated using receiver operating characteristic analysis.
Results: Among 345 pregnant individuals with chronic HCV, 5.2% (n = 18, 95% CI 2.9–7.6) developed ICP. Age, race and ethnicity, and insurance did not differ between groups; however, individuals with ICP were more frequently nulliparous compared with those without ICP (38.9% vs 15.0%; p = 0.007). Among nulliparous individuals (n = 56), 12.5% developed ICP compared to 3.2% among parous individuals without ICP in prior pregnancy (n = 9/282). Among parous individuals with history of ICP, 28.6% (n = 2/7) had an ICP recurrence. PTB occurred among 38.8% (n = 7/18) of individuals with ICP compared to 19.6% (n = 64/327) among those without ICP. Among individuals with ICP who delivered preterm, PTB indications were ICP (n = 5/7), acute cholecystitis (n = 1/7) and gestational hypertension (n = 1/7) whereas PTB among those without ICP was most due to premature rupture of membranes (n = 21/327) and preterm labor (n = 21/327). Among 17 individuals with ICP and bile acid, peak levels had a median of 26.6 μmol/L (IQR 16.7–63). Neither high (≥6 $\log_{10}$ IU/mL) HCV VL (33.3% ICP vs 45.3% no ICP; p = 0.32) nor peak bile acid (area under the curve 0.466, 95% CI 0.347–0.585) was associated with increased PTB risk.
Conclusion: In this multicenter cohort of pregnant individuals with chronic HCV, ICP occurred in 5% of pregnancies, representing an estimated ten-fold higher prevalence than population estimates. ICP was a frequent driver of PTB. These findings highlight a potentially modifiable PTB pathway that could be mitigated by HCV treatment during pregnancy.

WED-637
Preterm birth in pregnant individuals with chronic hepatitis C: findings from OSTRICH, a multicenter North American cohort

Marcela Smid[1], Jasmin Charles[1], Amanda Allshouse[1], Salman Yakub[1], Kara Rood[2], John Cafardi[3], Tatyana Kushner[4], Mia Biondi[5], Jordan J. Feld[6], Mark Yudin[7], Genevieve Eastbrook[8], Sarah Osmundson[9], Todd Davies[10], Cathleen Letterio[11], Kyung min Kwon[11], Sharon Hillier[12], Catherine Chappell[12]. *[1]University of Utah Health, Salt Lake City, United States; [2]The Ohio State University, Columbus, United States; [3]University of Cincinnati, Cincinnati, United States; [4]Icahn School of Medicine, New York, United States; [5]York University, Toronto, Canada; [6]University Health Network, Toronto, Canada; [7]Unity Health Toronto, Toronto, Canada; [8]London Health Sciences Centre Lhsc, London, Canada; [9]Vanderbilt University, Nashville, United States; [10]Marshall University, Huntington, United States; [11]Gilead Sciences, Foster City, United States; [12]Upmc Magee Womens, Franklin, United States*
Email: Marcela.Smid@hsc.utah.edu

Background and aims: Current AASLD and EASL guidelines recommend offering hepatitis C virus (HCV) treatment during pregnancy, yet obstetric safety data remain limited. The ongoing STORC trial evaluates second- and third-trimester sofosbuvir/velpatasvir exposure, with preterm birth (PTB) as the primary safety outcome. We conducted OSTRICH, a multicenter retrospective cohort across five North American STORC sites, to historically characterize pregnancy outcomes and identify factors associated with PTB among individuals with active HCV.
Method: We abstracted medical records for all singleton pregnancies 20 weeks' gestation with detectable HCV RNA between 2016–2023, prior to the start of STORC enrollment at five sites. PTB was defined as delivery < 37 weeks. Demographic and clinical variables associated with PTB in bivariable analyses were evaluated in adjusted multivariable logistic regression mode. Association between highest HCV viral load in pregnancy and PTB was evaluated using receiver operating characteristic analysis.
Results: Among 345 individuals, 20.6% (95% CI 16.4–25.2%) experienced PTB. Our cohort predominantly identified as White (89.9%), was multiparous (83.8%) and publicly insured (94.2%) with high proportion of individuals with substance use disorders (opioid use disorder 86.7%, methamphetamine use disorder 48.1%, cocaine use disorder 42.6%) and mental health conditions (depression 65.8%, anxiety 63.5%). In bivariable analysis, chronic hypertension (23.9% PTB vs 6.6% non-PTB; p < .001), pregestational diabetes (4.2% vs 0.7%; p = .061), (28.2% vs 12.0%; p < 0.001), and methamphetamine use in first trimester (49.3% vs 33.2%; p = .012) were more common among those with PTB compared to those without PTB. In adjusted models, chronic hypertension or pregestational diabetes (aOR 3.93, 95%CI 1.89–8.19), migraines (aOR 2.50, 95%CI 1.29–4.86), and methamphetamine use (aOR 1.87, 95%CI 1.07–3.24) were independently associated with PTB. Neither high (> = 6 log) HCV viral load during pregnancy (43.5% vs 45.0%; p = 0.8) nor highest viral load in pregnancy (AUC 0.512, 95% CI 0.433–0.590) was associated with increased PTB risk.
Conclusion: Among pregnant individuals with chronic HCV, PTB rate was approximately double national estimates. Chronic hypertension, pregestational diabetes, migraines, and methamphetamine use were independently associated with PTB, highlighting the importance of addressing medical and behavioral health comorbidities alongside HCV management.

