Results: This study included 2254 patients in the PC group (mean age 69.6 years, 74.3% male, 61.5% with viral hepatitis, mean AFP 37,395.5 ng/mL) and 9962 in the non-PC group (mean age 68.4 years, 77.1% male, 62.3% with viral hepatitis, mean AFP 43,988.6 ng/mL). PC utilization, when compared with patients without PC, was associated with lower rates of ICU admission (0.3% vs 1.1%, $p < 0.001$) and resuscitation (0.4% vs 2.7%, $p < 0.001$). PC was associated with increased use of opioid analgesics (66.8% vs 32.5% in non-PC group, $p < 0.001$), with a similar pattern for both strong opioids (45.7% vs 18.2% in non-PC group, $p < 0.001$) and weak opioids (44.5% vs 24.4% in non-PC group, $p < 0.001$). PC had no significant impact on the utility of nerve blocks ($p = 0.570$). The %DAH were 45.0% and 40.6% in the PC and non-PC groups, respectively ($p < 0.001$), and PC contact was an independent predictor of %DAH ≥50% (OR 1.14, 95%CI 1.03–1.26).
Conclusion: PC contact significantly reduced disease time burden. Furthermore, PC was associated with reduced use of aggressive therapies (ICU admission and resuscitation), and increased use of opioid analgesics. Our findings highlight the potential quality-of-life benefits of PC in the end-of-life care of HCC.

FRI-231
Clinical determinants of survival beyond two years in HCC patients receiving non-curative treatment
Burcu Gürbüz[1], Mustafa Utku Maraşlı[2], Hasan Sahin[2], Muhammet Furkan Çakmak[1], Bengi Ozturk[1], Taylan Kav[1], Onur Keskin[1]. *[1]Hacettepe University Faculty of Medicine, Department of Gastroenterology and Hepatology, Ankara, Türkiye; [2]Hacettepe University Faculty of Medicine, Department of Internal Medicine, Ankara, Türkiye*
Email: drburcuusta@gmail.com

Background and aims: Hepatocellular carcinoma (HCC) is a leading cause of cancer mortality. In patients not eligible for curative therapy, outcomes remain heterogeneous in real-world populations, and a subset of patients experience unexpectedly prolonged survival. We aimed to describe the clinical profile of patients who survived ≥2 years from diagnosis while managed with non-curative first-line therapy, and to identify predictors of long-term survival.
Method: We retrospectively included HCC patients followed at Hacettepe University Gastroenterology and Hepatology Clinic between January 2015–September 2023. Of 349 patients, 282 received non-curative first-line therapy. Long-term survival was defined as overall survival (OS) ≥2 years; predictors were assessed by backward stepwise multivariable logistic regression.
Results: A total of 282 patients received non-curative treatment were included. Median age was 65 years(25–90) and median OS was 15 months (0–168). Overall, 104/282(36.9%) had OS ≥2 years and 178/282(63.1%) had OS <2 years. The cohort was predominantly male (218/282, 77.3%); sex was not associated with OS ≥2 years($p = 0.175$). In univariate analysis, long-term survivors more often had ECOG 0–1 (85.6% vs 62.9%; $p < 0.001$), less tumor thrombus at diagnosis (23.1% vs 43.3%; $p < 0.001$), largest lesion <5 cm (76.0% vs 50.0%; $p < 0.001$), GGT <80 (52.9% vs 30.9%; $p < 0.001$), locoregional modalities (RFA/TARE/TACE) (87.5% vs 71.3%; $p = 0.001$), MASH etiology (15.4% vs 7.9%; $p = 0.048$) and platelet <150 × 109/L (60.6% vs 39.3%; $p < 0.001$). On ROC analysis, platelet 149.5×109/L was the optimal cut-off for OS ≥2 years. Logistic regression was performed in 274/282 (97.2%) with complete covariates (OS ≥2 years: 99; OS <2 years: 175). In final stepwise model, independent associations with OS ≥2 years were ECOG 0–1 (vs 2–3) OR 3.12 (95% CI 1.59–6.12;$p = 0.001$), GGT <80 (vs

≥80) OR 2.35 (95% CI 1.35–4.10;p = 0.003), and platelet <150 × 109/L (vs ≥150) OR 1.92 (95% CI 1.09–3.33;p = 0.026). Tumor size <5 cm (OR 1.76; 95% CI 0.96–3.24; p = 0.067) and absence of tumor thrombus (OR 1.74; 95% CI 0.96–3.16; p = 0.068) showed borderline significance.
Conclusion: In this cohort of non-curatively treated HCC patients, more than one-third survived ≥2 years. Long-term survival was independently associated with better performance status (ECOG 0–1), lower GGT, and lower platelet suggesting a distinct long-survivor phenotype among patients receiving non-curative first-line therapy.

FRI-232

Imaging-detected immune-related adverse events and clinical outcomes during Atezolizumab–Bevacizumab therapy in unresectable hepatocellular carcinoma: a dual-center study

Subin Heo[1], Jeayeon Park[2], Sang Hyun Choi[1], Dong Ho Lee[2]. *[1]Asan Medical Center, Seoul, Korea, Rep. of South; [2]Seoul National University Hospital, Seoul, Korea, Rep. of South*
Email: dhlee.rad@snu.ac.kr

Background and aims: Immune checkpoint inhibitors (ICIs) combined with bevacizumab constitute a standard first-line therapy for unresectable hepatocellular carcinoma (HCC). Emerging evidence suggests that immune-related adverse events (irAEs) are linked to improved treatment outcomes. However, the prognostic value of imaging-detected irAEs remains unclear. This study evaluated the incidence and clinical impact of imaging-detected irAEs during atezolizumab plus bevacizumab therapy.
Method: This retrospective dual-center study included consecutive patients with unresectable HCC treated with first-line atezolizumab plus bevacizumab. Serial follow-up CT or MRI examinations were systematically reviewed to identify imaging-detected irAEs. Objective response rate (ORR), overall survival (OS), and progression-free survival (PFS) were compared between patients with and without imaging-detected irAEs.
Results: Among 386 eligible patients, 44 (11.4%) developed imaging-detected irAEs. Most events (81.8%, 36/44) occurred within 6 months after treatment initiation (Median time-to-ocurrence: 3.3 months), and 90.9% (40/44) resolved on subsequent follow-up imaging, indicating transient phenomenon. Pulmonary infiltrations (n = 23) were the most frequent irAE, followed by bowel wall thickenings (n = 13). Patients with imaging-detected irAEs demonstrated significantly better treatment outcomes than those without irAEs. ORR was higher in the irAE group (43.2% vs. 22.5%; P = .005). After inverse probability of treatment weighting adjustment, both OS and PFS were significantly improved in the irAE group (OS: hazard ratio [HR], 0.62; 95% CI, 0.44–0.89; P = .008; PFS: HR, 0.60; 95% CI, 0.44–0.82; P = .001).
Conclusion: Imaging-detected irAEs are associated with favorable clinical outcomes in unresectable HCC and may serve as a prognostic indicator during atezolizumab plus bevacizumab therapy.

FRI-233

Pretreatment neutrophil-to-lymphocyte ratio as a predictive marker for tumor response to Atezolizumab plus Bevacizumab in hepatocellular carcinoma: a multicenter retrospective study

Young Mi Hong[1], Jun Sik Yoon[2], Yu Rim Lee[3], Jaehyun Yoon[4], Hyun Young Woo[5], Sang Youn Hwang[6], Yeo Wool Kang[7], Joonho Jeong[8], Jeong Eun Song[9], Sung Bum Cho[10]. *[1]Department of Internal Medicine, Pusan National University School of Medicine, Pusan National University Yangsan Hospital, Yangsan, Korea, Rep. of South; [2]Busan Paik Hospital, Inje University College of Medicine, Busan, Korea, Rep. of South; [3]School of Medicine, Kyungpook National University, Kyungpook National University Hospital, Daegu, Korea, Rep. of South; [4]Chonnam National University Hospital, Gwangju, Korea, Rep. of South; [5]College of Medicine, Pusan National University, Busan, Korea, Rep. of South; [6]Dongnam Institute of Radiologic & Medical Sciences, Busan, Korea, Rep. of South; [7]Department of Internal Medicine, Dong-A University College of Medicine, Busan, Korea, Rep. of South; [8]Ulsan University Hospital, University of Ulsan College of Medicine, Ulsan, Korea, Rep. of South; [9]Daegu Catholic University Medical Center, Daegu, Korea, Rep. of South; [10]Chonnam National University Hwasun Hospital, Gwangju, Korea, Rep. of South*
Email: 00gurum@hanmail.net

Background and aims: Atezolizumab combined with bevacizumab has been used in the treatment of advanced hepatocellular carcinoma (HCC). However, reliable predictive biomarkers for evaluating tumor response to this therapy remain limited. This study aimed to identify predictive factors in patient with HCC undergoing treatment with atezolizumab and bevacizumab.
Method: This multicenter retrospective study included 943 patients with HCC who received atezolizumab plus bevacizumab. Factors associated with tumor response were analyzed.
Results: According to the Response Evaluation Criteria in Solid Tumors, the rates of complete remission, partial response, stable disease, and progressive disease were 2.9%, 22.9%, 48.8% and 25.5%, respectively. The objective response rate (ORR) and disease control rate (DCR) were 25.8% and 74.6%, respectively. Progression free survival and overall survival were significantly associated with best tumor response ($P < 0.001$). Multivariate analysis identified BCLC stage (HR = 0.478, 95% CI = 0.278–0.821, $P = 0.007$) and neutrophil-to-lymphocyte ratio (NLR) (HR = 0.670, 95% CI = 0.488–0.920, $P = 0.013$) as independent predictive factors for objective tumor response. The ORR and DCR were 31.2% and 77.2%, respectively, in the NLR <2 group, and 23.7% and 73.5%, respectively, in the NLR ≥ 2 group ($P < 0.001$).
Conclusion: Pretreatment NLR was correlated with the tumor response, which was subsequently associated with survival outcomes. NLR may serve as a predictor of a lack of response to atezolizumab plus bevacizumab treatment. Therefore, NLR represents a readily measurable biomarker with the potential to support the timely identification of HCC patients who are more likely to benefit from atezolizumab and bevacizumab treatment.

FRI-234

Transjugular intrahepatic portosystemic shunt as a bridging strategy to hepatocellular carcinoma treatment in patients with refractory ascites or hydrothorax

Camille Imparato[1], Marika Rudler[2], Jihyun An[3], Josune Cabello Calleja[4], Maria Nieto[5], Charlotte Bouzbib[2], Hélène Larrue[6], Valentin Rolle[7], Coralie Fleurent[8], Hélène Regnault[9], Mehdi Younes[10], Suliman Alhaidari[11], Magdalena Meszaros[12], Coskun Ozer Demirtas[13,14], Osama Khattab[15], Paul Girot[16], Louise Lebedel[17], Sarah Mouri[2], Ju Hyun Shim[18], Michael Praktiknjo[4], Alvaro Giráldez-Gallego[5], Giuliana Amaddeo[9], Vincent Di Martino[10], Puneeta Tandon[11], Lucy Meunier[12], Laure Elkrief[8], Hale Gokcan[19], Isabelle Ollivier-Hourmand[17], Ju Dong Yang[15], Jean-Charles Nault[20,21], Florent Artru[22], Jean Paul Cervoni[10], Alexander Zipprich[23], Anahita Rabiee[13], Jonel Trebicka[4], Laura Turco[24], Vincenzo La Mura[25], Dominique Thabut[2], Lemaitre Caroline[26], Christophe Bureau[6], Manon Allaire[2,20]. *[1]Service d'hépato-gastroentérologie, CHU Charles Nicolle, Rouen, France; [2]AP-HP Sorbonne Université, hôpital universitaire Pitié-Salpêtrière, service d'hépato-gastroentérologie, Paris, France; [3]Department of gastroenterology and hepatology, hanyang university college of medicine, Guri, Korea, Rep. of South; [4]Department of internal medicine B, university hospital Muenster, Muenster, Germany; [5]Digestive diseases department, hospital universitario Virgen del Rocío, university of Seville, institute of biomedicine (HUVR/CSIC/US), university of Seville, Seville, Spain; [6]Service d'hépatologie hôpital Rangueil CHU Toulouse et université de Toulouse, Toulouse, France; [7]Service d'hépato-gastroentérologie, CHU Poitiers – La Miletrie, Poitiers, France; [8]Service d'hépato-gastroentérologie, hôpital Trousseau - CHU de Tours, Tours, France; [9]Service d'hépatologie, AP-HP Henri Mondor, Créteil, France;*

Email: manon.allaire@aphp.fr

Background and aims: The use of TIPS in patients with active hepatocellular carcinoma (HCC) remains controversial. This study aimed to assess outcomes after TIPS performed for refractory ascites or hydrothorax.
Method: We conducted a retrospective multicenter study across 15 centers, including consecutive patients with active HCC who underwent TIPS for refractory ascites or hydrothorax between 2007 and 2025. The primary endpoint was overall survival (OS), while secondary endpoints included ascites resolution and oncological outcomes following HCC-directed treatments after TIPS.
Results: A total of 54 patients with active HCC undergoing TIPS for refractory ascites (n = 49) or hepatic hydrothorax (n = 5) were included. Mean age was 65 years; 69% had alcohol-related liver disease, 41% had a history of acute variceal bleeding (AVB), and 94% presented varices the day of TIPS. Median MELD score was 12, 79% of patients were classified as Child-Pugh B and 30% presented with ALBI grade 3. The median largest tumor diameter was 25 mm. Multifocal disease was present in 56% of patients, and 9% had macrovascular invasion (25% Vp3 and 25% Vp4). Most patients were classified as BCLC stage A (52%), and 80% were within the Milan criteria. Median OS was 24 months. Ascites resolution following shunt creation was achieved in 56% of patients within a median delay of 2 months. When comparing patients with and without ascites resolution, no significant differences were observed in baseline liver function or HCC-related characteristics. In logistic regression analysis, only the use of non-selective beta-blockers before TIPS was associated with ascites resolution (OR 3.27, 95% CI 1.08–10.5; p = 0.04), whereas no tumor-related variables were significantly associated with this outcome. Following TIPS placement, 46% of patients received HCC-directed therapy, including liver transplantation (n = 6), ablation (n = 9; 7 complete responses and 2 progressive diseases), locoregional therapies (n = 6; 3 complete responses and 3 partial responses), and systemic treatments (n = 4). During follow-up, AVB occurred in 6% of patients, hepatic encephalopathy in 39%, and cardiac failure in 2%. New extrahepatic metastases developed in three patients but these patients presented active HCC under systemic treatment.
Conclusion: In selected HCC patients, TIPS allows control of ascites in a substantial proportion of cases, thereby enabling the implementation of curative or palliative treatment for HCC.

FRI-235
Antiviral therapy and post-resection outcomes in patients with hepatitis B virus-related hepatocellular carcinoma

Jaehong Jeong[1], Jung Pyo Hong[1], Dong Yun Kim[1], Jae Seung Lee[1], Mi Na Kim[1], Seung Up Kim[1], Beom Kyung Kim[1], Jun Yong Park[1], Do Young Kim[1], Sang Hoon Ahn[1], Hye Won Lee[1]. [1]Department of Internal Medicine, Yonsei University College of Medicine, Yonsei Liver Center, Severance Hospital, Seoul, Korea, Rep. of South
Email: lorry-lee@yuhs.ac

Background and aims: Hepatitis B virus (HBV) reactivation may occur after curative resection for HBV-related hepatocellular carcinoma (HCC), and antiviral choice could influence long-term outcomes. While tenofovir disoproxil fumarate (TDF) has been suggested to improve survival compared with entecavir (ETV), evidence including tenofovir alafenamide (TAF) remains limited. We compared overall survival (OS) and recurrence-free survival (RFS) among patients receiving ETV, TDF, or TAF after curative resection for HBV-related HCC.
Method: Confounding was controlled using inverse probability of treatment weighting (IPTW) for the average treatment effect with 99th-percentile trimming. Balance was assessed using maximum absolute standardized mean difference. OS and RFS were evaluated using Kaplan–Meier analysis and IPTW-weighted Cox models. Multivariable Cox analyses identified prognostic factors; for RFS, cirrhosis was used as a stratification factor due to non-proportional hazards.
Results: Among 1454 surgically treated patients between 2001 and 2025, 922 received ETV (n = 485), TDF (n = 371), or TAF (n = 66). Unweighted 60-month OS was 91.3%, 94.5%, and 98.1% (p = 0.132), and RFS was 70.0%, 70.8%, and 86.6% (p = 0.290) for ETV, TDF, and TAF, respectively. After IPTW, 60-month OS was 90.7%, 95.1%, and 97.1% (p = 0.069), and RFS was 69.8%, 71.4%, and 83.9% (p = 0.426). In multivariable analysis, TDF was associated with lower mortality versus ETV (adjusted hazard ratio 0.47; 95% CI 0.26–0.87; p = 0.016), whereas TAF showed no significant difference. Neither TDF nor TAF improved RFS compared with ETV.
Conclusion: TDF demonstrated a potential OS benefit compared with ETV after curative resection for HBV-related HCC, although RFS was comparable across agents. Larger cohorts with longer follow-up are needed to clarify the role of TAF.

FRI-236
Identification of serum proteomic signatures for predicting clinical outcomes of immunotherapy in advanced hepatocellular carcinoma

Ji Hoon Kim[1], Young-Sun Lee[1], Eunho Choi[1], Yang Jae Yoo[1], Jong Eun Yeon[1]. [1]Korea university guro hospital, Seoul, Korea, Rep. of South
Email: lys810@korea.ac.kr

Background and aims: Although combination immunotherapies, such as atezolizumab/bevacizumab and durvalumab/tremelimumab, have revolutionized the first-line treatment of advanced hepatocellular carcinoma (HCC), the lack of validated predictive biomarkers remains a clinical hurdle. This study aimed to identify circulating serum protein signatures that predict therapeutic response to atezolizumab/bevacizumab.
Method: Pre-treatment serum samples were obtained from 44 patients with advanced HCC across four tertiary centers. Patients were stratified into responders (CR/PR/SD, n = 32) and non-responders (PD, n = 12). We employed mass spectrometry-based proteomics to characterize the differential protein expression landscape between the two groups.
Results: Proteomic analysis revealed distinct molecular signatures associated with treatment resistance. Non-responders exhibited significantly elevated levels of pro-inflammatory markers, specifically C-reactive protein (CRP) and S100-A9. Conversely, several proteins involved in metabolic homeostasis and transport—including

TF, TTR, APOC3, CLU, RBP4, ITIH2, IGFALS, and SERPINC1—were downregulated in non-responders. Notably, network analysis identified APOC3 and CLU as highly interconnected central hubs, suggesting their pivotal roles in the systemic modulation of treatment response.
Conclusion: Circulating serum proteomic signatures, characterized by a balance between inflammatory markers and metabolic hub proteins, effectively predict the efficacy of atezolizumab/bevacizumab in advanced HCC. These findings provide a robust framework for non-invasive treatment stratification and personalized therapeutic strategies.