WED-638
Combined use of aMAP risk score and M2BPGi for stratifying hepatocellular carcinoma risk after SVR following direct-acting antiviral therapy

Tomoyuki Suehiro[1], Tomohito Kojima[1], Yuki Kugiyama[1], Yasuhide Motoyoshi[1], Akira Saeki[1], Shinya Nagaoka[1], Kazumi Yamasaki[1], Atsumasa Komori[1], Hiroshi Yatsuhashi[1]. *[1]NHO NagasakiMedical Center, Omura, Japan*
Email: chuntomo0902@gmail.com

Background and aims: The aMAP risk score has been reported to identify high-risk patients for hepatocellular carcinoma (HCC), and its usefulness for predicting HCC after sustained virologic response (SVR) following direct-acting antiviral (DAA) therapy has been demonstrated. However, the clinical significance of combining the aMAP risk score with Mac-2 binding protein glycosylation isomer (M2BPGi) in this setting remains unclear. We investigated the utility of the aMAP risk score and M2BPGi for predicting HCC after SVR.
Method: A total of 432 patients who achieved SVR after DAA therapy between 2013 and 2017 and had no prior history of HCC were enrolled. The aMAP risk score was calculated at baseline using the published formula. Predictive performance was assessed using receiver operating characteristic (ROC) analysis. Cumulative HCC incidence was evaluated using the Kaplan–Meier method and Cox

proportional hazards models. Post-hoc pairwise comparisons were performed using the log-rank test with Bonferroni correction.
Results: The median age was 67 years (59–75), with 173 males (39.6%). During a median follow-up of 7.4 years (0.2–11.9), HCC developed in 36 patients (8.3%). In ROC analysis at 5 years, M2BPGi showed the highest area under the curve (AUC: 0.8215, $p < 0.01$), whereas the aMAP risk score demonstrated high sensitivity (AUC: 0.8212, $p < 0.01$). An aMAP risk score >60 (HR 6.58, 95% CI 1.93–22.33, $p < 0.01$) and M2BPGi >4 (HR 3.30, 95% CI 1.63–6.69, $p < 0.01$) were identified as independent risk factors for HCC.Patients were stratified into three groups according to the combination of the aMAP risk score and M2BPGi. The 5-year cumulative HCC incidence was 0.0% in the Low-Low group, 6.5% in the intermediate group, and 19.3% in the High-High group. Kaplan–Meier analysis demonstrated significant differences in cumulative HCC incidence among the three groups. In Bonferroni-adjusted post-hoc comparisons, all pairwise group comparisons remained statistically significant (adjusted $p < 0.01$).
Conclusion: The combination of the aMAP risk score and M2BPGi enables comprehensive risk stratification for HCC after SVR. This combined approach clearly discriminates HCC risk even after adjustment for multiple comparisons and may be useful for optimizing HCC surveillance strategies.

WED-639

Hepatic recompensation after sustained virologic response in patients with hepatitis C virus–related decompensated cirrhosis: a Japanese multicenter study

Email: yuki.tahata@gh.med.osaka-u.ac.jp

Background and aims: Sustained virologic response (SVR) can be achieved in approximately 90% of patients with hepatitis C virus (HCV)-related decompensated cirrhosis treated with direct-acting antivirals (DAAs), and some experience hepatic recompensation. However, its frequency, associated factors, and impact on prognosis remain unclear.
Method: We enrolled 363 patients with HCV-related cirrhosis (compensated: 204; decompensated: 159) who achieved SVR after DAA treatment at 33 Japanese institutions between 2019 and 2021, with ≥1 year of follow-up after the end of treatment (EOT). Patients who died or were lost to follow-up within 1 year after the EOT were excluded. Decompensated cirrhosis was defined as Child–Pugh (CP) class B/C or CP class A with prior decompensation. Hepatic recompensation was defined as the absence of ascites and encephalopathy at 1 year after the EOT, CP class A, and no variceal bleeding for ≥1 year. First, baseline factors associated with recompensation were examined in decompensated patients. Second, liver transplantation (LT)-free survival, hospitalization-requiring decompensation, and hepatocellular carcinoma (HCC) occurrence were compared among compensated, recompensated, and non-recompensated groups.
Results: Among 159 patients with decompensated cirrhosis, hepatic recompensation was achieved in 59 (37.1%). Absence of ascites ($p < 0.001$), absence of hepatic encephalopathy ($p = 0.024$), lower international normalized ratio (INR) ($p = 0.016$), and higher albumin levels ($p = 0.029$) were identified as significant baseline factors associated with hepatic recompensation in multivariate logistic regression analysis. The 4-year LT-free survival and incidence rates of decompensation from 1 year after the EOT were 84.4%/8.2% in compensated cirrhosis, 91.8%/8.3% in recompensated cirrhosis, and 65.7%/30.6% in non-recompensated cirrhosis, respectively. Survival and decompensation outcomes in recompensated cirrhosis were comparable to those in compensated cirrhosis. In contrast, among patients without prior HCC, 4-year HCC occurrence rates were 14.1%, 25.6%, and 26.8%, with no significant differences.
Conclusion: Hepatic recompensation was achieved in approximately one-third of patients with HCV-related decompensated cirrhosis and was associated with the degree of ascites or hepatic encephalopathy, INR, and albumin levels. Hepatic recompensation improved survival and reduced decompensation but did not reduce HCC risk.

WED-640

Driving HCV elimination through dedicated hospital-based teams and pathways. A retrospective and prospective study in southern Italy

Pietro Torre[1], Enrica Serretiello[2], Giuseppe Di Siervi[1], Emilia Vaccaro[2], Tommaso Sarcina[1], Mariano Festa[1], Veronica Folliero[1], Giovanni Boccia[2], Mario Masarone[1], Gianluigi Franci[2], Marcello Persico[1]. *[1]University of Salerno, Salerno, Italy; [2]AOU San Giovanni di Dio e Ruggi d'Aragona, Salerno, Italy*
Email: pietrotorre90@gmail.com

Background and aims: Direct-acting antivirals (DAAs) have had an extraordinary impact on curing and limiting the spread of HCV infection. According to that, screening programs have been established worldwide to achieve the ambitious goal of elimination by

2030. This study aimed to first evaluate the proportion of HCV testing, the prevalence of infection, and the rate of treatment referral among previously admitted patients in a large hospital of Southern Italy, and subsequently to implement an improved diagnostic and linkage to care protocol.
Method: This retrospective and prospective study was conducted at the University Hospital of Salerno, Campania region. In the retrospective phase (covering the period from 2016 to 2023), data were retrieved regarding hospital admissions, the percentage of patients tested for HCV-Ab and HCV-RNA, and those patients who underwent antiviral therapy. In the prospective phase, initiated in 2025, all admitted patients screened for anti-HCV-Ab underwent reflex HCV-RNA testing and those who tested positive were systematically evaluated for antiviral therapy.
Results: Among 317,680 patients admitted to our hospital for various medical conditions within 2016–2023, 116,478 (36.7%) were screened for HCV-Ab. Out of these, 4214 (3.6%) resulted positive. Among HCV-Ab positive subjects, 2120 (50.3%) underwent HCV-RNA testing, and 1450 of these (68.4%), resulted positive. 60% of actively infected patients, with annual variations, underwent DAA therapy. In the prospective phase, 385 HCV-Ab–positive patients were identified over a 7-month period (prevalence of 3.3%). Of these, all were tested for HCV-RNA and the 68 patients (17.7%) with active infection, were all evaluated or underwent antiviral therapy, during hospitalization or through recall. Surgical and Emergency departments registered the highest share of actively infected patients. In both phases of the study, HCV prevalence increased with age.
Conclusion: In the context of declining infection prevalence, HCV testing and linkage-to-care should be reinforced in the hospital setting, where a considerable number of positive patients can still be found. Therefore, in addition to routine screening, a specific program for active infection testing (e.g., reflex testing) and subsequent treatment should be implemented and coordinated by a dedicated hospital-based team, to identify and cure as many HCV-infected individuals as possible.

WED-641

Evaluation of ALBI and FIB-4 scores to predict hepatocellular carcinoma in patients with chronic hepatitis C and sustained virological response to direct-acting antivirals

Paula Guedes[1], Juliana Piedade[2], Hugo Perazzo[3], Livia Villela-Nogueira[4], Helena Peixoto[4], Gustavo Pereira[2], Lailiane Novaes[2], Miriam Chinzon[2], Joyce Roma[2], Flavia Fernandes[5], Cristiane A. Villela-Nogueira[4]. *[1]Clementino Fraga Filho University Hospital, Bonsucesso Federal Hospital, Rio de Janeiro, Brazil; [2]Bonsucesso Federal Hospital, Rio de Janeiro, Brazil; [3]Oswaldo Cruz Foundation, Rio de Janeiro, Brazil; [4]Clementino Fraga Filho University Hospital, Rio de Janeiro, Brazil; [5]Pedro Ernesto University Hospital, Rio de Janeiro, Brazil*
Email: crisvillelanog@gmail.com