FRI-237

First-line therapy in super-older adults with hepatocellular carcinoma: comparative effectiveness of Lenvatinib versus Atezolizumab-Bevacizumab

Masamichi Kimura[1], Koji Nishikawa[1], Jun Imamura[1], Kiminori Kimura[1]. [1]*Tokyo Metropolitan Cancer and Infectious Diseases Center, Komagome Hospital, Tokyo, Japan*
Email: masa55@kuhp.kyoto-u.ac.jp

Background and aims: Evidence guiding first-line systemic therapy in super-older adults (≥80 years) with hepatocellular carcinoma (HCC) is scarce, as pivotal trials largely excluded this age group. We aimed to compare the real-world effectiveness and safety of lenvatinib (LEN) and atezolizumab + bevacizumab (Atezo + Bev) in this population and to assess whether early dose delivery, expressed as 8-week relative dose intensity (RDI), stratifies survival outcomes with LEN.
Method: We retrospectively analyzed 56 consecutive patients aged ≥80 years with unresectable/advanced HCC who initiated first-line LEN (n = 30) or Atezo + Bev (n = 26) between May 2018 and August 2025. All had Child–Pugh A liver function and ECOG 0–1 performance. The primary endpoint was overall survival (OS); secondary endpoints included progression-free survival (PFS) and adverse events (AEs). A prespecified Day-56 landmark analysis was performed in the LEN group to evaluate the association between 8-week RDI (≥75% vs <75%) and OS, mitigating immortal-time bias. Survival was analyzed using Kaplan–Meier and log-rank tests, supplemented by restricted mean survival time (RMST) at 12 months.
Results: Median OS was 14.7 months with LEN and 10.7 months with Atezo + Bev (hazard ratio [HR] 0.82, 95% CI 0.45–1.52; p = 0.52). Median PFS was 6.7 vs 9.7 months, respectively (HR 1.22, 95% CI 0.67–2.23; p = 0.51). Objective response and disease-control rates were 23%/67% for LEN and 15%/77% for Atezo + Bev. In the LEN cohort, an 8-week RDI ≥75% was achieved in 20% of patients and was associated with markedly prolonged OS (30.8 vs 14.7 months; HR 0.34, 95% CI 0.14–0.80; p = 0.019). At 12 months, RMST difference (ΔRMST) was +32 days favoring high-RDI LEN. Grade ≥3 AEs occurred in 37% (LEN) and 50% (Atezo + Bev) without treatment-related deaths. Anorexia and diarrhea were more frequent with LEN, while edema and gastrointestinal bleeding occurred only with Atezo + Bev.
Conclusion: Among super-older adults with HCC, LEN and Atezo + Bev demonstrated comparable real-world efficacy and tolerability. Importantly, maintaining early dose delivery (8-week RDI ≥75%) under LEN identified a subgroup with significantly improved survival. These findings highlight early dose intensity as a pragmatic biomarker for optimizing systemic therapy in frail ≥80-year-old patients and support a dose-delivery-guided algorithm: maintain high early RDI with LEN, and consider timely switch to Atezo + Bev if this target cannot be sustained.

Email: paiik.shinha@gmail.com

Background and aims: Hepatocellular carcinoma (HCC) is often diagnosed at an advanced stage, precluding upfront resection. Immunotherapy has profoundly changed the management of unresectable HCC, offering high tumour response rates and enabling potential conversion to surgery. However, multicentric data on perioperative safety and survival outcomes after resection in this setting remain limited.
Method: A multicentric retrospective study was conducted across eight French University Hospitals between 2019 and 2024. Patients initially deemed unresectable who received immunotherapy followed by surgery after achieving a radiologic tumour response were included. Primary endpoints were overall survival (OS) and disease-free survival (DFS). Secondary endpoints included postoperative morbidity (Clavien ≥ III), 90-day mortality, and pathological response.
Results: Thirty-six patients were included (86% male; median age 59 years; median BMI 25.6 Kg/m2). Before treatment, 53% were classified as BCLC stage C (VP4 n = 2, VP3 n = 10, VP2 n = 5, nodal metastases n = 2), and 8% as Child-Pugh B7. The median size of the largest lesion was 87 mm (range 57–101), with a median number of 3.5 nodules. All patients received a median of 11 cycles of immunotherapy (range 6 –18) before surgery. An objective partial response was achieved in all cases, with a tumour size reduction in 76% of cases. After immunotherapy, 35% of patients were reclassified as BCLC A, 39% as BCLC C, and liver function remained preserved in all but one case (Child-Pugh B7). A right hepatectomy wasperformed in 14 patients (56%). The overall rate of major complications (Clavien ≥ III) was 16%, with no 90-day mortality. Median hospital stay was 7 days, including a median of 2.6 days in intensive care. Complete tumour necrosis (100%) was observed in 9 patients (36%). The estimated OS was 96% at 3 months, 91% at 12 months, 81% at 24 months, and remained 81% at 60 months. DFS rates were 100% at 3 months, 95% at 12 months, 75% at 24 months, 58% at 60 months.
Conclusion: Conversion surgery after systemic immunotherapy for initially unresectable HCC is feasible and safe in experienced centres, showing low postoperative morbidity and favourable 2-year survival outcomes.
These findings support the curative potential of hepatic resection following combined immunotherapy and support the need for larger comparative studies to validate its long-term benefit.

FRI-239

Functional convergence towards short chain fatty acid metabolism shapes responsiveness to atezolizumab plus bevacizumab across Western and Eastern populations despite distinct gut microbial composition

Pei-Chang Lee[1], Chi-Jung Wu[1], Pasquale Lombardi[2], Leonardo Brunetti[2], Chieh-Ju Lee[1], I-Cheng Lee[1], Claudia Fulgenzi[2], Ya-Wen Hung[1], Chen-Ta Chi[1], Julian R. Marchesi[2], Rosemary Boyton[2], Daniel M Altmann[2], Catherine Reynolds[2], Despoina Chrysostomou[2], Rohini Sharma[2], Antonio D'Alessio[2], Alessio Cortellini[3], Ming-Chih Hou[1], Yi-Hsiang Huang[1], David J. Pinato[2]. *[1]Taipei Veterans General Hospital, Taipei, Taiwan; [2]Imperial College London, London, United Kingdom; [3]Campus Biomedico Rome, Rome, Italy*
Email: david.pinato@imperial.ac.uk

Background and aims: Gut microbial composition influences immunotherapy outcomes in hepatocellular carcinoma (HCC). We investigated whether geographic origin affects the association between gut microbiota and tumor response to atezolizumab plus bevacizumab (A+B) in Western and Eastern patients with HCC.
Method: Patients with unresectable HCC initiating first-line A+B therapy were prospectively enrolled from the United Kingdom and Italy (Western cohort, $n = 15$) and Taiwan (Eastern cohort, $n = 53$). Fecal samples were collected prior to treatment initiation and analyzed for microbial composition using linear discriminant analysis effect size based on full-length bacterial 16S rRNA gene sequencing. Microbial functional profiles and pathway inferences were predicted using Phylogenetic Investigation of Communities by Reconstruction of Unobserved States version 2 (PICRUSt2). Durable response was defined as an objective response or stable disease lasting longer than 8 months.
Results: Western and Eastern cohorts were comparable in pre-treatment characteristics: most patients had BCLC stage C disease (93.3% vs. 100%) and Child–Pugh class A liver function (86.7% vs. 100%), while etiology differed, with non-viral disease more frequent in Western patients (60.0%) and viral disease more frequent in Eastern patients (66.0%) (all $p > 0.05$). Baseline gut microbiota composition differed significantly between cohorts, as assessed by Bray–Curtis and unweighted UniFrac distances (both $p = 0.001$ by PERMANOVA). Despite this divergence, durable response rates were similar (46.7% vs. 39.6%, $p = 0.770$). Western durable responders were enriched in *Faecalibacterium prausnitzii*, *Faecalibacterium intestinalis*, and *Phocaeicola plebeius*, whereas *Akkermansia muciniphila* and *Acidaminococcus fermentans* predominated in Eastern durable responders. In contrast, Enterobacteriaceae were consistently enriched in non-responders. Notably, PICRUSt2 analysis demonstrated convergent enrichment of microbial functions related to short-chain fatty acid (SCFA) biosynthesis in durable responders, mediated through distinct metabolic pathways (PWY-5677 [$p = 0.019$] and PWY-7187 [$p = 0.046$] in Eastern responders; CENTEFRM-PWY [$p = 0.026$] and COA-PWY [$p = 0.043$] in Western responders).
Conclusion: Despite marked geographic differences in gut microbiota composition, convergence of SCFA-related microbial functions highlights microbial functional capacity as a unifying determinant of A+B efficacy across regions.

FRI-240

Clinical utility of tumor morphology for predicting aggressive and hyperaggressive recurrence after curative resection of hepatocellular carcinoma

I-Cheng Lee[1], Romeo Kuo-Cheng Wu[2], Chi-Ping Tan[1], Gar-Yang Chau[1], Jiing-Chyuan Luo[1], Yi-Hsiang Huang[1]. *[1]Taipei Veterans General Hospital, National Yang Ming Chiao Tung University, Taipei, Taiwan, [2]Keelung Hospital Ministry of Health & Welfare, Keelung, Taiwan*
Email: iclee@vghtpe.gov.tw

Background and aims: Recurrence after curative resection for hepatocellular carcinoma (HCC) is highly heterogeneous, and predictors of aggressive recurrence remain poorly defined. This study aimed to identify clinical, radiologic, and histologic predictors of aggressive and hyperaggressive recurrence after curative resection for HCC.
Method: Between 2007 and 2024, 906 of 1813 patients who developed recurrence after curative resection for HCC were retrospectively analyzed. Recurrence patterns included recurrence beyond the Milan criteria (aggressive recurrence), recurrence with macrovascular invasion, extrahepatic metastasis, and recurrence at BCLC stage C (hyperaggressive recurrence). Radiologic tumor morphology was classified as simple nodular (type I), simple nodular with extranodular growth (type II), confluent multinodular (type III), or infiltrative (type IV). Types III and IV were defined as high-risk morphology. Independent predictors were identified using multivariate analysis.
Results: Among the 906 patients with recurrent HCC, 353 (39.0%) developed aggressive recurrence, 63 (7.0%) had macrovascular invasion, 149 (16.4%) developed extrahepatic metastases, and 191 (21.1%) presented with BCLC stage C (hyperaggressive recurrence). Risks of aggressive recurrence for morphology types I–IV were 26.4%, 42.5%, 62.6%, and 65.1%, respectively. Corresponding risks for hyperaggressive recurrence were 12.4%, 19.0%, 40.0%, and 46.5%. On multivariate analysis, high-risk tumor morphology (hazard ratio [HR] 1.450, $p = 0.010$), BCLC stage, 7–11 criteria, poor differentiation, microvascular invasion, and AFP >400 ng/mL independently predicted aggressive recurrence. High-risk morphology was also an independent predictor of hyperaggressive recurrence (HR 2.193, $p < 0.001$), recurrence with macrovascular invasion (HR 2.091, $p = 0.012$), and extrahepatic metastasis (HR 2.199, $p < 0.001$), together with established tumor burden, adverse histologic features, and elevated AFP levels.
Conclusion: Radiologic tumor morphology, particularly high-risk patterns, in combination with the 7–11 criteria, histologic characteristics, and AFP level, effectively predicts aggressive and hyperaggressive recurrence of HCC after curative resection. These findings may improve postoperative risk stratification and inform surveillance strategies and future perioperative therapeutic trials.

FRI-241

Comparative efficacy and safety of second-line and later systemic therapies after first-line treatment failure in hepatocellular carcinoma: a systematic review and meta-analysis

Han Ah Lee[1], Moon Haeng Hur[2], Yuri Cho[3], Ju Hyun Shim[4], Bo Hyun Kim[3], Yong-Han Paik[5], Joon Hyeok Lee[5]. *[1]Chung-Ang University, Seoul, Korea, Rep. of South; [2]Seoul National University College, Seoul, Korea, Rep. of South; [3]National Cancer Center, Seoul, Korea, Rep. of South; [4]Asan Medical Center, Seoul, Korea, Rep. of South; [5]Samsung Medical Center, Seoul, Korea, Rep. of South*
Email: amelia86@naver.com

Background and aims: Establishing optimal second-line and later systemic treatment strategies after failure of first-line therapy has become an increasingly important challenge in hepatocellular carcinoma (HCC). However, evidence guiding treatment selection remains limited.
Method: We conducted a systematic review and meta-analysis of published studies evaluating second-line or later systemic therapies for HCC, excluding studies limited to sorafenib failure alone. Overall survival (OS), progression-free survival (PFS), and grade 3–4 adverse events (AEs) were pooled using meta-analytic methods.
Results: In the meta-analysis of second-line and later systemic therapies after failure of atezolizumab plus bevacizumab, lenvatinib demonstrated the most favorable survival outcomes. The pooled median OS was 12.42 months for lenvatinib (95% CI, 10.02–14.82; $I^2 = 89.4\%$), compared with 7.83 months for sorafenib (95% CI, 6.29–9.36; $I^2 = 7.36\%$). Regorafenib, cabozantinib, and ramucirumab showed pooled median OS of 9.19 months (95% CI, 3.60–14.78; $I^2 = 94.5\%$), 9.59 months (95% CI, 4.91–14.27; $I^2 = 91.4\%$), and 5.85 months (95% CI, 1.76–9.94; $I^2 = 20.6\%$), respectively. Compared with sorafenib,

lenvatinib significantly reduced the risk of death (risk ratio [RR], 0.64; 95% CI, 0.49–0.84; I^2 = 34.2%), whereas regorafenib and cabozantinib did not show significant benefit. The pooled median PFS was also longest with lenvatinib at 4.74 months (95% CI, 3.76–5.72; I^2 = 96.4%), followed by cabozantinib (3.96 months), regorafenib (3.05 months), and sorafenib (2.86 months). Lenvatinib significantly reduced the risk of disease progression compared with sorafenib (RR, 0.58; 95% CI, 0.42–0.80; I^2 = 65.3%). Reconstructed survival curves confirmed longer median OS (11.87 vs. 8.30 months) and PFS (3.80 vs. 1.93 months) with lenvatinib compared with sorafenib. The incidence of grade 3–4 AEs was comparable between lenvatinib (36%) and sorafenib (34%). After lenvatinib failure, atezolizumab plus bevacizumab achieved a pooled median OS of 14.98 months (95% CI, 9.57–20.38; I^2 = 42%) and PFS of 5.78 months (95% CI, 3.19–8.37; I^2 = 66%), along with the highest ORR (28.3%) and DCR (69.6%), although with a higher incidence of grade 3–4 AEs (53%).
Conclusion: Lenvatinib demonstrates clinical benefit after failure of atezolizumab plus bevacizumab, while multiple systemic therapies, including atezolizumab plus bevacizumab, may provide meaningful efficacy after lenvatinib failure.

FRI-242
Adequate surgical margin, not resection type, determines long-term outcomes after liver resection for hepatocellular carcinoma
Boram Lee[1]. [1]*Seoul National University Bundang Hospital, Gyeonggi-do, Korea, Rep. of South*
Email: boramsnubhgs@gmail.com

Background and aims: The oncologic superiority of anatomical resection (AR) over non-anatomical resection (NAR) for hepatocellular carcinoma (HCC) remains controversial. It is unclear whether reported survival benefits of AR are attributable to the resection type itself or to its association with wider surgical margins. This study aimed to evaluate the relative impact of resection type and margin adequacy on long-term oncologic outcomes after liver resection for HCC.
Method: A retrospective analysis was conducted of 1349 patients who underwent curative-intent liver resection for HCC between 2004 and 2022. Surgical margin width was defined as the shortest pathological distance from the tumor to the resection margin, with ≥1 cm considered adequate. Recurrence-free survival (RFS) and overall survival (OS) were compared according to resection type and margin status. Propensity score matching and multivariable Cox regression analyses were performed, with subgroup analyses stratified by tumor size (<5 cm vs. ≥5 cm).
Results: AR was associated with a higher likelihood of achieving a surgical margin ≥1 cm compared with NAR. However, after propensity score matching, no significant differences in OS or RFS were observed between AR and NAR. In patients with tumors <5 cm, margin adequacy was significantly associated with improved RFS regardless of resection type, whereas resection type itself was not an independent prognostic factor. In tumors ≥5 cm, neither margin width nor resection type significantly influenced survival outcomes. Multivariable analysis identified tumor size ≥5 cm and margin <1 cm as independent predictors of recurrence and mortality, while resection type was not.
Conclusion: Long-term oncologic outcomes after liver resection for HCC are determined primarily by surgical margin adequacy rather than by resection type. The prognostic impact of margin width is most pronounced in small tumors and diminishes in larger tumors where tumor biology predominates. Surgical strategies should prioritize achievable margin clearance while preserving functional liver reserve, rather than routinely favoring anatomical resection.

FRI-243
Neoadjuvant radiotherapy combined with lenvatinib and pd-1 blockade in resectable intrahepatic cholangiocarcinoma at high risk of recurrence: a prospective phase II study
Keren Li[1]. [1]*Beijing Tsinghua Changgung Hospital, Beijing, China*
Email: lkra03939@btch.edu.cn

Background and aims: Resectable intrahepatic cholangiocarcinoma (ICC) is associated with high postoperative recurrence rates, particularly in patients with adverse tumor and nodal factors. Effective neoadjuvant strategies for this high-risk population remain poorly defined. We conducted a prospective phase II study to evaluate neoadjuvant radiotherapy combined with lenvatinib and PD-1 blockade in resectable ICC patients at high risk of recurrence.
Method: This prospective, single-arm phase II study enrolled patients with resectable ICC and predefined high-risk features for recurrence. Neoadjuvant therapy consisted of radiotherapy targeting both the primary tumor and regional lymphatic drainage areas (regional lymph nodes: 200 cGy × 20 fractions; primary tumor: 300 cGy × 20 fractions), combined with toripalimab (240 mg intravenously every 3 weeks for four cycles) and lenvatinib (8 mg orally once daily, discontinued 7 days prior to surgery). The primary endpoint was 1-year recurrence-free survival. Secondary endpoints included overall survival, objective response rate, and safety.
Results: Between January 2023 and December 2024, 17 patients completed neoadjuvant treatment. Eight patients (47.06%) achieved conversion to curative-intent treatment following therapy, including surgical resection (n = 4) and liver transplantation (n = 2). One patient was scheduled for second-stage surgery and one was awaiting surgery. Disease progression precluding surgery occurred in four patients (23.53%). Three patients (17.65%) had stable disease but did not undergo surgery due to poor performance status or patient refusal. The combined neoadjuvant regimen was generally well tolerated, with no unexpected treatment-related toxicities observed.
Conclusion: Neoadjuvant radiotherapy combined with lenvatinib and PD-1 blockade demonstrated promising conversion potential with acceptable safety in resectable ICC patients at high risk of recurrence. This liver-directed multimodal approach may expand curative treatment opportunities and merits further investigation.