Background and aims: The risk of developing hepatocellular carcinoma (HCC) in chronic hepatitis C patients with advanced fibrosis and cirrhosis remains after sustained virological response (SVR) with direct-acting antivirals (DAA). Targeting patients at the highest risk of HCC would define better screening strategies. Our aim was to evaluate ALBI and FIB-4 scores as prognostic markers for HCC after SVR.
Method: A bicentric retrospective longitudinal study included patients with SVR and a liver stiffness measurement (LSM) ≥ 10 kPa at baseline. Pre-treatment (Pre-T) and 1 year after the end of treatment (1-yr-EOT) ALBI and FIB-4 scores were calculated. Delta was determined as the difference between the two measurements. The performance of these scores in identifying risk for HCC was analyzed.
Results: 450 patients (62 ± 10 years; 65.7% women; 56.5% white non-hispanic; BM I27.4 [24.4–30.2]; ALT 88 IU/L [55–135]; albumin 3.7 g/dL [3.5–4.0]; 38.9% with type 2 diabetes; 20% with clinically significant portal hypertension) were included and followed for 61 months [39–74]. LSM ≥ 12.5 kPa (F4) was identified in 68% of patients. The Pre-T median FIB-4 and ALBI were 3.35 (2.06–5.72) and −2.48 (−2.73 to −2.19), significantly higher than 1-yr-EOT: 1.99 (2.06–5.72) and −2.84 (−3.10 to −2.53) respectively ($p < 0.001$). At follow-up, 9.3% (n = 42) developed HCC; 95% had cirrhosis at Pre-T. At univariate analysis, weight ($p = 0.04$), 1-yr-EOT AST ($p = 0.005$), Pre-T platelets ($p < 0.001$) and 1-yr-EOT ($p < 0.001$), Pre-T ALBI ($p = 0.04$) and 1-yr-EOT ($p < 0.001$), Pre-T FIB-4 ($p < 0.001$) and 1-yr-EOT ($p = 0.001$) and delta FIB-4 ($p < 0.001$) were associated with HCC. At Cox regression analysis, 1-yr-EOT FIB-4 (HR 1.16; 95% CI 1.05–1.28, $p = 0.003$) and 1-yr-EOT ALBI (HR 4.43; 95% CI 2.02–9.70, $p < 0.001$) were associated with HCC occurrence. Adopting the values FIB-4 > 3.25 and ALBI > −2.5, individuals with higher cut-off points had a worse survival curve for both scores.
Conclusion: ALBI and FIB-4 values after one year of HCV treatment perform better and can be usefull in HCC risk stratification in SVR-HCV patients.

WED-642-YI

Trends in hepatocellular carcinoma following hepatitis C virus infection in sweden: progress toward WHO elimination goals

Anna Wadman[1], Snehal Patil[2], Scott Montgomery[2,3,4], Soo Aleman[5], Ann-Sofi Duberg[1,6], Charlotte Lybeck[1,6]. *[1]Department of Infectious Diseases, Orebro University Hospital, Örebro, Sweden; [2]Department of Clinical Epidemiology and Biostatistics, Faculty of Medicine and Health, Örebro University, Örebro, Sweden; [3]Karolinska Institutet-Solna, Solna, Sweden; [4]Department of Epidemiology and Public Health, University College London, London, United Kingdom; [5]Department of Infectious Diseases, Karolinska Institutet/Karolinska University Hospital, Stockholm, Sweden; [6]Department of Infectious Diseases, Faculty of Medicine and Health, School of Medical Sciences, Örebro, Sweden*
Email: anna.wadman@regionorebrolan.se

Background and aims: In many countries, including Sweden, the birth cohorts with the highest prevalence of hepatitis C virus (HCV) infection are now reaching ages associated with a high risk of primary liver cancer (PLC), particularly hepatocellular carcinoma (HCC). This aging HCV population poses a challenge to the World Health Organization's 2030 targets for reducing hepatitis-related morbidity and mortality. With effective direct-acting antiviral (DAA) therapies introduced in 2014, it remains unclear whether HCC incidence has declined in recent years. This study aimed to investigate temporal trends in PLC/HCC incidence and the relative hazard of PLC among individuals diagnosed with HCV between 1990 and 2022, with extended follow-up to 2023.
Method: We conducted a nationwide cohort study including individuals diagnosed with HCV infection in Sweden between 1990 and 2022 (n = 59,084), irrespective of treatment or virological cure. The HCV cohort was compared with a tenfold matched reference cohort from the general population without diagnosed HCV (n = 589,641). PLC, including HCC, was identified through linkage to the Swedish Cancer Register, Cause of Death Register, National Patient Register, and the national quality register for liver cancer (SweLiv). Crude as well as age- and sex-standardized incidence rates were calculated.
Results: During 872,669 person-years of follow-up, 2917 HCC cases (4.9%) occurred in the HCV cohort, compared with 1044 (0.2%) in the matched cohort. Crude and age- and sex-standardized HCC incidence rates increased steadily in the HCV cohort until 2014 (5.27 per 1000 PY; 95% CI 4.51–6.03), followed by a decline by 2023 (1.92 per 1000 PY; 95% CI 1.32–2.50). Overall, 39.8% of the HCV cohort received DAA treatment during the study period. Among all HCC cases registered in SweLiv from its start in late 2008 (n = 1976), screening-detected HCC accounted for 40.7% (659/1618) of cases in the HCV cohort and 20.9% (75/358) in the reference cohort.
Conclusion: With follow-up to 2023, individuals with chronic HCV infection continue to carry an elevated risk of PLC/HCC compared

with the general population. Incidence trends suggest a decline after 2014, in the era of direct-acting antiviral therapy, though individuals with prior infection remain at risk. Continued surveillance and treatment are essential to reduce the liver cancer burden.

WED-643

COVID-19 pandemic had minimal impact on the effort spent on the enhancement programme of treatment coverage for all adult patients with chronic hepatitis C virus (HCV) infection

Vicki Wing-Ki Hui[1], Mandy Sze-Man Lai[1], Jimmy Che-To Lai[1], Vincent Wai-Sun Wong[1], Terry Cheuk-Fung Yip[1], Grace Lai-Hung Wong[1]. [1]*The Chinese University of Hong Kong, Sha Tin, Hong Kong*
Email: wonglaihung@cuhk.edu.hk

Background and aims: Enhanced coverage of direct-acting antiviral (DAA) therapy for all adult patients with chronic hepatitis C virus (HCV) infection since October 2020 in Hong Kong SAR, China, amidst the COVID-19 pandemic in 2020–2023. This study evaluated the impact of COVID-19 pandemic on this enhancement programme of DAA treatment coverage.
Method: All individuals living with chronic HCV infection who had at least one positive result for antibody for HCV (anti-HCV), HCV RNA or HCV genotype between January 2000 and December 2024 were identified. DAA therapy for HCV was defined with the prescription of sofosbuvir/velpatasvir, sofosbuvir/ledipasvir, glecaprevir/pibrentasvir, elbasvir/grazoprevir, dasabuvir/ombitasvir/ paritaprevir, daclatasvir/asunaprevir or boceprevir. Crude all-cause mortality incidence rates were calculated as events per 1000 person-years with 95% confidence intervals.
Results: We first identified 10,225 consecutive individuals with HCV markers checked. 4733 (46.3%) patients were prescribed with at least one course of DAA therapy; among treated patients, mean age was 55.82 ± 12.90 years and 3236 (68.37%) were male. The annual number of treated patients increased after programme implementation, from 776 (2020) to 1126 (2021), and remained substantial through the pandemic period (962 in 2022; 808 in 2023) with stabilization in 2024 (817). Regimen choice shifted toward simplified fixed-dose combinations, dominated by glecaprevir/pibrentasvir and sofosbuvir/velpatasvir. Crude all-cause mortality incidence rates per 1000 person-years were 234.59 (95% CI 220.92–248.89) and 11.05 (8.25–14.49) for non-DAA and DAA users, respectively, when follow-up was truncated at 1 year; the corresponding 3-year mortality incidence rates were 118.51 (112.65–124.59) and 10.01 (8.42–11.82), respectively.
Conclusion: COVID-19 pandemic had minimal impact on the effort spent on the enhancement programme of DAA treatment coverage. It was likely due to the endeavours mentioned in the Hong Kong Hepatitis Action Plan 2020–2024, which had counteracted the negative impact of the COVID-19 pandemic on hepatitis elimination.
Funding: This work was supported by the Investigator Sponsored Research of Gilead Sciences (Reference: IN-HK-987-7181).

WED-644

Impact of sustained virological response on the prognosis of patients with HCV-related cirrhosis: a large-scale multicenter cohort study from the pre-and post-DAA eras

Hiroshi Yatsuhashi[1], Hayato Yamana[2], Shinobu Imai[3], Atsushi Naganuma[4], Rie Sugimoto[5], Motoyuki Kohjima[6], Tsutomu Yamashita[7], Satoru Iwamoto[8], Keisuke Ario[9], Masaaki Shimada[10], Shintaro Takaki[11], Takeaki Satoh[12], Kiyoshi Furuta[13], Ryotaro Sakamori[14], Kazumi Yamasaki[1]. Email: Yatsuhashihiroshi@gmail.com