FRI-244
Efficacy of second-line therapies and the prognostic value of the crafity score in advanced hepatocellular carcinoma following Atezolizumab plus Bevacizumab failure: a real-world study
Jinpeng Li[1], Jinlong Song[1]. [1]*Shandong Cancer Hospital and Institute, jinan, China*
Email: jls7286@163.com

Background and aims: Hepatocellular carcinoma (HCC) accounts for approximately 90% of all primary liver malignancies and presents a significant therapeutic challenge due to its heterogeneity. The efficacy of second-line treatments following disease progression on first-line atezolizumab plus bevacizumab (Atez/Bev) in advanced HCC remains a subject of ongoing debate. This study aimed to evaluate real-world clinical outcomes of second-line therapies post-Atez/Bev failure and to identify prognostic factors influencing survival.
Method: We retrospectively analyzed 68 patients with advanced or metastatic HCC who received second-line regorafenib, lenvatinib, or ramucirumab following progression on first-line Atez/Bev at Shandong Cancer Hospital and Institute between October 2020 and June 2024. Tumor response was assessed according to Response Evaluation Criteria in Solid Tumors (RECIST) v1.1. Median overall survival (OS) and progression-free survival (PFS) were estimated using the Kaplan-Meier method. Multivariate analyses were performed using the Cox proportional hazards model to identify independent prognostic factors.
Results: The cohort was predominantly male (85.3%), with a median age of 59 years (range, 28–76 years). All patients had progressed on

first-line Atez/Bev prior to receiving second-line therapy. Regorafenib was the most frequently administered agent (70.7%), followed by lenvatinib (12.1%) and ramucirumab (10.3%). Patients treated with regorafenib exhibited a prolonged median PFS of 4.5 months and a median OS of 8.5 months compared to other regimens. Univariate analysis demonstrated that Child-Pugh class B, elevated alpha-fetoprotein (AFP) levels (>200 ng/mL), extrahepatic spread, and a high CRAFITY score were significantly associated with increased mortality risk. Multivariate analysis identified extrahepatic spread (hazard ratio [HR]: 0.45, P = .021), CRAFITY score (HR: 0.32, P = .008), and AFP level (HR: 2.15, P = .032) as independent predictors of OS.
Conclusion: While second-line therapies following Atez/Bev failure demonstrate varying degrees of efficacy, survival outcomes observed in this cohort are consistent with current literature. Extrahepatic spread, AFP levels, and CRAFITY scores emerged as key prognostic factors. These findings highlight the potential for personalized treatment strategies to improve clinical outcomes in this refractory patient population.

FRI-245
Association of radiotherapy with atezolizumab plus bevacizumab with survival in advanced hepatocellular carcinoma
Gyungsun Lim[1], Hyunjae Shin[1], Byeong Geun Song[2], Sung Won Chung[3], Jeong Il Yu[4], Hee Chul Park[4], Moon Haeng Hur[1], Yun Bin Lee[1], Eun Ju Cho[1], Jeong-Hoon Lee[1], Su Jong Yu[1], Jung-Hwan Yoon[1], Yoon Jun Kim[1]. *[1]Department of Internal Medicine and Liver Research Institute, Seoul National University College of Medicine, Seoul, Korea, Rep. of South; [2]Department of Internal Medicine, Samsung Medical Center, Seoul, Korea, Rep. of South; [3]Department of Gastroenterology, Liver Center, Asan Medical Center, University of Ulsan College of Medicine, Seoul, Korea, Rep. of South; [4]Department of Radiation Oncology, Samsung Medical Center, Sungkyunkwan University, Seoul, Korea, Rep. of South*
Email: yoonjun@snu.ac.kr

Background and aims: Immunotherapy is the standard first-line therapy for advanced hepatocellular carcinoma (HCC). Radiotherapy (RT) is well established for achieving local control and may also induce systemic immune effects. We evaluated the association of RT with outcomes in patients receiving Atezolizumab plus Bevacizumab (Ate+Bev).
Method: Patients who received RT during Ate+Bev therapy (n = 88) in 2017–2023 were compared with patients treated with Ate+Bev alone (n = 396). Overall survival (OS), progression-free survival (PFS), and freedom from local progression (FFLP) were analyzed with multivariable Cox models from the start of Ate+Bev to HCC progression or death.
Results: Median follow-up was 18.3 months and the median interval from Ate+Bev start to RT was 32 days. Combining RT with Ate+Bev was associated with longer OS (adjusted hazard ratio [aHR] = 0.71, 95% confidence interval [CI] = 0.53–0.97, p = 0.030), PFS (aHR = 0.57, 95% CI = 0.45–0.74, p < 0.001), and FFLP (aHR = 0.65, 95% CI = 0.44–0.95, p = 0.027) compared to Ate+Bev alone. This association was consistent across subgroups (interaction p > 0.05). In RT recipients, OS (aHR = 1.38, 95% CI = 0.65–2.93, p = 0.40) and PFS (aHR = 0.92, 95% CI = 0.55–1.52, p = 0.73) did not differ according to the timing of RT. RT-related adverse events occurred in 3.4% of patients and total adverse events between groups were comparable (p = 0.211).
Conclusion: Combining RT with Ate+Bev was associated with longer OS, PFS and FFLP. These findings support the potential role of RT as an effective adjunct to immunotherapy and warrant prospective validation.

FRI-246
Multi-omics analysis of combined immunotherapy - chemotherapy benefit in advanced intrahepatic cholangiocarcinoma
Ningning Zhang[1], Xuanchen Liu[1]. *[1]Tianjin Medical University Cancer Institute and Hospital, Tianjin, China*
Email: mail4ningning@gmail.com

Background and aims: The combination of immunotherapy and chemotherapy has become a first-line treatment for advanced intrahepatic cholangiocarcinoma (ICC). However, a significant proportion of patients do not achieve sustained clinical benefit. This study aimed to identify gut microbiota, peripheral blood metabolites, and immune features associated with sustained benefit from this regimen, and to explore the potential regulatory mechanisms of the gut microbiota-bile acid-immune axis.
Method: This study enrolled 78 treatment-naïve patients with advanced ICC receiving first-line toripalimab plus GEMOX, classified as sustained benefit (DCB, n = 55) or non-sustained benefit (noDCB, n = 23) groups. Pretreatment fecal samples underwent metagenomic sequencing. Peripheral blood from all patients was analyzed by flow cytometry for immune cells/cytokines, and a subset (n = 39) was analyzed for bile acid metabolomics. LASSO and ROC analyses identified predictive factors. Correlation and mediation analyses were performed on the cohort with complete multi-omics data (n = 39) to investigate interactions.
Results: The DCB group exhibited higher gut microbial diversity and was enriched with beneficial bacteria (e.g., Faecalibacterium prausnitzii), while the noDCB group was enriched with potentially harmful bacteria. Metagenomic pathways related to bile acid synthesis and metabolism were upregulated in the DCB group, whereas virulence-related pathways were enriched in the noDCB group. Immune profiling showed higher PD-1 expression on $CD8^+$ T cells in the DCB group, and higher Tregs and IL-8 in the noDCB group. Multiple primary and secondary bile acids (e.g., TCDCA-3S, TLCA-3S) were elevated in the DCB group. LASSO regression identified 11 predictors of sustained benefit. Seven indicators, including TBS, NLR, Tregs, PD-1^+CD8^+ T cells, Faecalibacterium prausnitzii, Bacteriophage sp., and TCDCA-3S, showed moderate predictive value (AUC > 0.7). Correlation and mediation analyses in the 39-patient cohort revealed a significant positive correlation among Faecalibacterium prausnitzii, TCDCA-3S, and PD-1^+CD8^+ T cells. Mediation analysis supported that F. prausnitzii may upregulate PD-1 expression on $CD8^+$ T cells by modulating TCDCA-3S levels.
Conclusion: The study proposes a potential "Faecalibacterium prausnitzii - TCDCA-3S - PD-1^+CD8^+ T cells" regulatory axis, offering insights for predictive biomarker development and mechanistic understanding.

FRI-247
Association between prophylactic antibiotics and post-ablation infections in hepatocellular carcinoma patients: a retrospective multicenter cohort study
Ting Luo[1], Jie Yu[1], Ping Liang[1]. *[1]Department of Interventional Ultrasound, Chinese PLA General Hospital, Beijing, China*
Email: luotingemma56@163.com

Background and aims: The role of prophylactic antibiotics in preventing infections following hepatocellular carcinoma (HCC) ablation remains unclear. We aimed to clarify whether prophylactic antibiotics reduce infection rates after HCC ablation and to identify patient subgroups who might benefit.
Method: This retrospective, multicenter cohort study included HCC patients who underwent percutaneous thermal ablation between May 2018 and April 2024, classified into prophylactic antibiotic (PA) and non-prophylactic antibiotic (non-PA) groups. The primary outcome was infection, categorized as severe or non-severe, while secondary outcomes included duration of hospitalization, costs, and fever. Propensity Score Matching (PSM) and Overlap Weighting (OW)

were employed to control for baseline differences, and the Firth's penalized likelihood method was applied to all logistic regression analysis.
Results: A total of 2446 patients (mean age 60.4 ± 10.6 years; 520 women) from six centers were included. Comparing the PA and non-PA groups, the PA group showed lower overall infection rates than the non-PA group (4.1% vs. 6.6%, P < 0.05 in primary cohort), which was comparable after adjustment (P = 0.1 after PSM and P = 0.32 after OW). Logistic regression analysis revealed that BCLC B, high glucose level, and history of biliary surgery were independent risk factors of infection in both PSM and OW cohort (all P < 0.05).
Conclusion: Routine prophylactic antibiotic use is not necessary in percutaneous HCC thermal ablation; however, it may be considered for selected patients.

FRI-248
The prognostic role of the SMARS score in patients with hepatocellular carcinoma receiving Atezolizumab/Bevacizumab
Maximilian Moos[1], Felix Hahn[1], Friedrich Foerster[1], Roman Kloeckner[2], Constantin Scholz[1], Tobias Bäuerle[1], Lukas Müller[1], Aline Mähringer-Kunz[1]. [1]*University Medical Center Mainz, Mainz, Germany;* [2]*University Medical Center Schleswig-Holstein, Luebeck, Germany*
Email: maximilian.moos2@unimedizin-mainz.de

Background and aims: This study aimed to evaluate the prognostic performance of the recently introduced SMARS score in patients with hepatocellular carcinoma (HCC) undergoing systemic immunotherapy. Specifically, we assessed whether this novel imaging-based score enables reliable risk stratification in this setting.
Method: We retrospectively analyzed 90 patients with HCC treated at our center between January 2020 and May 2024. The SMARS score, incorporating tumor shape, mosaic architecture, alpha-fetoprotein (AFP) level, rim arterial phase hyperenhancement and satellite lesions, was calculated from baseline CT according to Bao et al. Overall survival (OS) was assessed with Kaplan–Meier analysis, and prognostic factors were evaluated using uni- and multivariable Cox regression models.
Results: Higher SMARS scores were associated with impaired OS using the previously published cutoff of –0.49. In uni- and multivariate Cox regression, the SMARS score emerged as a significant prognostic factor. Univariate Cox regression demonstrated that four SMARS components were significantly associated with OS, including tumor shape (HR 2.08, 95% CI 1.25–3.40; p = 0.003), mosaic architecture (HR 1.64, 95% CI 1.04–2.59; p = 0.036), AFP-level (HR 1.80, 95% CI 1.12–2.90; p = 0.016) and rim arterial phase hyperenhancement (HR 2.03, 95% CI 1.24–3.33; p = 0.005). Satellite lesions were not significantly associated with OS (HR 1.70, 95% CI 0.97–3.00, p = 0.061). In the multivariable analysis, only tumor shape remained independently associated with OS (HR 2.06, 95% CI 1.25–3.40; p = 0.004).
Conclusion: Imaging-based SMARS score is an independent prognostic marker in patients with HCC undergoing systemic therapy with atezolizumab/bevacizumab. These findings extend previous evidence by confirming the prognostic relevance of SMARS beyond loco-regional approaches and highlight its potential to guide patient stratification in the era of systemic immunotherapy.

FRI-249
Real-world outcomes of sequential transarterial chemoembolization followed by Atezolizumab–Bevacizumab in patients with unresectable hepatocellular carcinoma
Soe Thiha Maung[1,2], Jonggi Choi[3], Roongruedee Chaiteerakij[1], Sung Won Chung[3]. [1]*Faculty of Medicine, Chulalongkorn University, Bangkok, Thailand;* [2]*Ma Har Myaing Hospital, Yangon, Myanmar;* [3]*Asan Medical Center, University of Ulsan College of Medicine, Seoul, Korea, Rep. of South*
Email: dr.sthm92@gmail.com

Background and aims: Repeated transarterial chemoembolization (TACE) for unresectable hepatocellular carcinoma (uHCC) often leads to deteriorating hepatic reserve. While atezolizumab plus bevacizumab (Atezo/Bev) is the standard systemic therapy, the optimal timing for transition, specifically whether to strictly wait for TACE refractoriness, remains debated. We evaluated the impact of hepatic function and TACE history on outcomes in patients switching to Atezo/Bev, aiming to identify prognostic determinants beyond conventional refractoriness criteria.
Method: We retrospectively analyzed 154 patients with uHCC who transitioned to Atezo/Bev after prior TACE. The index date was defined as Atezo/Bev initiation, serving as baseline for all clinical variables. TACE refractoriness followed Japan Society of Hepatology criteria. Prognostic factors for overall survival (OS) and progression-free survival (PFS) were assessed using Cox regression. Exploratory analyses included change-point analysis of international normalized ratio (INR) at index and impact of early transition (≤4 vs. >4 TACE sessions).
Results: At the index date, 76.0% of patients met the criteria for TACE refractoriness. However, refractoriness status itself was not an independent predictor for either OS (p = 0.37) or PFS (p = 0.09). Instead, baseline hepatic function and cumulative TACE burden were the primary determinants. In multivariable analysis, elevated INR (adjusted hazard ratio [aHR] 24.03, p = 0.001), higher AST (aHR 1.02, p = 0.04), and a greater number of prior TACE sessions (aHR 1.07, p = 0.004) were independent adverse predictors for PFS. Notably, a non-linear threshold effect was observed for baseline INR; PFS remained relatively stable at INR <1.20 but declined sharply at INR ≥1.20 (median 6.47 vs. 3.57 months; log-rank p = 0.003). In change-point modeling, the risk of progression increased steeply only after the INR exceeded 1.20 (HR 2.05 per 0.1 increase, p < 0.05). Furthermore, early transition (after ≤4 TACE sessions) was associated with significantly better PFS (aHR 0.68, p = 0.04) compared to later transition, independent of refractoriness.
Conclusion: In patients transitioning from TACE to Atezo/Bev, hepatic reserve and cumulative TACE burden more strongly influenced outcomes than TACE refractoriness. An INR around 1.20 marked a threshold for poorer prognosis. Early switch to Atezo/Bev, before INR ≥1.20 and with limited TACE, may improve outcomes.

FRI-250
Integrating locoregional therapies with immune checkpoint inhibitors may improve outcomes in advanced HCC
Mzamo Mbelle[1,2], Barbaros Ucar[3], Debashis Sarker[3], Paul Ross[3], Kiruthikah Thillai[3], Marie Kionisala[3], Eleni Petraki[3], Sarah Selemani[3], Dylan Lewis[1], Praveen Peddu[1], Maria Guerra Veloz[1], Mary D Cannon[1], Abid Suddle[1], Niloufar Safinia[2], Antonio D'Alessio[3,4]. [1]*Institute of Liver Studies, King's College Hospital, Denmark Hill, London, United Kingdom;* [2]*Roger Williams Institute of Liver Studies, Kings College London, London, United Kingdom;* [3]*Department of Medical Oncology, King's College Hospital and Guy's and St Thomas' Hospital, London, United Kingdom;* [4]*Division of Cancer, Imperial College London, London, United Kingdom*
Email: mzamo.mbelle@nhs.net

Background and aims: The survival benefit of combining locoregional therapy (LRT) with systemic immune checkpoint inhibition (ICI) in advanced hepatocellular carcinoma (HCC) remains poorly defined. With the advent of atezolizumab-bevacizumab (AB), emerging evidence suggests a potential synergistic effect between LRT and immune-based therapies. This study evaluated the impact of LRT administered concurrently with AB on survival and treatment response in a real-world cohort.
Method: We retrospectively analysed patients with advanced HCC treated with AB at King's College Hospital from September 2020 to September 2025. Demographic, clinical, and radiological data were collected. LRT included ablative (microwave ablation [MWA], irreversible electroporation [IRE]), embolic (transarterialchemoembolization [TACE], selective internal radiation therapy [SIRT]), and

radiation modalities (stereotactic body radiotherapy [SBRT]) delivered during ICI therapy after MDT discussion. Survival outcomes were assessed using Kaplan–Meier and logrank tests, and logistic regression was used to identify predictors of response and survival.
Results: Among 207 patients, 169 (82%) were male, with a median age of 65 years (IQR 57–72). MASLD was the most common aetiology (35.7%). Median maximal tumour diameter was 50 mm (IQR 30–96); 102 (60%) had multifocal disease, 63 (31%) macrovascular invasion, and 28 (15%) extrahepatic metastases. The median AB treatment duration was 4 months (IQR 2–10). Concurrent LRT was delivered in 25 patients: indications included consolidation after radiological response (28%), treatment of intrahepatic progression (20%), and radiotherapy for extrahepatic oligometastasis or palliation (32%). Adjunctive therapies included TACE in 24%, SIRT in 20%, MWA in 12%, and SBRT in 36% of patients. Median follow-up was 21 months (95% CI 16–24). One-year OS was 83.3% (95% CI 71.0–97.8) in responders versus 61.8% (95% CI 54.4–72.4) in non-responders ($p = 0.0018$). Concurrent LRT independently predicted improved survival (HR 0.07, 95% CI 0.01–0.18). Median OS was 14.9 months (95% CI 11.9–22.2) in patients who did not receive LRT, while it was 40.8 months (95% CI 29.8–NR; $p < 0.001$) for LRT-treated patients.
Conclusion: In this real-world cohort, concurrent LRT during AB treatment was associated with a significant improvement in OS for selected patients with advanced HCC. These findings support further prospective trials to refine timing, treatment choice, and patient selection for combined LRT-ICI approaches in advanced HCC.

Background and aims: Immune checkpoint inhibitors (ICIs) improve survival in patients with mismatch repair–deficient/microsatellite instability–high (dMMR/MSI-high) tumors. Since 2022, ICIs in combination with gemcitabine and cisplatin have become the standard of care for patients with advanced biliary tract cancers (BTC). Patients with dMMR/MSI-high BTC represent a rare subgroup. Here, we examined clinical characteristics, safety, and outcomes of patients with dMMR/MSI-high BTC in a German multicenter real-world cohort.
Method: Patients with dMMR/MSI-high BTC treated with systemic therapy at 10 German centers were included. Clinicopathological baseline characteristics, median overall survival (OS), median progression-free survival (PFS), response rates, and adverse events (AEs) were retrospectively analyzed. Prognostic and predictive factors were assessed using Kaplan–Meier analysis and binary logistic regression.
Results: Between 2018 and 2025, 21 patients with dMMR/MSI-high BTC were included. Median follow-up was 23 months (95% CI 19.3–26.7). The majority of patients had intrahepatic cholangiocarcinoma ($n = 12$, 57%), while nine patients (43%) had extrahepatic cholangiocarcinoma. Affected mismatch repair genes were MLH1 (53%), PMS2 (29%), MSH6 (28%), and MSH2 (19%). Common co-alterations included KRAS (38%) and TP53 (29%). In first-line setting, four patients (19%) received immunotherapy alone, 15 patients (71%) immuno-chemotherapy, and two patients (10%) chemotherapy alone. Median duration of first-line treatment was 17 months (95% CI 8.6–25.4). Second-line treatment was administered in eight patients (38%). Median OS was not reached, while median PFS was 19 months (95% CI 8.8–29.2). Favourable outcomes were observed in responders and in patients treated with immunotherapy alone. Overall response rate was 57%, including five complete and seven partial responses, and disease control rate was 86%. Occurrence of immune-related adverse events (irAEs) was associated with complete response (OR 10.5, 95% CI 1.1–107.2, $p = 0.047$). Overall, grade 1–2 irAEs occurred in one patient and grade 3–4 irAEs in five patients, leading to discontinuation of immunotherapy in four patients.
Conclusion: Immunotherapy-based treatment results in favourable responses and outcomes in patients with dMMR/MSI-high BTC and can be safely administered.

FRI-252

First-line Atezolizumab plus bevacizumab versus lenvatinib or sorafenib in Egyptian patients with unresectable hepatocellular carcinoma: a retrospective real-world study

Ahmed Radwan[1], Wafaa El-Akel[2], Hend Shousha[2], Sahar M Hassany[1], Mohamed Abdelmalek[1], Nariman Zaghloul[1], Sara Mahrous[1], Gamal Esmat[2], Mohamed Hassany[3], Mohamed AbdAllah[4], Ehab F. Moustafa[1]. *[1]Tropical medicine and gastroenterology department, Assiut University, Assiut, Egypt; [2]Endemic medicine department, Cairo University, Cairo, Egypt; [3]Tropical medicine and hepatology research institute, Cairo, Egypt; [4]Medical Research and clinical studies institute, National Research Center, Giza, Egypt*
Email: hendshousha@yahoo.com

Background and aims: Atezolizumab plus Bevacizumab is the typical first-line treatment for unresectable Hepatocellular Carcinoma (HCC), demonstrating superior survival compared to Sorafenib or Lenvatinib in some real-world studies. This study aims to compare the safety and outcomes of Atezolizumab-bevacizumab versus lenvatinib or sorafenib in Egyptian patients with unresectable HCC in a real-world setting.
Method: This retrospective analysis encompassed patients with advanced HCC eligible for systemic therapy and attended the National Committee for Control of Viral Hepatitis clinic at Al-Rajhi Hospital,

Assiut University. Recruitment occurred from June 2022 to March 2025, with follow-up until November 2025. Baseline demographics, tumor characteristics, adverse events (AEs), and tumor response were collected. The primary aim was overall survival (OS).
Results: Our analysis included 107 patients; 40 (37.4%) patients received atezolizumab-bevacizumab, 21 (19.6%) received Lenvatinib while 46 (43%) received Sorafinib. There was no significant difference among the three groups in age, gender distribution, comorbidities, baseline routine laboratory results or tumor characteristics. Chronic hepatitis C was the predominant etiology in all groups (92.5%, 61.9%, 100%, respectively) followed by non-viral etiology (7.5%, 28.6%, 0%). The mean duration of treatment was significantly longer in group 1 (317.75, 153.76, 198.3 days, respectively, $p < 0.01$). Partial response was achieved in 4(10%) in group 1 and none in the other groups. Stable disease was achieved in 12 (30%), 8(38.1%) and 6(13.04%), respectively. By the end of the study 20(50%), 6(28.6%), 38(82.6%) patients died in each group respectively, $p < 0.01$. The Kaplan-Meier survival curve indicated median OS of 16.567, 14.367, and 6.100 months, respectively, $p < 0.01$. The mean time to progression was higher in group 1 (13.651, 9.261, 7.206 months, respectively; p 0.01). Concerning AEs, dermatological manifestations and increased transaminases were more prevalent with Sorafinib. Conversely, there was no notable difference among the groups concerning the hypertension, diarrhea, hepatic decompensation, fatigue, or abdominal pain. In the whole population, Cox Regression for mortality revealed that treatment with atezolizumab-bevacezumab was associated with a longer OS (p 0.002).
Conclusion: Atezolizumab-bevacizumab is associated with significant survival benefit and longer TTP compared to Lenvatinib/Sorafinib with comparable safety.

FRI-253

Tumour seeding with percutaneous radiofrequency ablation of primary hepatocellular carcinoma

Chunpeng Nie[1], Riya Prajapati[1], Marcus Vaska[2], Stephen Congly[1,3,4].
[1]Division of Gastroenterology and Hepatology, Department of Medicine, University of Calgary, Calgary, Canada; [2]Knowledge Resource Service, Alberta Health Services, Calgary, Canada; [3]Division of Medical Transplant, Department of Medicine, University of Calgary, Calgary, Canada; [4]Arnie Charbonneau Cancer Institute, University of Calgary, Calgary, Canada
Email: chunpeng.nie@ucalgary.ca

Background and aims: Percutaneous radiofrequency ablation (RFA) is a common, less invasive alternative to resection of hepatocellular carcinoma (HCC). The risk of tumour seeding along the needle track is of concern given its potential consequences to potential future treatments. A systematic review was conducted to understand the overall risk of tumour seeding with RFA of HCC.
Method: EMBASE, MEDLINE (Ovid), CINAHL and Web of Science were reviewed from inception until July 31, 2024, with the search strategy assisted by a medical librarian. Inclusion criteria were prospective or retrospective human cohort studies including randomized control trials (RCTs) and case series of any percutaneous RFA of a lesion found to be a HCC reporting the rate of tumour seeding. Studies reporting on non-liver cancers were excluded and note was made regarding biopsy concurrent with RFA. Two individuals independently screened abstracts and extracted data; discrepancies were resolved by a third individual.
Results: A total of 1038 unique abstracts were identified. 189 underwent full text review and 52 studies were included in the analysis. All studies were prospective or retrospective cohort studies. The overall rate of tumour seeding was 1.37% (range 0–15.2%) in 11,228 patients. The median length of follow-up was 28 months (range 8–123 months). Internally cooled electrodes (68%) were most common and 37% of studies used multiple types of electrodes. Needle track ablation was performed in 32 studies, with lower rates of seeding (0.97%), compared to avoidance of track ablation in 3 studies (2.77%). Multiple studies suggested subcapsular tumours as a risk factor for seeding. Study quality was assessed via the Newcastle-Ottawa Scale; 29 studies were of good quality, 15 of fair quality, and 8 of poor quality.
Conclusion: The risk of needle track seeding with percutaneous RFA of primary HCC is 1.37% per patient. There is significant heterogeneity in technique and equipment in RFA and there is mixed quality, primarily observational literature regarding the risk of needle track seeding. More study is required to identify risk factors and mitigating techniques for needle track seeding.

FRI-254

To better predict hepatic decompensation during immunotherapy for advanced hepatocellular than with Child-Pugh and ALBI: development and validation of a predictive model, an international multicentre study

Massih Ningarhari[1], Emeline Cailliau[1], Léa Bruges[1], Jean-Charles Nault[2], Nathalie Ganne-Carrié[2], Pierre Nahon[2], Claudia Campani[2,3], Fabio Marra[3], Alessio Mastro[3], Dominique Thabut[4], Sarah Mouri[4], Mathilde Wagner[4], Marie Lequoy[5], Violaine Ozenne[5], Giuliana Amaddeo[6], Hélène Regnault[6], Maria Stella Franzè[6,7], Mohamed Bouattour[8], Maxime Ronot[9], Clemence Hollande[9], Guillaume Lassailly[1], Elise Lemaître[1], Line Carolle Ntandja Wandji[1], Stéphane Cattan[1], Sébastien Dharancy[1], Alexandre Louvet[1], Philippe Mathurin[1], Alain Duhamel[1], Manon Allaire[4]. *[1]CHU Lille, Hopital Huriez, Pole Medico-Chirurgical, Lille, France; [2]APHP, Avicenne, Bobigny, France; [3]University of Firenze, Florence, Italy; [4]APHP, Pitié-Salpêtrière, Paris, France; [5]APHP, Saint-Antoine, Paris, France; [6]APHP, Henri Mondor, Créteil, France; [7]University of Messina, Messina, Italy; [8]AP-HP, Hôpital Beaujon, Liver Cancer and Innovative Therapy, CLICHY, France; [9]APHP, Beaujon, Clichy, France*
Email: massih.ningarhari@chu-lille.fr

Background and aims: Hepatic decompensation impacts outcomes of patients with hepatocellular carcinoma (HCC) treated with immunotherapy. Identification of at-risk patients is crucial. The Child-Pugh (CPS) and ALBI scores have limitations for such purpose.
Method: Prospectively collected data of patients without baseline decompensation treated with Atezolizumab-Bevacizumab for advanced HCC were analysed for clinical decompensation event (CDE) (overt ascites, variceal (EV) bleeding, encephalopathy, and/or jaundice) as a primary endpoint, censored at 2 years. Among 12 candidate variables, in a multivariate Fine & Gray model considering death and end of treatment (+28 days) as competing events, stepwise downward selection was applied in a discovery cohort (DC, n = 448, missing data imputed using fully conditional specification, m = 20) and externally validated (VC, n = 346). Calibration and discriminant performances were compared to CPS and ALBI using Harrell's c adjusted for competing risks. Association with overall survival (OS) was tested using a Cox proportional hazards model.
Results: In the DC (cirrhosis 79%, BCLC-C 73%, CPS-B 14%, ALBI 2/3 67%, grade 2/3 EV 25%, grade 1 ascites 17%, median time on treatment 7.6 months (IQR: 3.3–16.6)), CDE occurred in n = 133 (cumulative incidence at 2 years 30.4%). Five variables were retained for the new model: ALBI grade (subhazard-ratio (sHR) = 2.00 [95% confidence interval : 1.25–3.21] for 2 vs. 1; sHR = 2.77 [95% CI: 1.30–5.87] for 3 vs. 1), grade 2/3 EV (sHR = 2.46 [95% CI: 1.62–3.73]), past history of CDE (sHR = 1.53 [95% CI: 1.04–2.26]), grade 1 ascites (sHR = 2.02 [95% CI: 1.37–2.97]), and platelet count (sHR per log(G/L) increase = 0.62 [95% CI: 0.45–0.85]). Median Harrell's c was 0.75 (min-max 0.74–0.76) for ALBIPHy vs. 0.57 for CPS vs. 0.62 for ALBI. Median OS was 15.2 months [IQR: 7.1-NR]. The model associated with OS (HR 1.48 [95% CI: 1.26–1.74] per point, $p < 0.001$). Patients stratified into 3 risk groups had increasing rates of discontinuation (5%, 25%, and 38%) and death (5%, 20%, and 30%) without tumor progression. In the VC, Harrell's c reached 0.70 (min-max: 0.69–0.70), and calibration slope 0.81 (min-max: 0.78–0.83).

Conclusion: This new model (ALBI, portal hypertension markers, and history of decompensation) better predicts hepatic decompensation during immunotherapy than CPS or ALBI alone, and could be a valuable tool to identify patients that would benefit the most from hepatology expertise, and a potential stratification factor in future studies.

FRI-255-YI

Sub-stratification of Child-Pugh B patients and dynamic evolution of liver function revealed differential benefit from atezolizumab/bevacizumab in unresectable hepatocellular carcinoma

Anne Victoire Odent[1], Claudia Campani[2], Mohamed Bouattour[3], Yann Touchefeu[4], Victoria Delhoume[4], Olivier Rosmorduc[1], Alina Pascale[1], Jihyun An[5], Han Chu Lee[6], Hélène Regnault[1], Dominique Thabut[1], Giuliana Amaddeo[1], Massih Ningarhari[7], Isabelle Ollivier-Hourmand[8], Chloe Metivier[8], Maxime Ronot[1], Line Carolle Ntandja Wandji[2], Violaine Ozenne[1], Sabrina Sidali[2], Fabio Marra[9], Clemence Hollande[1], Nathalie Ganne[1], Pierre Nahon[1], Jean Marie Peron[10], Marie Lequoy[1], Rohini Sharma[11], Eric Trépo[12], Sarah Mouri[1], Manon Allaire[1], Ju Hyun Shim[6], Jean-Charles Nault[2].

Email: naultjc@gmail.com

Background and aims: We aimed to identify, among patients with advanced hepatocellular carcinoma (HCC) and Child-Pugh B cirrhosis, typically excluded from clinical trials, a subgroup that may benefit from first-line atezolizumab/bevacizumab (A/B).
Method: We conducted an international multicenter study including patients with unresectable HCC treated with first-line A/B between 2020 and 2024 across 12 centers in Europe and Asia. A cohort of Child-Pugh B patients treated with sorafenib served as a control. Baseline clinical, biological, and tumor features were correlated with radiological response, progression-free survival (PFS), and overall survival (OS).
Results: Among 1499 patients with HCC treated by A/B in first line, 246 (16.4%) had Child-Pugh B cirrhosis. Compared with Child–Pugh A patients, Child–Pugh B patients were younger, more often had cirrhosis of alcoholic or hepatitis B viral origin, and had larger tumors with a higher frequency of portal vein tumor thrombosis. The median follow-up was 35.7 months. Within Child-Pugh B, 72% were B7, 21.5% B8, and 6.5% B9; 73% had ALBI grade 2 and 27% grade 3. Median OS and PFS were significantly shorter in Child-Pugh B (8.1 and 5.2 months) versus Child-Pugh A (16.8 and 8.6 months; both $p < 0.001$). Two-year OS was 20% for Child-Pugh B versus 38% for Child-Pugh A. Child-Pugh B patients treated with A/B had longer OS than those treated with sorafenib ($p = 0.002$). In multivariate analysis, chronic hepatitis C (HR = 0.65, CI95% = 0.44–0.95, P = 0.027), presence of extrahepatic metastasis (HR = 1.49, CI95% = 1.10–2.03, P = 0,011) and ALBI grade 3 (HR = 1.54, CI95% = 1.10–2.15, P = 0,012) were independently associated with a high risk of death. A score combining ALBI grade 1/2 and metastatic status identified prognostic subgroups (10.3 vs 7.9 vs 4.2 months; $p < 0.0001$). Improvement from Child pugh B to Child-Pugh A occurred in 31% at the first imaging evaluation. Patients who received recent treatment showed greater improvement in liver function at the first evaluation compared with those treated more than 6 months earlier or never treated (P = 0.04, Cochran–Armitage trend test). Radiological response (HR = 0.58, p = 0.021) and liver function improvement (HR = 0.59, p = 0.006) correlated with reduced mortality using a time-dependent analysis.
Conclusion: Although Child-Pugh B patients have poorer survival, a subgroup, those with ALBI grade 1/2 and no extrahepatic metastasis, can derive meaningful benefit from A/B therapy. Improving underlying liver disease may contribute to better outcomes.

FRI-256

Durable response is associated with long-term survival even in patients with poor hepatic reserve after Atezolizumab plus Bevacizumab: a multicenter 3-year overall survival cohort with a 6-month landmark analysis

Masatsugu Ohara[1], Goki Suda[1], Risako Kohya[1], Yutaka Yasui[2], Kaoru Tsuchiya[2], Masayuki Kurosaki[2], Joji Tani[3], Shinya Maekawa[4], Nobuyuki Enomoto[4], Makoto Chuma[5], Manabu Morimoto[6], Shun Kaneko[7], Mina Nakagawa[7], Yasuhiro Asahina[7], Atsumasa Komori[8], Yuki Kugiyama[8], Jun Ito[9], Sonoe Yoshida[1], Yoshiya Yamamoto[10], Takuya Sho[1], Ren Yamada[11], Shunichi Hosoda[1], Yoshimasa Tokuchi[10], Akimitsu Meno[1], Takashi Kitagataya[1], Naoki Kawagishi[1], Masato Nakai[1], Koji Ogawa[1], Naoya Sakamoto[1].

Email: masatsu-ohara@pop.med.hokudai.ac.jp

Background and aims: Long-term overall survival (OS) after atezolizumab plus bevacizumab (Atez/Bev) for unresectable hepatocellular carcinoma (uHCC) has not been sufficiently characterized in real-world cohorts with mature follow-up beyond 3 years. In addition, the relative prognostic contributions of treatment-induced durable disease control and baseline hepatic reserve should be evaluated while minimizing immortal time bias. We therefore investigated long-term outcomes in a mature 3-year OS cohort and assessed their independent and relative impacts using a 6-month landmark analysis.
Method: This multicenter retrospective study included 257 uHCC patients treated with Atez/Bev between October 2020 and January 2022 and followed for more than 3 years. Durable response was defined as stable disease (SD), partial response (PR), or complete response (CR) maintained for more than 6 months. Overall survival was first described in the entire cohort. To mitigate immortal time bias, a 6-month landmark population was constructed, and multivariable Cox proportional hazards models were fitted including age, AFP, BCLC stage, modified ALBI grade (mALBI 1–2a vs ≥2b), and durable response.
Results: In the entire cohort, the 2- and 3-year OS rates were 39.2% and 25.3%, respectively, reflecting mature long-term observation. Durable response was achieved in 110 patients (42.8%). In the 6-month landmark population (n = 216), durable response was observed in 110 patients (50.9%). Median OS was 12.3 months in patients without durable response and 28.6 months in those with durable response ($P < 0.001$). In the 6-month landmark multivariable Cox model, durable response was the strongest predictor of OS (HR 0.41, 95% CI 0.30–0.57, $P < 0.0001$), exceeding the prognostic impact of preserved hepatic reserve (mALBI 1–2a; HR 0.50, 95% CI 0.37–0.68, $P < 0.0001$). Older age and elevated AFP were also significant predictors of poorer OS, whereas BCLC stage was not. Notably, durable response was associated with improved long-term survival even among patients with poor hepatic reserve (mALBI ≥2b).
Conclusion: In a mature 3-year OS cohort of uHCC treated with Atez/Bev, achieving durable response lasting more than 6 months was more strongly associated with long-term survival than baseline

hepatic reserve. These findings highlight durable response as the principal determinant of long-term benefit from Atez/Bev therapy.