Background and aims: While interferon (IFN)-based therapies had limited efficacy in patients with hepatitis C virus (HCV)-related cirrhosis, the introduction of direct-acting antivirals (DAAs) in 2014 has enabled sustained virological response (SVR) rates exceeding 90% in Japan. This multicenter study aimed to evaluate the impact of SVR on the long-term prognosis of patients with HCV-related cirrhosis by comparing cohorts from the pre- and post-DAA eras.
Method: We enrolled outpatients with HCV-related cirrhosis from 36 National Hospital Organization (NHO) hospitals during two distinct periods: 2011 (pre-DAA cohort) and 2017 (post-DAA cohort). The 3-year and 5-year survival rates, along with the impact of antiviral therapy, were prospectively examined. SVR was defined as undetectable serum HCV RNA 24 weeks after therapy completion.
Results: A total of 1680 patients were analyzed (2011 cohort: n = 876; 2017 cohort: n = 804). The SVR rate significantly increased from 4% in the 2011 cohort to 58% in the 2017 cohort ($P < 0.001$). Consequently, the 2017 cohort demonstrated superior 3-year (80% vs. 64%) and 5-year (68% vs. 46%) survival rates compared to the 2011 cohort. The mortality rate per person-year was significantly lower in the 2017 cohort (0.077 vs. 0.145, $P < 0.001$). Pooled analysis of both cohorts revealed that SVR significantly improved survival across most Child-Pugh (CP) classes: • CP-A (n = 1185): 5-year survival was 85% (SVR) vs. 60% (non-SVR) and 50% (untreated) ($P < 0.001$). • CP-B (n = 412): 5-year survival was 61% (SVR) vs. 46% (non-SVR) and 27% (untreated) ($P < 0.001$). • CP-C (n = 83): No significant survival benefit was observed between SVR, non-SVR, and untreated groups. Multivariate analysis identified five independent prognostic factors for survival: age, gender, Child-Pugh classification, SVR status, and liver cancer stage. Notably, the cohort year (2011 vs. 2017) was not an independent factor, suggesting that the improved prognosis in the later cohort was primarily driven by SVR attainment.
Conclusion: The widespread adoption of IFN-free DAA therapy since 2014 has dramatically increased SVR rates among patients with HCV-related cirrhosis in Japan, leading to a significant improvement in overall survival. SVR remains the key driver of improved prognosis, particularly in patients with Child-Pugh A and B cirrhosis.

Viral hepatitis C – Therapy and resistance

TOP-614

Hepatitis elimination and liver care in south-east Austria (HEAL-S) – HCV cohort

Lavra Rebol[1,2], Natalie Hasl[1], Victoria Rieper[1], Angela Horvath[1,2], Harald Kessler[1], Vanessa Stadlbauer[1,2]. [1]*Medizinische Universität Graz, Graz, Austria;* [2]*Center of Biomarker Research CBmed GmbH, Graz, Austria*
Email: vanessa.stadlbauer@medunigraz.at

Background and aims: The World Health Organization (WHO) aims to eliminate hepatitis C virus (HCV) as a public health threat by 2030. Austria is well-positioned to contribute to this goal because highly effective direct-acting antiviral (DAA) therapies have been available since 2014. However, despite their proven efficacy, DAAs have not reached their full potential. Many individuals remain untreated, often due to a lack of awareness about infection or treatment options. These undiagnosed patients pose a significant obstacle to achieving elimination. We hypothesized that a substantial proportion of people with unknown HCV status in Southeast Austria still require therapy.

Method: We retrieved all HCV nucleic acid amplification test (NAAT) results recorded between January 1, 2014, and December 31, 2023, from the molecular laboratory database of the Medical University of Graz, serving a catchment area of approximately 1.2 million inhabitants. Records were pseudonymized prior to analysis. We identified patients whose most recent NAAT indicated detectable HCV RNA. Datasets from patients with detectable HCV RNA were then de-pseudonymized and cross-checked against the mortality registry, health insurance status, and institutional patient records to ensure accuracy. Eligible individuals were contacted up to three times (once by mail and twice by telephone) and invited to receive antiviral treatment.
Results: A total of 24,150 HCV NAAT datasets from 8,164 patients were extracted. From 2014 to 2023, 804 patients (9.8%) had a most recent NAAT result that showed detectable HCV RNA. Of those patients, 38 (4.7%) experienced reinfection. Of the 804 patients, 263 (32.7%) had died, 118 (14.7%) had no contact information, 33 (4.1%) had already received treatment, 23 (2,9%) had moved outside the catchment area, and 20 (2.5%) were excluded due to comorbidities or other contra-indications. Thus, 347 patients (43.2%) were eligible and contacted. Of those, 211 (60.8%) could not be reached, 42 (12.1%) reported a sustained virologic response (SVR), 18 (5.2%) declined treatment, 6 (1.7%) had died, 6 (1.7%) remained undecided, and 5 (1.4%) had contraindications. 59 (17.0%) of the eligible patients could be linked to care.
Conclusion: The HEAL-S HCV cohort demonstrates that a data-driven macro-elimination strategy is feasible in low-prevalence settings. This strategy can link a substantial number of individuals to care and meaningfully contribute to the WHO's goal of eliminating HCV by 2030.