FRI-257

Serum TGF-β1 and IDO1 kinetics for the prediction of clinical outcomes among first-line immunotherapy treated patients with hepatocellular carcinoma

Spyridon Pantzios[1], Polyxeni Nikolakopoulou[2], Orestis Sidiropoulos[1], Antonia Syriha[1], Georgios Zogas[1], Maria-Stella Malatesta[1], Despoina Gyriki[1], Antonios Chatzigeorgiou[2], Ioannis Elefsiniotis[1]. [1]*Academic Department of Internal Medicine-Hepatogastroenterology Unit, General Oncology Hospital of Kifisia "Agioi Anargyroi", National and Kapodistrian University of Athens, Athens, Greece;* [2]*Department of Physiology, Medical School of Athens, National and Kapodistrian University of Athens, Athens, Greece*
Email: spiros_pant@hotmail.com

Background and aims: Though serum immunosuppressive cytokines, such as TGF-β1 and IDO1, play an important role in cancer immunity and patient prognosis, they have been rarely studied as prognostic biomarkers in immunotherapy-treated hepatocellular carcinoma (HCC) patients. The aim of our study was to evaluate the correlation of baseline and on-treatment values of TGF-β1/IDO1 with overall survival (OS) and progression-free survival (PFS) in HCC patients treated with 1st line atezolizumab-bevacizumab (A/B) or tremelimumab-durvalumab (STRIDE).
Method: We retrospectively evaluated 86 immunotherapy-treated HCC patients. The baseline characteristics of all patients were evaluated and baseline and sequential (2 and 4 months of treatment) serum TGF-β1/IDO1 were measured. We compared baseline TGF-β1 and IDO1 median levels according to patients' baseline characteristics and studied their correlation with OS and PFS. We also studied the correlation of the on-treatment change of these values from baseline with OS and PFS.
Results: Patients with cirrhosis and diabetes had significantly lower baseline TGF-β1 ($p = 0.007$ and $p = 0.039$, respectively), as had patients without extrahepatic disease ($p = 0.03$) and within up-to-7 criteria ($p = 0.002$). There was no difference in OS and PFS between patients with low versus high baseline TGF-β1, when median baseline TGF-β1 values was used as cut-off. Patients who had increased serum TGF-β1 in 2 and 4 months of treatment compared to baseline had statistically significantly better OS than those with decreased values (29 vs. 12 months, $p = 0.023$ and 41 vs. 14 months, $p = 0.04$, respectively). Patients without progressive disease (PD, $p = 0.01$) had significantly higher baseline serum IDO1 levels than those with PD, as had those with objective response compared to those without ($p = 0.049$), and patients within ($p = 0.05$), compared to those exceeding up-to-7 criteria. Baseline IDO1 was significantly correlated with PFS after multivariate analysis ($p = 0.015$, HR = 0.615), but not with OS. Patients with higher baseline IDO1 had significantly better PFS than those with lower baseline levels, when median baseline IDO1 was used as cut-off (17.6 vs. 14.6 months, respectively, $p = 0.046$). No correlation of IDO1 change in 2 or 4 months of treatment with OS and PFS was observed.
Conclusion: On-treatment rises in serum TGF-β1 and higher baseline IDO1 emerge as accessible biomarkers for risk stratification and treatment monitoring in first-line A/B or STRIDE-treated HCC patients, a finding that needs prospective validation.

FRI-361

Preoperative transarterial radioembolization is comparable to primary liver resection but shows more favorable outcomes than preoperative transarterial chemoembolization in hepatocellular carcinoma beyond the Milan criteria

Jeayeon Park[1], Yunmi Ko[1], Hyunjae Shin[1], Moon Haeng Hur[1], Yun Bin Lee[1], Eun Ju Cho[1], Jeong-Hoon Lee[1], Su Jong Yu[1], Jung-Hwan Yoon[1], Yoon Jun Kim[1]. [1]*Seoul National University Hospital, Seoul national university college of medicine, Seoul, Korea, Rep. of South*
Email: yoonjun@snu.ac.kr

Background and aims: Resectable hepatocellular carcinoma (HCC) beyond the Milan criteria represents a clinically heterogeneous with variable classification across staging systems. Owing to the increased risk of recurrence and inconsistent guideline recommendations, treatment strategies for this population remain undefined, ranging from primary liver resection to locoregional therapies. With the emerging role of transarterial radioembolization (TARE), we compared the clinical outcomes of primary liver resection, preoperative transarterial chemoembolization (TACE), and preoperative TARE.
Method: We retrospectively reviewed consecutive patients with HCC beyond the Milan criteria who underwent primary liver resection, preoperative TACE, or preoperative TARE at Seoul National University Hospital. The primary endpoint was overall survival (OS), and the secondary endpoint was recurrence-free survival (RFS). Survival outcomes were analyzed using Kaplan–Meier estimates with log-rank tests, and Cox proportional hazards models with inverse probability of treatment weighting (IPTW) were applied to adjust for confounding.
Results: A total of 226 patients were included (primary resection, n = 127; preoperative TACE, n = 52; preoperative TARE, n = 47), with a median follow-up of 37.2 months. After IPTW adjustment, baseline characteristics were well balanced among groups. Median OS was not reached in the primary resection and preoperative TARE groups but was 60.7 months in the preoperative TACE group. Compared with primary resection, preoperative TACE was associated with worse OS (hazard ratio [HR] 3.01; 95% confidence interval [CI] 1.57–5.75; P = 0.004), whereas OS with preoperative TARE was comparable (HR 1.17; 95% CI 0.51–2.70; P = 0.57). Preoperative TARE showed superior OS compared with preoperative TACE (HR 0.40; 95% CI 0.16–0.96; P = 0.04). Similarly, RFS was worse with preoperative TACE than with primary resection (HR 1.80; 95% CI 1.11–2.92; P = 0.02), while RFS with preoperative TARE was comparable to primary resection (HR 0.85; 95% CI 0.49–1.48; P = 0.57).
Conclusion: In patients with resectable HCC beyond the Milan criteria, preoperative TARE was associated with clinical outcomes comparable to those of primary liver resection. In real-world settings where upfront resection is not feasible, preoperative TARE may be considered an alternative treatment strategy.

Email: asier.rabasco@tu-dresden.de

Background and aims: Atezolizumab–Bevacizumab (AtezoBev) is first line standard of care for advanced hepatocellular carcinoma (HCC) requiring systemic treatment. However, approximately 25–30% of patients experience disease progression. We aimed to develop and externally validate baseline non-invasive clinical-biological and imaging-based models to predict disease control (DC) under AtezoBev.
Method: We included 480 patients with unresectable HCC treated with AtezoBev as first-line systemic therapy and no prior liver transplantation from five French centers. Patients were split into development (n = 256) and validation (n = 224) cohorts by center. Tumor response was assessed every 3 months using RECIST 1.1 criteria. DC was defined as absence of progression, including stable disease, partial and complete responses. Abdominal CT scans obtained within 3 months prior to treatment initiation were available for 257 patients (development n = 115, validation n = 152) and used to train and validate a deep-learning (DL) imaging model based on a pretrained CT foundation model. A baseline clinical model was developed using logistic regression with LASSO selection. Performance was assessed using the area under the receiver operating characteristic curve (AUROC) and Brier score.
Results: Median patient age was 67.0 years (87% male). Cirrhosis was present in 74%, 44% had viral infection, alcohol consumption was present in 38% and metabolic syndrome in 36%. Median platelet counts were 171.500/mm^3, median INR was 1.10 and 68% were ALBI grade 2 or higher. Extrahepatic lesions were present in 30%, with 36% showing vascular invasion, 61% being BCLC-C and 59% treatment-naive for HCC (no prior HCC-directed therapy). Median AFP levels were 78.0 ng/mL. 29% showed progressive disease. The DL imaging model was unable to classify DC, with a validation AUROC (median [95% confidence interval]) of 0.46 [0.31–0.58] (Brier: 0.25). The clinical model signature included 7 features: AFP with log-odds ratio (LOR) of −0.80, age (LOR: 0.65), extrahepatic lesion presence (LOR: −1.08), prior HCC treatment (LOR: −1.28), ALBI grade (LOR: −0.10), INR (LOR: 0.50) and platelet counts (LOR: −0.38), showing an AUROC of 0.70 [0.62–0.78] (Brier:0.20) in validation.
Conclusion: A baseline clinical model moderately predicted DC under AtezoBev, outperforming a whole-abdominal DL imaging approach. These findings suggest that readily available clinical parameters provide prognostic value, whereas imaging models may benefit from regional analyses focused on the liver.

FRI-363

A dynamic prognostic model using alpha-fetoprotein and serial hemogram-based inflammatory biomarkers for unresectable hepatocellular carcinoma treated with first-line immunotherapy

Yujie Ran[1], Huanhuan Cao[1,2], Minghui Zhu[1], Yixuan Wang[1], Chunxiu Zhong[1], Kunyuan Wang[1], Hongyan Liu[1], Dingli Liu[1], Huaiyu Chen[1], Jinzhang Chen[1], Yabing Guo[1], Rong Fan[1]. *[1]Department of Infectious Diseases, Nanfang Hospital, Southern Medical University, Guangzhou, China; [2]Department of Infectious Diseases, Dongguan People's Hospital, The Tenth Affiliated Hospital of Southern Medical University, Southern Medical University, Dongguan, China*
Email: rongfansmu@163.com

Background and aims: Immune checkpoint inhibitor (ICI) has improved the prognosis of unresectable hepatocellular carcinoma (HCC) patients, but outcomes vary greatly. We aimed to develop a dynamic risk model integrating baseline clinical features and early longitudinal key serum biomarker trajectories to optimize prognosis estimation in first-line ICI-treated HCC patients.
Method: This multicenter retrospective cohort study enrolled 410 unresectable HCC patients receiving first-line ICIs (training cohort, N = 286; external validation cohort, N = 124), with overall survival (OS) as the primary endpoint. Baseline predictors were selected by LASSO-Cox regression. Longitudinal measurements of alpha-fetoprotein, lymphocyte, neutrophil, monocyte and platelet counts (collected pre- and within 6 months of ICI initiation) were converted into 5 multivariate functional principal-component (MFPC) scores. A joint Cox model integrating baseline factors and MFPC scores was developed and externally validated.
Results: Training and validation cohorts had median follow-ups of 15.0 months (IQR 8.2, 24.6) and 12.2 months (IQR 6.2, 22.8), respectively, with BCLC C stage comprising 74.5% and 64.7% of each cohort. The baseline-only model (albumin, lactate dehydrogenase, neutrophil-to-lymphocyte ratio, tumor numbers >3, and extrahepatic metastasis) yielded an AUC of 0.610 (95%CI 0.497–0.722) at 12 months in validation set. Adding longitudinal MFPC scores significantly improved discriminative performance: the dynamic model yielded time-dependent AUCs of 0.895 (95%CI 0.842–0.949), 0.827 (95%CI 0.759–0.894) and 0.783 (95%CI 0.689–0.877) at 12, 24 and 36 months in the training cohort. External validation confirmed good discriminative ability, with AUCs of 0.803 (95%CI 0.715–0.890), 0.808 (95%CI 0.714–0.902), and 0.832 (95%CI 0.734–0.930) at the same time points. The integrated dynamic model outperformed the baseline-only model and existing clinical scoring systems (e.g., ALBI, mALBI, EZ-ALBI, CRATIFY). Dynamic model-based stratification defined low-, intermediate-, and high-risk groups with markedly distinct median OS: 49.4, 22.1, and 8.1 months in the training cohort ($p < 0.001$), and 40.6, 17.6, and 10.0 months in the validation cohort ($p < 0.001$).
Conclusion: This dynamic model integrating early longitudinal biomarker trajectories significantly enhances prognosis estimation in first-line ICI-treated HCC, offering robust, personalized risk stratification for clinical application.

FRI-364-YI

Hepatic decompensation is driven by underlying liver disease rather than immunotherapy choice in inresectable hepatocellular carcinoma

Email: loudevyrouxel@gmail.com

Background and aims: Immunotherapy combinations have transformed the treatment of HCC, but their effects on hepatic decompensation remain unclear. This project compares the incidence of ascites, hepatic encephalopathy (HE), and variceal bleeding (AVB) under atezolizumab–bevacizumab (Atezobev) versus durvalumab–tremelimumab (DurvaTreme).
Method: This multicenter retrospective study included patients treated with first-line AtezoBev or DurvaTreme. Patients were matched 1:1 using propensity score methods. Hepatic decompensation (defined as the occurrence of ascites, HE, and/or AVB) occurring after treatment initiation and prior to progression (per RECIST 1.1) was compared between the two groups.
Results: Among 1053 patients, 908 received AtezoBev and 145 DurvaTreme. Patients treated with DurvaTreme more frequently had a history of AVB (23% vs. 12%, p = 0.001) and ascites (23% vs. 15%, p = 0.008). After matching, 280 patients were analyzed; in both groups, about 60% were BCLC-C, 35% had vascular invasion, 20% had prior AVB, 24% had prior ascites, 50% had varices, 8% had ascites, 40% received non-selective beta-blockers, 60% were Child-Pugh A, and 24% were ALBI grade 1. After a median follow-up of 20.1 months, OS was similar between patients treated with AtezoBev and DurvaTreme (median OS 20.8 months vs. not reached, p = 0.25). Hepatic decompensation occurred in 27.9% patients treated with AtezoBev and 23.6% patients treated with DurvaTreme (p = 0.49), with a median time to decompensation of 3.47 and 1.97 months (p = 0.02), respectively. AVB was more frequent in the AtezoBev group (13.8% vs. 5.7%, p = 0.03), whereas the incidence of HE and ascites did not differ between groups. Early hepatic decompensation within the first 3 months of treatment, was more frequent in the AtezoBeva group (18.5% vs. 6.4%, p < 0.001). Hepatic decompensation-related death occurred in 13.5% patients in the AtezoBev group and 23.1% patients in the DurvaTreme group (p = 0.31). Only history of ascites (OR 3.37, p = 0.001) was independently associated with hepatic decompensation, but not the type of treatment received.
Conclusion: AtezoBev and DurvaTreme were associated with similar OS, but differed in the pattern of hepatic decompensation, with higher rates of AVB and observed in the AtezoBev group. These differences were largely driven by baseline liver disease severity, particularly a history of ascites, which emerged as the main determinant of decompensation risk, rather than treatment choice itself.

FRI-365
Hepatocellular carcinoma stage, treatment patterns, and survival outcomes in a contemporary multicentre international cohort

Email: e1354047@u.nus.edu

Background and aims: Hepatocellular carcinoma (HCC) remains a major cause of cancer-related mortality globally. The underlying etiologies of HCC and its therapeutic approaches have evolved substantially; however, data on how these shifts have influenced the Barcelona Clinic Liver Cancer (BCLC) stage at diagnosis, treatment patterns, and patient survival are limited.
Method: We performed a large, retrospective, multicenter cohort study including 2887 adults (75.8% male) diagnosed with HCC across ten tertiary liver centers in Asia, Oceania, and North America. Survival outcomes were compared using restricted mean survival time (RMST).
Results: The median age of the cohort was 64 years (IQR 57–73), and 83.1% were of Asian ethnicity. The proportion of patients with hepatitis C virus–related HCC decreased over time (28.82% in 2005–2014 vs. 13.46% in 2015–2024, p < 0.001), whereas HCC associated with metabolic dysfunction–related steatohepatitis increased (24.75% vs. 27.19%, p = 0.001). The distribution of BCLC stages at diagnosis remained stable, with 62.66% at stage 0/A, 18.43% at stage B, and 18.91% at stage C (p = 0.122). Regarding treatment, 49% received therapy with curative intent, 36.9% received non-curative interventions, and 14.0% received supportive care. Notably, curative treatments were administered less frequently over time (57.8% in 2005–2014 vs. 46.3% in 2015–2024, p < 0.001). Survival rates improved across the study period, with 1-, 3-, and 5-year survival rising from 90.7%, 77.7%, and 68.4% (2005–2014) to 90.7%, 81.0%, and 74.7% (2015–2024, p < 0.001).
Conclusion: Despite improvements in overall survival for HCC, the proportion of patients diagnosed at an early BCLC stage has not increased, and the use of curative therapies has declined. These findings highlight the need for enhanced strategies to facilitate early detection of HCC.

FRI-366
Differential therapeutic effectiveness of atezolizumab plus bevacizumab in unresectable HCC by chronic hepatitis B viral activity
Yunmi Ko[1], Hyunjae Shin[1], Jeong-Hoon Lee[1], Byeong Geun Song[2], Moon Haeng Hur[1], Youngsu Park[3], Jeayeon Park[1], Yuri Cho[3], Yun Bin Lee[1], Eun Ju Cho[1], Bo Hyun Kim[3], Su Jong Yu[2], Dong Hyun Sinn[2], Yoon Jun Kim[1], Jung-Hwan Yoon[1]. *[1]Seoul National University Hospital, Seoul, Korea, Rep. of South; [2]Samsung Medical Center, Seoul, Korea, Rep. of South; [3]National Cancer Center, Goyang, Korea, Rep. of South*
Email: yhstella@gmail.com

Background and aims: Atezolizumab plus bevacizumab (Atezo/Bev) is recommended as the first-line therapy for unresectable hepatocellular carcinoma (uHCC). Previous studies suggested differential immunotherapy responses between viral and non-viral HCC; however, the mechanisms remained unclear. We investigated the impact of hepatitis B virus (HBV) DNA detectability, an indicator of viral replication activity that may influence the intrahepatic immune microenvironment, on Atezo/Bev outcomes.
Method: This retrospective study included patients with uHCC, initially treated with Atezo/Bev at three hospitals in Korea. Patients were categorized as chronic hepatitis B (CHB) with undetectable HBV DNA (CHB/undetectable-DNA), CHB with detectable HBV DNA (CHB/detectable-DNA), or non-viral. Primary and secondary outcomes were progression-free survival (PFS) and overall survival (OS).

Results: We included 549 consecutive patients: CHB/undetectable-DNA (n = 216), CHB/detectable-DNA (n = 171), and non-viral groups (n = 162). After propensity score matching, baseline characteristics were well-balanced. CHB/undetectable-DNA group had significantly longer PFS than both CHB/detectable-DNA (hazard ratio [HR] = 0.66, 95% confidence interval [CI] = 0.44–0.98, *P* = 0.04) and non-viral groups (HR = 0.61, 95% CI = 0.37–0.98, *P* = 0.048). PFS did not differ between CHB/detectable and non-viral groups (HR = 1.28, 95% CI = 0.86–1.91, *P* = 0.23). CHB/detectable-DNA group showed significantly shorter OS than both CHB/undetectable-DNA (HR = 1.75, 95% CI = 1.04–2.94, *P* = 0.03) and non-viral groups (HR = 2.48, 95% CI = 1.35–4.52, *P* = 0.003). OS was comparable between CHB/undetectable-DNA and non-viral groups (HR = 0.79, 95% CI = 0.34–1.84, *P* = 0.58).
Conclusion: Undetectable HBV DNA was associated with longer PFS and OS than detectable HBV DNA in CHB patients with uHCC receiving first-line Atezo/Bev. These findings suggest that HBV DNA detectability may negatively influence immunotherapy outcomes. Antiviral treatment may mitigate this effect and improve the therapeutic effectiveness of Atezo/Bev.

FRI-367
Clinical relevance of conversion therapy after atezolizumab plus bevacizumab in hepatocellular carcinoma: a multicenter study

Takuya Sho[1], Goki Suda[1], Tamami Abe[2], Masashi Ninomiya[3], Hidekatsu Kuroda[2], Yoshiyuki Ueno[4], Naoya Sakamoto[1]. [1]*Department of Gastroenterology and Hepatology, Hokkaido University Hospital, Sapporo, Japan;* [2]*Department of Gastroenterology and Hepatology, Iwate Medical University Hospital, Yahaba-cho, Japan;* [3]*Department of Gastroenterology and Hepatology, Tohoku University, Sendai, Japan;* [4]*Faculty of Medicine, Yamagata University, Yamagata, Japan*
Email: shotaku0128@yahoo.co.jp

Background and aims: Atezolizumab plus bevacizumab therapy can enable conversion to curative treatments such as resection or ablation in selected patients with hepatocellular carcinoma (HCC). However, clinical characteristics and predictive factors associated with successful conversion remain unclear. This study aimed to clarify the clinical relevance of conversion therapy following atezolizumab–bevacizumab and to identify factors associated with conversion.
Method: This multicenter study included patients with HCC who received atezolizumab–bevacizumab across 16 institutions. Outcomes included objective response rate, progression-free survival, overall survival, and rates of conversion therapy, clinical complete response, and drug-free status. Factors associated with conversion were assessed using multivariable analyses. Liver function was evaluated using the modified albumin–bilirubin grade.
Results: A total of 692 patients were enrolled (median follow-up, 14.2 months; median age, 72 years). At baseline, 58.6% had modified albumin–bilirubin grade 1–2a, and 41.9% had Barcelona Clinic Liver Cancer stage B disease. Portal vein tumor thrombosis and extrahepatic spread were present in 27.9% and 37.4%, respectively. The objective response rate was 31.2% by Response Evaluation Criteria in Solid Tumors and 42.6% by modified RECIST. Median progression-free survival and overall survival were 7.1 months and 21.1 months, respectively. Conversion therapy, clinical complete response, and drug-free status were achieved in 4.0%, 6.6%, and 5.1% of patients. In advanced-stage disease, patients without intrahepatic tumors showed higher rates of clinical complete response (16.4% vs 4.3%, p = 0.002) and drug-free status (10.9% vs 3.2%, p = 0.019). Overall survival was significantly longer in the conversion group than in the non-conversion group (median not reached vs 19.9 months, p < 0.001). Multivariable analysis identified baseline modified albumin–bilirubin grade 1–2a, ≥75% maximum reduction in AFP from baseline during treatment, and objective response by modified RECIST at initial evaluation as factors associated with conversion.
Conclusion: Conversion after atezolizumab–bevacizumab therapy was associated with favorable survival outcomes, higher rates of clinical complete response and drug-free status, and preserved liver function. Conversion therapy may be considered in patients with preserved baseline liver function and an early favorable tumor response.

FRI-368
Cytokeratin 19 expression stratifies outcomes with hepatic arterial infusion chemotherapy but not atezolizumab plus bevacizumab in advanced hepatocellular carcinoma

Kwon Yong Tak[1], Keungmo Yang[1], Hee Sun Cho[1], Ji Won Han[1], Suho Kim[2], Jung Suk Oh[2], Jeong Won Jang[1], Pil Soo Sung[1]. [1]*Division of Gastroenterology and Hepatology, Department of Internal Medicine, Seoul St Mary's Hospital, The Catholic University of Korea, Seoul, Korea, Rep. of South;* [2]*Department of Radiology, Seoul St Mary's Hospital, The Catholic University of Korea, Seoul, Korea, Rep. of South*
Email: eworldcupzps@naver.com

Background and aims: Cytokeratin 19 (CK19)-positive hepatocellular carcinoma (HCC) exhibits biliary/progenitor features and aggressive biology, raising uncertainty regarding the optimal therapeutic strategy for this subgroup. We evaluated the prognostic and predictive value of CK19 expression according to treatment modality in patients with advanced HCC treated with hepatic arterial infusion chemotherapy (HAIC) or atezolizumab plus bevacizumab.
Method: We retrospectively analysed consecutive patients with advanced HCC who received atezolizumab plus bevacizumab or HAIC between January 2020 and July 2025. Only patients with available tumour biopsy and immunohistochemical assessment of CK19 were included. Overall survival (OS) and progression-free survival (PFS) were compared by CK19 status within each treatment group using Kaplan-Meier analysis and log-rank testing. Objective response rate (ORR), including overall and intrahepatic responses, was evaluated by radiologic assessment, excluding non-evaluable cases. Categorical variables were compared using chi-square tests.
Results: We included 136 patients treated with atezolizumab plus bevacizumab (CK19-positive n = 95; CK19-negative n = 41; median follow-up 8.7 months) and 101 treated with HAIC (CK19-positive n = 36; CK19-negative n = 65; median follow-up 7.4 months). In the atezolizumab plus bevacizumab group, OS and PFS did not differ by CK19 status (OS p = 0.3643; PFS p = 0.8144), and ORR was similar for both overall (p = 0.8264) and intrahepatic responses (p = 0.7889). In contrast, in the HAIC group, CK19-positive tumours showed improved OS and PFS compared with CK19-negative tumours (OS p = 0.0365; PFS p < 0.0001). ORR was higher in CK19-positive than CK19-negative tumours after HAIC for both overall response (41.7% vs 19.4%, p = 0.0316) and intrahepatic response (47.2% vs 22.6%, p = 0.0213).
Conclusion: CK19 expression identifies a subgroup of advanced HCC with differential outcomes following HAIC, whereas outcomes with atezolizumab plus bevacizumab were not stratified by CK19 status. CK19 assessment may support biomarker-informed selection of HAIC in advanced HCC, warranting prospective validation.

FRI-369-YI
Recurrence patterns and post-recurrence survival after curative resection for hepatocellular carcinoma: a Milan criteria–based stratification

Chi-Ping Tan[1], I-Cheng Lee[1,2], Romeo Kuo-Cheng Wu[1,3], Gar-Yang Chau[4], Jiing-Chyuan Luo[1,2], Yi-Hsiang Huang[1,2,5,6]. [1]*Division of Gastroenterology and Hepatology, Department of Medicine, Taipei Veterans General Hospital, Taipei, Taiwan;* [2]*School of Medicine, College of Medicine, National Yang Ming Chiao Tung University, Taipei, Taiwan;* [3]*Division of Gastroenterology and Hepatology, Department of Medicine, Keelung Hospital, Ministry of Health and Welfare, Keelung, Taiwan;* [4]*Department of Surgery, Taipei Veterans General Hospital, Taipei, Taiwan;* [5]*Institute of Clinical Medicine, National Yang Ming Chiao Tung University, Taipei, Taiwan;* [6]*Department of Medical Research, Taipei Veterans General Hospital, Taipei, Taiwan*
Email: iclee@vghtpe.gov.tw

Background and aims: Despite curative resection, hepatocellular carcinoma (HCC) is associated with a high recurrence rate. However, recurrence patterns and long-term post-recurrence survival (PRS) remain incompletely characterized. This study aimed to delineate recurrence patterns and identify prognostic factors influencing PRS following curative resection for HCC.
Method: We retrospectively analyzed 1813 patients who underwent curative resection for HCC between 2007 and 2023. Recurrence patterns, post-recurrence treatments, and factors associated with PRS were evaluated, with stratification according to recurrence within or beyond the Milan criteria.
Results: During a median follow-up of 63.3 months, 906 patients developed HCC recurrence, of whom 61.0% and 39.0% experienced recurrence within and beyond the Milan criteria, respectively. Among patients with recurrence within the Milan criteria, independent predictors of poorer PRS included early recurrence (hazard ratio [HR] = 2.103, $p < 0.001$), recurrent tumor size > 2 cm (HR = 1.497, $p = 0.011$), multiple recurrent tumors (HR = 2.110, $p < 0.001$), AFP > 20 ng/mL (HR = 1.677, $p = 0.001$), and ALBI grade 2–3 (HR = 1.850, $p < 0.001$). For patients with recurrence beyond the Milan criteria, baseline microvascular invasion (HR = 2.348, $p = 0.004$), recurrent macrovascular invasion (HR = 1.620, $p = 0.042$), confluent multinodular or infiltrative-type recurrent tumor morphology (HR = 3.281, $p < 0.001$), AFP > 400 ng/mL (HR = 1.867, $p = 0.001$), ALBI grade 2–3 (HR = 2.130, $p < 0.001$), and diabetes mellitus (HR = 2.016, $p < 0.001$) were independently associated with PRS. Risk scores derived from PRS predictors stratified patients with recurrence within the Milan criteria into three risk groups, with median PRS of 149.6, 68.8, and 33.4 months, respectively ($p < 0.001$). Similarly, patients with recurrence beyond the Milan criteria were stratified into three risk groups with median PRS of 44.8, 18.8, and 4.7 months, respectively ($p < 0.001$).
Conclusion: Post-recurrence survival following curative resection for HCC is strongly influenced by recurrence patterns as well as tumor- and host-related factors. These findings may facilitate individualized post-recurrence management, optimize the timing of referral for salvage liver transplantation, and inform the design of future clinical trials.

FRI-370

Prognostic and predictive value of single-nucleotide polymorphism signature in patients with resected hepatocellular carcinoma: a multicentre retrospective study

Email: wjhuang@jnu.edu.cn

Background and aims: Current prognostic scoring systems based on clinicopathologic variables are inadequate for identifying patients with hepatocellular carcinoma (HCC) who would benefit from adjuvant therapy with atezolizumab plus bevacizumab following surgery. We developed a single-nucleotide polymorphisms (SNP)-based classifier to improv postoperative risk stratification and prediction of adjuvant therapy benefit for these patients.
Method: In this retrospective, multicentre study, we developed a 12-SNP classifier derived from blood-based SNP profiles correlated with recurrence-free survival from 332 patients with resected HCC in training set. We assessed intratumour heterogeneity by analysing two regions of paraffin-embedded specimens from the same tumours in the training set. We validated the classifier's prognostic and predictive performance in an internal testing set (n = 222), two independent external validation sets (n = 250 and n = 304), and TCGA dataset (n = 306). we conducted a nested case-control dataset (n = 388) to evaluate classifier's ability for identifying patients likely to benefit from atezolizumab plus bevacizumab adjuvant therapy.
Results: The twelve-SNP-based classifier demonstrated consistent predictive accuracy in blood samples and two different regions of the training set. The twelve-SNP-based classifier precisely predicted recurrence-free survival of patients in training and four validation sets. In the nested case-control analysis, atezolizumab-bevacizumab adjuvant therapy was associated with improved recurrence-free survival (HR 2.210, 1.246–3.599; $p = 0.0054$) and overall survival (HR 2.870, 1.194–6.900; $p = 0.0184$) in the high-risk subgroup as defined by the twelve-SNP-based classifier. Combining the classifier with clinical risk factors (tumor diameter, number of tumors, vascular invasion, and tumor differentiation) further improved the prognostic stratification.
Conclusion: Our twelve-SNP classifier is a reliable prognostic and predictive tool for disease recurrence in patients with resected HCC. It has the potential to identify patients who would benefit from adjuvant therapy with atezolizumab plus bevacizumab, thereby

aiding in patient counseling and enabling more personalized management of individuals with this disease. Compared to previous predictors, our twelve-SNP-based classifier is not influenced by the technical sources of variation with different platforms in different centers.

FRI-371

CT-derived skeletal muscle mass improves risk stratification in patients undergoing major surgery for perihilar cholangiocarcinoma – a retrospective single center cohort study

Paula Medio Torrubiano[1], Jens Rolinger[1], Ivan Capobianco[1], Alfred Königsrainer[1], André Mihaljevic[1], Silvio Nadalin[1].
[1]*Universitätsklinikum Tübingen, Tübingen, Germany*
Email: jens.rolinger@icloud.com

Background and aims: Perihilar cholangiocarcinoma (PHC) is a rare but aggressive malignancy, with surgical resection as the only potentially curative treatment. Perioperative risk stratification remains challenging. CT-derived muscle indices are widely used as surrogates for sarcopenia, although muscle quantity alone does not fulfil current diagnostic criteria. This study aims to investigate skeletal muscle index (SMI) as a continuous CT-based body composition parameter for perioperative risk stratification.
Method: This retrospective single-center study included patients undergoing major liver resection for suspected perihilar cholangiocarcinoma between 2006 and 2024. Preoperative CT scans were used to quantify skeletal muscle index (SMI) at the L3 level. The primary endpoint was major postoperative complications (Clavien–Dindo ≥III). Secondary endpoints included 90-day mortality, overall survival (OS), and recurrence-free survival (RFS). Multivariable logistic regression was performed using a clinical baseline model including body mass index (BMI), ASA class, and Charlson Comorbidity Index (CCI). Incremental prognostic value of SMI was assessed using likelihood ratio testing and changes in model discrimination (AUC). Associations with OS and RFS were evaluated using Cox regression.
Results: Among 288 surgically explored patients, 184 underwent major liver resection; after exclusion of incomplete imaging, 163 patients were included. Median POS was 27.6 months, median RFS was 14.5 months. Median SMI was 44.8 (range = 19.4–69.6). R0 resection was achieved in 99 patients (60.7%), major postoperative complications occurred in 71 patients (43.6%). The clinical baseline model demonstrated limited discrimination for major complications (AUC 0.588). Addition of continuous CT-derived SMI significantly improved model fit (likelihood ratio $p = 0.007$) and increased discrimination to an AUC of 0.641 ($\Delta AUC = 0.053$). A trend towards BMI-dependent effect modification was observed (SMI × BMI interaction $p = 0.089$). SMI was not associated with 90-day mortality (OR 1.10 per 5-unit increase, $p = 0.460$), OS (HR 1.03, $p = 0.619$), or RFS (HR 0.94, $p = 0.297$).
Conclusion: In line with current literature, CT-derived skeletal muscle mass alone is not suitable to define sarcopenia. However, when interpreted as a continuous body composition parameter, SMI provides meaningful incremental value for perioperative risk stratification beyond established clinical factors.

FRI-372

Percutaneous ablation versus stereotactic body radiotherapy for early-stage hepatocellular carcinoma: a propensity score–matched study

Jules Ventre[1], Armand Abergel[1,2], Benjamin Buchard[1], Baptiste Gleyzolle[3], Emmanuel Buc[1], Constance Hordonneau[1], Clarisse Gaume[1], Antoine Gayard[1], Leon Muti[1], Marie-Charlotte Masson[4], Thomas Guilmoteau[1]. [1]*CHU Clermont-Ferrand, Clermont-Ferrand, France;* [2]*Clermont-Ferrand University Hospital, Clermont-Ferrand, France;* [3]*Centre Jean Perrin, Clermont-Ferrand, France;* [4]*CHU Clermont-Ferrand, Clermont-Ferrand, France*
Email: jventre@chu-clermontferrand.fr

Background and aims: Percutaneous ablation (PA), surgical resection, and liver transplantation are standard treatment options for the treatment of early-stage hepatocellular carcinoma (HCC).
Stereotactic body radiotherapy (SBRT) is not currently regarded as a standard treatment according to the 2022 Barcelona Clinic Liver Cancer (BCLC) recommendations. The aim of this study was to compare PA and SBRT for the treatment of early-stage HCC, with a primary focus on survival outcomes.
Method: This retrospective, bicentric study was conducted at the University Hospital and the Cancer Center both in Clermont-Ferrand. The primary endpoints were overall survival (OS) and progression-free survival (PFS). Secondary endpoints included local tumor control and safety. Propensity score matching was performed to minimize selection bias between treatment groups.
Results: One hundred and forty nine patients were treated with PA and 157 patients with SBRT. Three hundred and forty four lesions were analysed: 175 in the PA group and 169 in the SBRT group. The majority of patients was male (89% in both groups). Patients treated with SBRT were significantly older, with a higher proportion aged over 65 years compared with the PA group (74.6% vs. 60.0%). Liver function was comparable between groups, with most patients classified as Child–Pugh A. After propensity score matching, there was no significant difference in overall survival between the two groups ($p = 0.72$), with a median OS of 40 months in the PA group and 34 months in the SBRT group. Progression-free survival differed significantly between treatments, with a median PFS of 54 months in the PA group and 37 months in the SBRT group. SBRT was associated with significantly improved local tumor control compared with PA, while both treatment modalities demonstrated acceptable safety profiles.
Conclusion: SBRT and PA were associated with similar overall survival in patients with early-stage HCC. While progression-free survival differed between groups, SBRT achieved superior local tumor control with a favorable safety profile. These findings support SBRT as a valuable alternative for patients with technical limitations or contraindications to percutaneous ablation. Further prospective studies are necessary to better define the role of SBRT in the therapeutic strategy for hepatocellular carcinoma.