Email: michal.brzdek@gmail.com

Background and aims: Direct-acting antivirals (DAAs) have revolutionised the management of chronic hepatitis C virus (HCV) infection. However, real-world data on the effectiveness and safety of DAA therapy in patients with history orthotopic liver transplantation (OLTx) remain limited. This study aimed to evaluate the clinical characteristics, effectiveness, and safety of DAA therapy in liver transplant recipients with chronic hepatitis C in a nationwide, real-world cohort.
Method: A retrospective analysis was performed of all consecutive adult patients who underwent OLTx before starting DAA therapy between July 2015 and December 2024 in the EpiTer-2 project, that included 20,586 patients treated because of chronic hepatitis C.
Results: A total of 141 patients participated in the study, with most being men (66%) and aged 50 years or older. Most patients (80%) had comorbidities, and nearly a quarter of the population had cirrhosis of the transplanted liver at the start of antiviral therapy. The median time from OLTx to initiation of antiviral therapy was 24 months. Overall, SVR was achieved in 96.4% of patients in the intention-to-treat analysis and in 98.6% after excluding patients lost to follow-up. Treatment was well tolerated. Serious adverse events were reported in five patients. During DAA treatment and 12 weeks of follow-up after treatment, two deaths were reported. Subgroup analysis by time from OLTx to antiviral therapy (≤24 vs. >24 months) revealed no differences in effectiveness and safety despite some baseline clinical variations.
Conclusion: DAA therapy in liver transplant recipients with chronic HCV infection is highly effective and well-tolerated.

FRI-634
Sustained virologic response rates following incomplete direct-acting antiviral therapy for hepatitis C: a real world study
Jihad Slim[1], Murad Qirem[1], Shahd Yaghi[1], Kevin Leyden[2], Corey Rosmarin-DeStefano[2], Sheena Duprey[2]. *[1]Saint Michael's Medical Center, Newark, United States; [2]North Jersey Community Research Initiative, Newark, United States*

Background and aims: Direct-acting antivirals (DAAs) have transformed hepatitis C virus (HCV) treatment, achieving cure rates exceeding 95% with guideline-recommended therapy durations. Emerging data suggest that the high antiviral potency of DAAs may allow some patients to achieve sustained virologic response (SVR) even when treatment is interrupted or shortened. Understanding real-world SVR outcomes following incomplete treatment is therefore important to better understand the full therapeutic potential of modern HCV regimens.
Method: We conducted a retrospective analysis of prospectively collected data from patients treated for HCV through a mobile medical unit-based phlebotomy, telehealth provider visits, specialty pharmacy dispensing, and nurse-led follow-up. Patients who did not complete their full prescribed DAA course but had post-treatment HCV RNA testing were included. Treatment exposure was categorized by the percentage of treatment delivered by the pharmacy. The primary outcome was SVR at 12 weeks after treatment completion (SVR12).
Results: Among 2,461 patients prescribed DAA therapy between February 2022 and October 2025, 147 (5.9%) did not complete their intended treatment course. Of these, 104 patients received partial therapy and 43 received no antiviral treatment. Among patients receiving partial therapy, 51 patients had post-treatment viral load data available. Overall, 25 of 51 patients (49%) achieved SVR12 despite incomplete therapy. SVR12 rates increased with longer treatment duration, occurring in 61.1% (11/18) of patients who received two-thirds of their prescribed therapy (8 out of 12 weeks), 66.6% of those who received half of their prescribed DAA (4 out of 8 weeks) and 43.8% (7/16) of those who received a third (4 out of 12 weeks); whereas only 27.2% (3/11) who received ≤25% of therapy achieved SVR12. These findings demonstrate a clear association between duration of DAA exposure and likelihood of cure while highlighting that SVR12 remains achievable despite incomplete therapy.
Conclusion: In this real-world cohort, a substantial proportion of patients achieved SVR12 despite incomplete DAA therapy, underscoring the potent antiviral activity of modern regimens. Although full-course treatment remains the standard of care, the occurrence of SVR following incomplete therapy highlights the importance of continued follow-up and re-engagement of individuals living with HCV with barriers to treatment adherence.

Proton-pump inhibitor Omeprazole did not affect the plasma pharmacokinetics of Bemnifosbuvir and Ruzasvir fixed-dose combination in healthy participants

Xiao-Jian Zhou[1], Brett Smith[2], Maureen Montrond[1], Keith Pietropaolo[1], Bruce Belanger[1], Shannan Lynch[1], Dayle James[1], Maria Arantxa Horga[1], Janet Hammond[1]. *[1]Atea Pharmaceuticals, Inc, 225 Franklin Street, Suite 2100, Boston, United States; [2]Altasciences, Los Angeles, United States*
Email: zhou.xj@ateapharma.com