FRI-377

Comparative efficacy and prognostic analysis of different targeted-immunotherapy regimens in advanced hepatocellular carcinoma

Yan Xu[1], Kai Tan[1], Xiaojun He[1], Xiaoling Hu[2], Shengxiong Jia[1], Xilin Du[1]. [1]*Tangdu Hospital, Fourth Military Medical University, Xi An, China;* [2]*Southern Theater Air Force Hospital, Guang Zhou, China*
Email: xuyan630@126.com

Background and aims: To compare the efficacy of different targeted agents combined with PD-1 inhibitors in patients with hepatocellular carcinoma (HCC) and to identify prognostic factors for overall survival (OS) in a real-world setting.
Method: This retrospective study analyzed 360 patients with advanced HCC receiving combined targeted therapy and immunotherapy (targeted-immunotherapy). Patients were categorized into four groups: lenvatinib plus a PD-1 inhibitor (n = 226), bevacizumab plus a PD-1 inhibitor (n = 73), donafenib plus a PD-1 inhibitor (n = 37), and apatinib plus camrelizumab (n = 24). Treatment response was evaluated using the modified Response Evaluation Criteria in Solid Tumors (mRECIST). Survival analyses, including tests for proportional hazards assumptions and multivariable Cox regression, were performed using the survival package in R. Kaplan-Meier curves were visualized with the survminer and ggplot2 packages.
Results: No statistically significant difference in OS was observed among the four treatment regimens (P = 0.31). Subgroup analyses revealed comparable OS between bevacizumab plus atezolizumab and bevacizumab plus sintilimab (28 months, 95% CI: 20–38 vs. 42 months, 95% CI: 30–47, P = 0.116), as well as between lenvatinib plus

pembrolizumab and lenvatinib plus tislelizumab (27 months, 95% CI: 24–38 vs. 28 months, 95% CI: 22–37, P = 0.693). Underlying hepatitis etiology did not significantly affect OS (P = 0.6873). Patients who achieved an objective response to targeted-immunotherapy had markedly superior median OS compared to non-responders (37 months, 95% CI: 33–48 vs. 24 months, 95% CI: 23–27; P < 0.001). Furthermore, patients who underwent subsequent curative-intent surgery post-treatment showed significantly longer median OS than those who did not (51 months, 95% CI: 30–56 vs. 29 months, 95% CI: 27–32; P = 0.015). The conversion surgery rates did not differ significantly among the major regimens: 10.96% for bevacizumab-based, 9.29% for lenvatinib-based, and 10.53% for donafenib-based combinations.

Conclusion: In this real-world cohort, first-line lenvatinib-, bevacizumab-, and donafenib-based PD-1 inhibitor combinations demonstrated comparable survival outcomes in advanced HCC. Achieving an objective response and successful conversion to curative surgery were independent favorable prognostic factors, highlighting the critical importance of tumor downstaging and surgical eligibility in optimizing long-term survival.

FRI-378

Sequential therapy patterns and prognostic impact of first-line treatment response in unresectable hepatocellular carcinoma patients with failure of Atezolizumab plus Bevacizumab

Ji Won Yang[1,2], Ye Rim Kim[1], Dongman Yu[1], Jihyun An[3], Yeongseok Hwang[1], Han Chu Lee[1], Ju Hyun Shim[1]. *[1]Department of Gastroenterology, Liver Center, Asan Medical Center, University of Ulsan College of Medicine, Seoul, Korea, Rep. of South; [2]Liver Center, Asan Medical Center, University of Ulsan College of Medicine, Seoul, Korea, Rep. of South; [3]Hanyang University Guri Hospital, Hanyang University College of Medicine, Guri, Korea, Rep. of South*
Email: s5854@amc.seoul.kr

Background and aims: Optimal subsequent treatment strategies following first-line Atezolizumab plus bevacizumab (Atezo/Bev) in unresectable hepatocellular carcinoma (HCC) remain unclear, particularly beyond the second-line treatment settings. We evaluated patterns of sequential treatment after Atezo/Bev and examined the impact of both treatment response to the preceding systemic therapy and the type of systemic agents used at each subsequent treatment line on survival outcomes.

Method: In this single-center retrospective cohort study, we analyzed 353 patients with unresectable HCC, who received Atezo/Bev ≥3 cycles (May 2022–December 2023) and underwent subsequent treatment. At each treatment line, overall survival (OS) and progressive-free survival (PFS) were evaluated by type of systemic agents and stratified by the best response to the prior therapy (progressive disease [PD] vs. non-PD groups).

Results: Of the total patients, 307 (87.0%) received second-line systemic therapy, and 279 (90.9%) of them underwent the initial response evaluation. Tyrosine kinase inhibitors (TKIs) constituted most of the second-line therapy (lenvatinib or sorafenib in >80% of the patients). Median OS was comparable between lenvatinib and sorafenib (9.5 vs. 8.3 months; *P = NS*), whereas lenvatinib was significantly associated with longer median PFS (5.3 vs. 2.8 months; *P* < 0.05). Survival outcomes after second-line treatment did not differ between patients achieving PD and non-PD after first-line Atezo/Bev (median OS, 7.8 vs. 9.4 months; and median PFS, 3.7 vs. 4.2 months; both *Ps = NS*). In the third-line settings, TKIs predominated and showed comparable survival outcomes with immune checkpoint inhibitors (ICIs) (median OS and PFS, 6.9 vs. 4.0 months; and 1.7 vs. 1.8 months, respectively; *Ps = NS*). Furthermore, treatment response of second-line systemic treatment showed no significant association with survival outcomes of subsequent therapy (median OS and PFS for PD vs. non-PD groups, 7.4 vs. 6.1 months and 1.8 vs. 1.6 months, respectively; *Ps = NS*).

Conclusion: TKIs were predominant subsequent therapies after first-line Atezo/Bev for HCC, with second-line lenvatinib achieving longer PFS than sorafenib, while survival outcomes were similar between TKIs and ICIs in later-line settings. Survival after subsequent treatment was not significantly influenced by response to prior treatment. Further multi-center prospective studies are warranted to determine the optimal treatment sequence after Atezo/Bev.

FRI-379

Comparison of surgical resection, percutaneous ablation, and transarterial chemoembolization for hepatocellular carcinoma patients with recompensated cirrhosis: a multicenter, retrospective, cohort study

Can Zhang[1], Nijin Wu[2], Hang Zheng[3], Qiqi Liu[4], Ping Lü[1], Mingyue Wang[1], Xinke Wang[1], Tianru Zhang[1], Ping He[1], Zhen Zhang[5], Qiang Zhu[6], Yuemin Feng[1]. *[1]Department of Gastroenterology, Shandong Provincial Hospital Affiliated to Shandong First Medical University, Jinan, Shandong, China; [2]Department of Infectious Diseases, The First Affiliated Hospital of Wenzhou Medical University, Wenzhou, Zhejiang, China; [3]Department of Gastroenterology, The First Affiliated Hospital of Wenzhou Medical University, Wenzhou, Zhejiang, China; [4]Department of Gastroenterology, Shandong Provincial Hospital, Cheeloo College of Medicine, Shandong University, Jinan, Shandong, China; [5]Department of Gastroenterology, The First Affiliated Hospital of Shandong First Medical University & Shandong Provincial Qianfoshan Hospital, Jinan, Shandong, China; [6]Department of Infectious Diseases, Shandong Provincial Hospital Affiliated to Shandong First Medical University, Jinan, Shandong, China*
Email: 2190246001@qq.com

Background and aims: The concept of recompensated cirrhosis was introduced by the Baveno VII consensus in 2021 and was later recognized in the European Association for the Study of Liver (EASL) guidelines in 2023. However, few studies have focused on the treatment strategies for hepatocellular carcinoma (HCC) patients with recompensated cirrhosis. This study compared the clinical efficacy and safety of curative treatments, including surgical resection and percutaneous ablation, versus palliative treatment (transarterial chemoembolization, TACE) in HCC patients with recompensated cirrhosis.

Method: This multicenter retrospective cohort study included 135 patients from three hospitals who were treated between January 1, 2008, and June 30, 2024: 102 received curative treatment (58 surgical resection, 44 percutaneous ablation) and 33 received palliative treatment (TACE). Overall survival (OS), progression-free survival (PFS), and complications were assessed and compared, using inverse probability of treatment weighting (IPTW) and subgroup analyses.

Results: Patients who received curative treatment more often had hepatitis B-related HCC, solitary tumor nodules, smaller tumors, and earlier tumor stages. After IPTW adjustment, baseline characteristics were effectively balanced. The five-year OS rates were 68.3% and 60.1% for the curative and palliative groups, respectively, while the five-year PFS rate was identical (51.0%) in both groups. No statistically significant differences in OS (p = 0.22) or PFS (p = 0.39) were observed between groups. Subgroup analysis indicated that the PFS benefit of curative treatment was more pronounced in patients with lower tumor burden (tumor size < 3 cm, Barcelona Clinic Liver Cancer (BCLC) stage 0/A, single lesion), better liver function (favorable Child–Pugh score), and stable recompensation (duration ≥ 5 years). Within the curative group, surgical resection and percutaneous ablation showed comparable OS (p = 0.83), but surgical resection was associated with significantly better PFS (p = 0.002). The curative group had a significantly higher incidence of complications, including liver dysfunction and electrolyte disturbances.

Conclusion: For HCC patients with recompensated cirrhosis, the OS were comparable between curative treatment group (surgical resection/percutaneous ablation) and palliative treatment group (TACE). Patients with low tumor burden, well-preserved liver

function, and stable recompensation status may achieve better PFS after curative treatments.

FRI-380

AADN score: predicting response to transarterial chemoembolization, sintilimab and lenvatinib in patients with hepatocellular carcinoma

Xue Zhang[1], Liying Ren[1], Shaoping She[1], Dongbo Chen[1], Hongsong Chen[1]. [1]*Peking University Hepatology Institute, Beijing, China*
Email: zxx20010205@163.com

Background and aims: Although the triple therapy of transarterial chemoembolization (TACE) combined with immune checkpoint inhibitors and tyrosine kinase inhibitors is becoming an effective treatment for unresectable hepatocellular carcinoma (uHCC). However, there is still a lack of effective tools for predicting therapeutic effects at present.
Method: Based on multicenter data, this study constructed and validated an AADN score as variables to predict overall survival in patients treated with this combination therapy. This study included 188 uHCC cases (training cohort: n = 101, validation cohort: n = 87) from three different hospitals. who treated with TACE, sintilimab and lenvatinib.
Results: In multivariate analysis, alpha-fetoprotein ≥ 100 ng/mL [hazard ratio (HR) = 2.579, P = 0.010], alkaline phosphatase > 120 U/L, (HR = 2.234, P = 0.021), direct bilirubin > 7.3 μmol/L (HR = 2.931, P = 0.007) and neutrophil to lymphocyte ratio > 2.5 (HR = 3.127, P = 0.006) were identified as independent prognostic factors and were used to establish the AADN score. Kaplan-Meier survival curves and time-dependent receiver operating characteristic curves were used to assess the accuracy of the AADN score, with area under receiver operating characteristic curve values of 0.827 (training cohort, 95% confidence interval: 0.743–0.911) and 0.832 (validation cohort, 95% confidence interval: 0.742–0.923). According to the score, the patients were divided into low-risk, intermediate-risk and highrisk groups. Overall survival and progression-free survival were significantly different between groups.
Conclusion: The AADN score can distinguish the prognostic risk of uHCC patients treated with TACE, sintilimab and lenvatinib, provides a basis for individualized treatment decision-making, and have clinical application prospect.

FRI-381

Inhibition of the renin–angiotensin system does not improve the outcomes of hepatocellular carcinoma treated with atezolizumab–bevacizumab

Email: fabio.marra@unifi.it

Background and aims: Immune checkpoint inhibitor–based combinations (ICIs), including atezolizumab–bevacizumab (AB), have improved outcomes in unresectable HCC, although responses remain heterogeneous. Concomitant medications may modulate treatment efficacy through systemic and tumor microenvironment–mediated effects. Inhibition of the renin–angiotensin system (RAS) has been shown to potentiate the effects of immunotherapy in different solid cancers, acting on angiogenesis, fibrosis, and immune regulation. Nonetheless, the clinical impact of RAS inhibition in patients with HCC receiving ICIs remains controversial.
Method: We conducted a retrospective multicenter analysis of the national ARTE cohort, which includes patients with unresectable HCC treated with A + B, comparing those receiving therapy with angiotensin converting enzyme inhibitors (ACEi) and/or angiotensin receptor blockers (ARB) at treatment initiation with those not exposed. Overall survival (OS), progression-free survival (PFS), objective response rate (ORR), and disease control rate (DCR) were first evaluated using Kaplan–Meier analyses, univariate and multivariate Cox and logistic regression models. Confounding variables were then addressed by propensity score subclassification based on relevant clinical, hepatic, and tumor-related variables, and survival outcomes were subsequently re-assessed.
Results: A total of 538 patients were analyzed. In multivariate analyses, ACEi/ARB use was associated with worse OS (HR 1.29, 95% CI 1.00–1.66; p = 0.05) and a trend toward reduced DCR (OR 0.63, 95% CI 0.39–1.02). No associations were observed for PFS or ORR. After propensity score adjustment, patients receiving ACEi/ARB therapy (n = 182) had a numerically shorter median OS (17.0 vs 19.4 months) compared with non-users (n = 325), although this difference was not significant (p = 0.36).
Conclusion: In a large multicenter cohort of HCC patients treated with AB, concomitant ACEi/ARB therapy did not improve outcomes and was associated with a trend towards of poorer survival.

Background and aims: Current guidelines recommend systematically screening patients with type 2 diabetes (T2D) for MASLD and liver fibrosis. However, data on steatotic liver disease (SLD) in patients with T2D is scarce in the general population. The aim of this study was to assess the prevalence of MASLD, MetALD, ALD, and liver fibrosis severity, in T2D patients in the general population.
Method: We used the LiverScreen prospective cohort (30,199 subjects over 40 years old from nine European countries screened for liver fibrosis (LSM-VCTE >8 kPa). We defined SLD as hepatic steatosis (CAP ≥ 275 dB/m), MASLD as SLD with at least 1 cardiometabolic risk factor (CMRF) and alcohol intake <14 Units/week (U/w) for women, and <21 for men; MetALD as SLD with at least 1 CMRF and alcohol intake ≥14 but <35 U/w for women and ≥21 but <42 U/w for men; ALD as SLD and alcohol intake ≥35 U/w for women and ≥42 U/w for men. Significant fibrosis (SF) was defined as LSM ≥8 kPa, and advanced fibrosis (AF) as LSM ≥12 kPa.
Results: Of the 29,716 subjects (483 with missing data excluded), 9,119 (30.7%) had SLD and 3,087 (10.4%) had T2D (mean age: 64 years; female: 46%; obese: 49%). T2D patients with MASLD did not differ from those without MASLD in terms of age (63 vs. 65 years), gender (45% vs. 47% female), T2D duration (11 vs. 9 years), hypertension (71% vs. 67%), and dyslipidemia (83% vs. 78%), except for the prevalence of obesity (63% vs. 32%). The prevalence of MASLD was significantly higher in T2D patients than in those without T2D (53% vs. 25%; $p < 0.001$). The prevalence of MetALD (2.9% vs. 1.9%, $p < 0.001$) and ALD (0.9% vs. 0.4%, $p < 0.001$) was also higher. In T2D patients with MASLD, the prevalence of SF (17.7% vs. 5.7%, $p < 0.001$) and AF (7.1% vs. 1.4%, $p < 0.001$) was significantly higher than in non-T2D patients. The same was true for MetALD and ALD.
Conclusion: In a large European general population cohort, the prevalence of MASLD was twice as high in patients with type 2 diabetes as in those without, and the prevalence of advanced fibrosis was five times higher. These results underscore the urgent need for the early detection of MASLD and advanced liver fibrosis in patients with type 2 diabetes.

Comparative incidence of end-stage complications in type 2 diabetes reveals a high liver disease burden: nationwide cohort study of 539,914 persons

Hannes Hagström[1,2], Sofia Ullman[1], Juan-Jesus Carrero[3], Soffia Gudbjornsdottir[4], Emil Hagström[5], Daniel Andersson[1,2], Ying Shang[1]. *[1]Karolinska Institutet, Huddinge, Sweden; [2]Karolinska University Hospital, Huddinge, Sweden; [3]Karolinska Institutet-Solna, Solna, Sweden; [4]Gothenburg University, Göteborg, Sweden; [5]Uppsala Universitet, Uppsala, Sweden*
Email: hannes.hagstrom@ki.se

Background and aims: Type 2 diabetes is common in the general population and is associated with several severe organ complications. Most of these complications are actively screened for in routine healthcare. The prevalence of steatotic liver disease in type 2 diabetes is considerable and may lead to cirrhosis, but screening is not adhered to despite being mentioned in guidelines. Here, we estimated and compared the cumulative incidence of the most common end-stage organ complications in a large representative Swedish cohort.
Method: We used data from the Swedish National Diabetes Register, capturing >90% of patients with type 2 diabetes in Sweden to identify patients with type 2 diabetes between 2002 and 2022. This cohort was linked to validated national registers to ascertain severe complications associated with type 2 diabetes: severe retinopathy; end-stage kidney disease; major adverse cardiovascular events; diabetic foot-related outcomes; and major adverse liver outcomes. The event definitions were based on ICD-10 codes, agreed upon by a multi-disciplinary group of experts across different disease areas and designed to represent comparable severity to patients. Incidence rates of outcomes were calculated, and competing risks were considered when estimating the cumulative incidence of outcomes.
Results: We identified 539,914 patients with a first registration in the national diabetes register (median age 63 years, 45% female, median duration of diabetes one year, median BMI 29.9 kg/m2) free of the investigated outcomes at baseline. During follow-up, major adverse cardiovascular events was the most common severe complication with a 5-year cumulative incidence of 11.1%. Major adverse liver outcomes was the second most common complication at five years, with a cumulative incidence of 0.8%, in contrast to diabetic foot-related outcomes (0.65%), severe retinopathy (0.43%) and end-stage kidney disease (0.27%).
Conclusion: This nationwide cohort study found that liver cirrhosis was the second most common end-organ complication in type 2 diabetes within five years from registration in the national diabetes register. The data support initiatives to increase early detection and treatment of pre-cirrhotic liver disease in type 2 diabetes.