Background and aims: Proton pump inhibitors (PPIs), such as omeprazole (OMEP), are commonly used concomitant medications among HCV patients receiving DAA therapy. PPIs can reduce the absorption of several classes of HCV DAAs potentially impacting efficacy, resulting in their restricted use. Bemnifosbuvir (BEM) and ruzasvir (RZR) are potent/pan-genotypic inhibitors of the HCV NS5B polymerase and NS5A protein, respectively. Their fixed-dose-combination (FDC) is in phase 3 trials for chronic HCV. We report the results from a phase 1 study evaluating the effect of OMEP on the plasma pharmacokinetics (PK) of BEM and RZR in healthy participants.
Method: Twenty healthy participants received a single dose of BEM 550 mg/RZR 180 mg as 2 FDC tablets each containing 275 mg BEM and 90 mg RZR on Day 1. Participants received omeprazole (OMEP) 20 mg once-daily (QD) from Days 4 to 13 and 40 mg QD from Days 14 to 22. On Days 8, 13 and 18, respectively, participants received a single dose of BEM/RZR simultaneously with, 0.5 h before, and 2 h after OMEP. Dosing occurred on an empty stomach. Intensive PK sampling was performed over 120 h and plasma levels of BEM (and metabolites) and RZR were quantitated using validated bioanalytical methodologies.
Results: BEM and RZR were safe and well-tolerated when administered alone or with OMEP. Most AEs were mild in severity and self-limiting. Headache and nausea (grade 1) were the only AEs reported in more than 2 subjects. Concomitant OMEP did not meaningfully affect the plasma exposure measured as area under the plasma concentration-time curve (AUC) of BEM, its guanosine nucleoside AT-273 (surrogate for the active intracellular triphosphate metabolite AT-9010) or RZR: geometric mean ratios (GMRs) were 0.91, 1.13 and 1.09 for BEM, AT-273 and RZR respectively when simultaneously co-administered with 20 mg OMEP; GMRs were 0.91, 1.14, 1.28 respectively when dosed 0.5 h before 20 mg OMEP; and were 0.83, 1.14 and 0.86 respectively for BEM, AT-273 and RZR when dosed 2 h after the higher 40 mg QD dose of OMEP.
Conclusion: BEM/RZR FDC was safe and well-tolerated when administered alone or concomitantly with OMEP. While OMEP 20 mg, a common dose for GERD did not affect the plasma exposure to BEM/AT-273/RZR, a higher 40 mg dose of OMEP with BEM/RZR dosed 2 h later to allow for maximal acid-suppressive effect did not meaningfully reduce plasma exposure to BEM/AT-273/RZR either. Results support concomitant use of OMEP 20 mg or 40 mg with BEM/RZR in HCV-infected individuals without restriction.

FRI-636

Bemnifosbuvir and ruzasvir administered as a fixed-dose-combination have low potential to inhibit P-gp, BCRP or OATP1B1/3 mediated transport

Xiao-Jian Zhou[1], Gaetano Morelli[2], Maureen Montrond[1], Keith Pietropaolo[1], Bruce Belanger[1], Shannan Lynch[1], Dayle James[1], Maria Arantxa Horga[1], Janet Hammond[1]. *[1]Atea Pharmaceuticals, Inc, 225 Franklin Street, Suite 2100, Boston, United States; [2]Altasciences, Montreal, Canada*
Email: zhou.xj@ateapharma.com

Background and aims: Bemnifosbuvir (BEM) and ruzasvir (RZR) are potent, pan-genotypic inhibitors of the HCV NS5B polymerase and NS5A protein, respectively. The fixed-dose-combination (FDC) of these two investigational drugs is in phase 3 clinical development for the treatment of chronic HCV. BEM and RZR were identified in vitro as inhibitors of drug transporters P-glycoprotein, breast cancer resistant protein (BCRP) and organic anion transporting polypeptide 1B1 (OATP1B1) and OATP1B3. A Ph 1 study in healthy participants was conducted to assess the clinical implications of these results using digoxin (DIG) and rosuvastatin (ROSU) as P-gp and BCRP/OATP1B1/1B3 index substrates, respectively.
Method: Two groups of healthy participants (n = 18/arm, 36 total) were enrolled to evaluate the effect of a single dose of BEM 550 mg/RZR 180 mg as 2xFDC tablets on the plasma pharmacokinetics (PK) of a single dose of DIG 0.25 mg and ROSU 10 mg, respectively. Within each arm, participants were randomized according to a 3-period, 3-sequence crossover design with 6 participants/sequence and received in each period on an empty stomach the index substrate alone, with simultaneously administered BEM/RZR or 2 hours ahead of BEM/RZR. Serial plasma samples were collected and quantitated for DIG or ROSU concentrations.
Results: A single dose of BEM 550 mg/RZR 180 mg simultaneously administered increased the peak concentration of DIG by 58.9% (measured as geometric mean ratio, GMR) without affecting its overall exposure. When dosed staggered, BEM/RZR did not affect the PK of DIG. A single dose simultaneous BEM/RZR increased the peak and total plasma exposure of ROSU by 78.5% and 39.8%, respectively, whereas staggered dosing reduced these effects by approximately half. There was no effect on vital signs, ECG, and no SAEs.
Conclusion: A single dose of BEM 550 mg/RZR 180 mg administered as 2xFDC tablets only slightly increased the plasma exposure of the P-gp and BCRP/OATP1B1/3 index drugs DIG and ROSU. With GMR<2, BEM/RZR therefore have low potential to exhibit clinically meaningful inhibition of these transporters. No dose adjustment will be needed for drugs that are sensitive substrates of P-gp or BCRP/OAT1B1/3 when co-administered with BEM/RZR; staggered dosing may lessen any DDI risk.