Background and aims: MASLD in normal-weight ("lean") individuals may represent a distinct phenotype with unique histology, non-invasive tests (NITs), and outcomes. We evaluated the clinical characteristics and outcomes of lean MASLD in a large multinational cohort.
Method: G-MASLD project includes adults with MASLD, liver biopsy, laboratory, and follow-up data from 41 countries. Lean by BMI (L-BMI) had BMI<25 kg/m^2 (<23 kg/m^2 in Asians) and lean by waist circumference (L-WC) had WC <94/80 cm in men/women (<85/80 cm in Asians). Diagnostic accuracy of FIB-4 and liver stiffness measurement (LSM) for advanced fibrosis (AF, F3-F4) was assessed using ROC curves. Outcomes were all-cause mortality and clinical events (hepatocellular carcinoma, decompensation, transplantation, or death).
Results: Of 18,326 MASLD patients, 6.7% were L-BMI and 6.0% were L-WC. Concordance between lean MASLD definitions was moderate (kappa = 0.41). Prevalence of L-BMI was 11% (L-WC 12%) in MASLD patients enrolled in Asia, 7% (4%) in Europe, 3% (7%) in MENA region, 6% (2%) in Latin America, 3% (2%) in North America. Compared with non-lean MASLD, lean MASLD had fewer metabolic comorbidities, less AF (L-BMI 29% vs. 37%; L-WC 22% vs. 41%), and lower NAS scores with less inflammation and hepatocyte ballooning (all $p < 0.01$). NITs showed mixed patterns: FIB-4 was similar or slightly higher in lean MASLD (L-BMI: 1.77 ± 1.22 vs. 1.54 ± 1.33; L-WC: 1.61 ± 1.49 vs. 1.57 ± 1.29), whereas LSM was lower (L-BMI: 10.1 ± 9.0 vs. 12.6 ± 9.5 kPa; L-WC: 9.3 ± 8.6 vs. 12.7 ± 9.4; all $p < 0.001$). FIB-4 accuracy for AF was reduced in lean MASLD (AUC L-BMI: 0.762 vs. 0.791; L-WC: 0.700 vs. 0.779), while LSM remained reliable (AUC L-BMI: 0.869 vs. 0.831; L-WC: 0.863 vs. 0.836); (all $p < 0.01$). In multivariable models adjusted for country, age, sex, and metabolic factors, lean MASLD by BMI or WC was not independently associated with mortality while AF remained the predictor (aHR 2.10 for all-cause mortality; 3.34 for clinical events; both $p < 0.001$). In lean MASLD, mortality was associated with older age and AF regardless of the definition and regions of the world.
Conclusion: In this multinational cohort, lean MASLD was more common in Asia and presented with milder histologic severity and fewer metabolic risks. FIB-4 underperformed for detecting AF in lean patients, whereas LSM remained accurate. Overall, lean MASLD had outcomes similar to overweight/obese MASLD, with AF rather than the lean status driving the risks of adverse outcomes.

Email: linhuapeng5@163.com

Background and aims: Metabolic dysfunction-associated steatotic liver disease (MASLD) is an increasingly important cause of hepatocellular carcinoma (HCC). Current clinical pathways prioritise non-invasive identification of advanced fibrosis (AF), yet whether AF-based stratification alone is sufficient to guide HCC surveillance, and how HCC prediction scores should be incorporated, remains uncertain.
Method: In a multinational cohort of 16,603 patients with MASLD across the US, Europe and Asia, AF risk was classified using liver stiffness measurement, Fibrosis-4 and guideline-based pathways. HCC incidence across AF strata and the performance of published HCC prediction scores were systematically evaluated, including downstream and longitudinal risk analyses.
Results: Over a median follow-up of 4.3 years, 139 patients developed HCC. Across all frameworks, HCC incidence increased stepwise with AF risk; however, 5-year cumulative incidence in AF high-risk populations ranged from 3.0% to 5.2%, frequently below established surveillance cost-effectiveness thresholds. Among evaluated models, aMAP and the Toronto HCC Risk Index (THRI) demonstrated the most consistent discrimination within AF high-risk strata (C-index 0.75–0.80). Applied downstream of AF stratification, both scores identified subsets of AF high-risk patients with markedly elevated 5-year HCC incidence (>7.5%), while consistently classifying low-risk groups with minimal risk (<0.8%). In contrast, HCC incidence remained below surveillance thresholds in patients at low to moderate AF risk, regardless of score values.

Conclusion: AF-based stratification alone does not reliably identify MASLD patients who clearly warrant HCC surveillance. A guideline recommended AF assessment followed by application of aMAP or THRI in AF high-risk patients more effectively identifies surveillance-eligible subgroups.

An artificial intelligence model to better predict hepatocellular carcinoma risk in patients with metabolic dysfunction-associated steatotic liver disease: a large-scale 20-year cohort study

Ming-Ying Lu[1,2], Pei-Chien Tsai[1], Ming-Lun Yeh[1,2], Chung-Feng Huang[1], Jee-Fu Huang[1], Wan-Long Chuang[1], Ming-Lung Yu[1,2]. [1]*Hepatobiliary Division, Department of Internal Medicine, Kaohsiung Medical University Hospital, Center of Hepatitis Research, College of Medicine and Center of Metabolic Disorders and Obesity, Kaohsiung Medical University, Kaohsiung, Taiwan;* [2]*Center of Excellence for Metabolic Associated Fatty Liver Disease, National Sun Yat-sen University, Kaohsiung, Taiwan*
Email: fish6069@gmail.com

Background and aims: Metabolic dysfunction-associated steatotic liver disease (MASLD) has gradually replaced viral hepatitis in leading to hepatocellular carcinoma (HCC). The current non-invasive tests for fibrosis assessment, such as fibrosis-4 index (FIB-4) and liver stiffness measurement, provide modest accuracy in HCC risk stratification. We aimed to develop an artificial intelligence (AI)-driven model best stratifying HCC risks among MASLD subjects.
Method: This large-scale, long-term cohort study enrolled 573,581 subjects without viral hepatitis B and C with mean follow-up of 19.0 years. MASLD is defined as hepatic steatosis with at least one of the five cardiometabolic risk factors (n = 175,299). The diagnosis of HCC was recorded in the Catastrophic Illness Certification database of the National Health Insurance. AI is a powerful tool in healthcare. It can capture complex, nonlinear relationships between the variables and HCC. Integrating 18 routine clinical parameters, an eXtreme Gradient Boosting (XGBoost)-based model was developed for HCC risk assessment.
Results: Of 573,581 subjects, 2,472 (0.4%) developed newly onset HCC. Multivariate Cox regression revealed that higher levels of FIB-4, alpha-fetoprotein and direct bilirubin, as well as the presence of MASLD, diabetes, male, smoking, and alcohol consumption, were independent risk factors of HCC. In contrast, higher levels of albumin and total bilirubin significantly correlated to lower HCC risk. The XGBoost model achieved excellent performance, with area under the curve (AUC) values of 0.999 and 0.921 in the training (n = 401,507) and validation datasets (n = 172,074), respectively. When applied to 175,299 MASLD subjects, the model maintained robust predictive accuracy (AUC = 0.971). The AI-MASLD-HCC model stratified MASLD patients into high-, medium-high, medium-low, and low-risk subgroups, with the 25-year cumulative probabilities of HCC being 48.5%, 30.9%, 12.7%, and 0.2% ($p < 0.0001$), with annual incidence of 3.51%, 1.79%, 0.66%, and 0.01%, respectively. The MASLD-HCC AI model can identify 79.3% of HCCs from the high, medium-high, and medium-low risk groups, and outperforms the FIB-4 index, SAFE score, aMAP score, MASLD-HCC score, NAFLD fibrosis score, and HCC-RIFLE score.
Conclusion: A MASLD-HCC AI model was successfully developed to best predict HCC among MASLD subjects and offers more refined and clinically meaningful HCC risk stratification.

TOP-129

A machine learning model for predicting hepatocellular carcinoma in patients with MASLD

Han Ah Lee[1], Young Youn Cho[1], Hyung Joon Kim[1], Seung Up Kim[2], Jeong-Hoon Lee[3]. [1]*Chung-Ang University, Seoul, Korea, Rep. of South;* [2]*Yonsei University College of Medicine, Seoul, Korea, Rep. of South;* [3]*Seoul National University College, Seoul, Korea, Rep. of South*
Email: amelia86@naver.com

Background and aims: The risk of hepatocellular carcinoma (HCC) is significantly elevated in patients with metabolic dysfunction–associated steatotic liver disease (MASLD). This study aimed to develop and validate a machine learning model for predicting HCC in a large, multicenter MASLD cohort.
Method: A total of 18,484 MASLD patients from six Korean hospitals (2001–2022) were included. Patients from Severance Hospital were divided into a training cohort (n = 3,721) and an internal validation cohort (n = 4,370), while patients from the remaining institutions comprised the external validation cohort (n = 10,393). To account for substantial differences in HCC incidence among hospitals, two additional external validation subsets were created. Four machine learning algorithms—gradient boosting machine (GBM), random survival forest (RSF), deep neural network (DNN), and survival support vector machine (surv-SVM)—were developed using 12 variables selected from prior evidence and multivariable Cox regression results. Model performance was compared using the C-index, AUROC, AUPRC, sensitivity, specificity, and F1 score across all cohorts.
Results: During a median follow-up of 51.6 months, 357 HCC events occurred (incidence: 0.45 per 100 person-years). GBM demonstrated the strongest performance in the training cohort (C-index 0.95, AUROC 0.98, AUPRC 0.36), with well-balanced sensitivity (0.93) and specificity (0.97). Internal validation confirmed stable performance (C-index 0.90, AUROC 0.89, AUPRC 0.19), outperforming RSF and the Cox-based scoring model. External validation sets 1–3 consistently supported the robustness of GBM, with AUROCs ranging from 0.83 to 0.89, C-indices from 0.82 to 0.88, and AUPRCs from 0.19 to 0.25, indicating superior discrimination in imbalanced data. SHAP analysis identified liver cirrhosis, age, diabetes, LDL-cholesterol, and anti-hypertensive medication use as major contributors to increased HCC risk, while higher platelet count and albumin were associated with decreased risk.
Conclusion: This multicenter study developed and validated a GBM-based machine learning model using 12 readily available clinical variables for predicting HCC in MASLD patients. The model demonstrated consistently strong performance across internal and multiple external validation cohorts, exceeding that of traditional Cox-based approaches. External validation in non-Korean populations and prospective evaluation of clinical utility remain necessary.

THU-085

Metabolic dysfunction-associated steatotic liver disease in Europe: latest insight into disease incidence and burden

Ahmed Abdulelah[1]. [1]*St George's University Hospitals NHS Foundation Trust, London, United Kingdom*
Email: ahmadalhassani99@gmail.com

Background and aims: Metabolic dysfunction-associated steatotic liver disease (MASLD) is the most prevalent aetiology of liver disease in the developed countries and imposes a significant health and socioeconomic burden. Therefore, evaluating the temporal trends in the incidence and burden, which is measured through evaluation of disability-adjusted life years (DALY), is of paramount significance as it enables risk stratification and implementation of targeted policy measures.
Method: Data including the age-standardised incidence rate (ASIR) and the age-standardised DALY rate (ASDR) of MASLD for Europe (Central Europe, Western Europe, and Eastern Europe) for the period 1990–2023 were retrieved from the Global Burden of Disease database to evaluate the temporal trends in disease incidence and burden. Joinpoint analysis was performed to calculate the Annual Percent Change (APC) and the Average Annual Percent Change (AAPC).
Results: Over a span of 3 decades, an estimated total of 112,355,332 MASLD cases with a male predominance of 55.6% were reported across Europe. Western Europe accounted for 50.0% of cases, followed by Eastern Europe which accounted for 32.4% of the cases, and Central

Europe which accounted for 17.6% of cases. A statistically significant incline in MASLD ASIR was observed across the 3 European regions with Western Europe encountering the highest incline (AAPC 0.66, 95%CI 0.65 to 0.67, p < 0.001), followed by Eastern Europe (AAPC 0.36, 95%CI 0.35 to 0.36, p < 0.001) and Central Europe (AAPC 0.34, 95%CI 0.31 to 0.35, p < 0.001). Stratification by gender revealed identical trends with females generally experiencing higher degrees of incline in the ASIR across the 3 regions in comparison to males. Interestingly, a variation in the temporal trends in MASLD ASDR was observed across the 3 regions. Western Europe experienced a statistically significant decline in the ASDR with an AAPC of –0.45 (95%CI –0.53 to –0.38, p < 0.001). In contrast, Central Europe and Eastern Europe encountered a statistically significant incline in MASLD burden with the latter experiencing a higher degree of incline (AAPC 3.59, 95%CI 3.46 to 3.72, p < 0.001).
Conclusion: Overall, Europe has experienced a significant increase in the incidence of MASLD across all of its regions coupled with a prominent increase in disease burden in Eastern and Central Europe while Western Europe experienced a decline in disease burden. These findings mandate prompt recognition and intervention to tackle the associated disease burden.

THU-086
Prevalence, characteristics and clinical outcomes for metabolic dysfunction–associated steatohepatitis and metabolic dysfunction–associated steatotic liver disease in the United Kingdom: a clinical practice research datalink study

Margherita Bortolini[1], Chalini Lankage[1], Johnny Lau[2], Joe Hollinghurst[2], Kushala Abeysekera[3]. [1]*Novo Nordisk Ltd., London, United Kingdom;* [2]*Health Economics and Outcomes Research Ltd., Cardiff, United Kingdom;* [3]*University of Bristol, Bristol, United Kingdom*
Email: mgfb@novonordisk.com

Background and aims: Metabolic dysfunction–associated steatotic liver disease (MASLD) and metabolic dysfunction–associated steatohepatitis (MASH) are common causes of chronic liver disease, associated with cardiometabolic morbidity and mortality. We aimed to estimate prevalence of MASH, MASLD, and "high-likelihood of MASH" in the UK, whilst describing characteristics and clinical outcomes for each cohort.
Method: Adults (18+ years) with at least 365-days of registration data from Clinical Practice Research Datalink Aurum and linked secondary care and mortality data in England between 01 January 2008 and 01 January 2023 were eligible. MASH and MASLD were identified via diagnostic codes; "high-likelihood MASH" was defined as: MASLD plus type-2 diabetes (T2D) and/or obesity, FIB-4 >1.3, and repeated elevated alanine aminotransferase. Prevalence, baseline characteristics, and clinical outcomes (liver, cardiovascular, and all-cause mortality (ACM)) were summarised descriptively.
Results: Up to 33,714,568 people were eligible for analysis each year. Prevalence of MASH, MASLD, and "high-likelihood MASH" increased over the study, reaching 0.046% in 2023 (from 0.0056% in 2008), 1.1% (from 0.17%), and 0.018% (from 0.0012%) respectively. In 2023, 1.6% of people with MASLD were deemed "high likelihood MASH" (from 0.7% in 2008). Patients with MASH [MASLD; "high-likelihood MASH"] in 2023 were 60 [58; 65] years, 51% [50%; 56%] were male, 85% [80%; 86%] were of white ethnicity, 33% [32%; 27%] were most deprived (deciles 8–10), and the most common comorbidities were overweight/obesity 76% [74%; 91%], T2D 51% [32%; 62%], dyslipidaemia 38% [30%; 40%], and depression 39% [35%; 34%]. Prevalence of adverse liver, CV and ACM outcomes in patients with MASH were high in the year of diagnosis, at 29%, 15%, and 16% respectively. In MASLD and "high-likelihood MASH" cohorts, 3.8% and 7.1% respectively experienced adverse liver outcomes, 8.0% and 8.1% experienced CV outcomes, and 4.0% and 2.0% died.
Conclusion: Utilising a population database with almost 50% coverage, we provide recent population-level estimates of MASH/MASLD prevalence in the UK but speculate this substantially underestimates true burden due to changes in coding practices. Patients across the MASLD spectrum are at significant risk of adverse liver and CV outcomes following diagnosis. Accurate coding initiatives are required to identify patients who would benefit from early management and cardiometabolic risk improvement.

THU-087
Liver metabolic stress and fibrosis modify APOE ε4–associated cognitive vulnerability and amyloid burden

Young Hyeon Ahn[1], Sung-Hoon Yoon[2]. [1]*Department of Gastroenterology, Soonchunhyang University Cheonan Hospital, Cheonan-si, Korea, Rep. of South;* [2]*Department of Psychiatry, Wonkwang University Hospital, Iksan-si, Korea, Rep. of South*
Email: ysh92614@naver.com

Background and aims: Metabolic liver stress is increasingly recognised as a systemic condition with extrahepatic consequences, including neurodegeneration. We examined whether simple liver–metabolic indices are associated with domain-specific cognition and cortical amyloid burden, and whether these associations are modified by apolipoprotein E (APOE) ε4 status.
Method: We analyzed 583 adults with available metabolic, cognitive, and genetic data. Exposures included the triglyceride–glucose (TyG) index, aspartate aminotransferase/alanine aminotransferase (AST/ALT) ratio, and Fibrosis-4 (FIB-4) stage (low, intermediate, high). Cognitive performance was assessed using global and domain-specific standardized neuropsychological indices. Linear regression models were adjusted for age, sex, education, hypertension, diabetes, and dyslipidemia, with testing for effect modification by APOE ε4 status. In a subset, cortical amyloid burden was quantified using global standardized uptake value ratios from amyloid PET imaging.
Results: Higher liver–metabolic stress, reflected by TyG index and AST/ALT ratio, was associated with poorer global and domain-specific cognitive performance, including lower K-MMSE scores (TyG $\beta \approx -1.5$; 95% CI –2.5 to –0.5; AST/ALT $\beta \approx -1.9$; 95% CI –3.0 to –0.7), independent of cortical amyloid burden. The cognitive impact of fibrosis burden differed by APOE ε4 status: compared with ε4 non-carriers in the low FIB-4 stage, ε4 carriers with intermediate or high FIB-4 stages showed substantially lower global and visuospatial scores. In the amyloid PET subset, APOE ε4 carrier status alone was not associated with amyloid burden, whereas ε4 carriers with high FIB-4 stage exhibited higher cortical amyloid than non-carriers (interaction $\beta \approx 0.21$; 95% CI 0.01–0.40).
Conclusion: Routine liver–metabolic indices captured complementary aspects of late-life cognitive vulnerability. TyG index and AST/ALT ratio were associated with cognitive performance largely independent of amyloid burden, whereas fibrosis burden, assessed by FIB-4 staging, interacted with APOE ε4 status to influence both cognition and cortical amyloid deposition. These findings support a brain–liver–metabolic axis in neurodegenerative risk and identify APOE ε4 carriers with elevated FIB-4 as a high-risk subgroup for enhanced risk stratification and longitudinal monitoring.

THU-089
Liver disease severity in index patients with metabolic dysfunction-associated steatotic liver disease predicts the disease in first-degree relatives: a call for targeted screening

Halit Akarca[1], Volkan Yılmaz[2], Dilara Turan Gökçe[2], Rıfat Aydın[1], Elif Başarır[1], Özge Koç[2], Esra Tunc[3], Zeynep Melekoğlu Ellik[2], Mesut Gumussoy[2], Hale Gokcan[2], Ramazan Idilman[2]. [1]*Ankara university school of medicine, department of internal medicine, Ankara, Türkiye;* [2]*Ankara university school of medicine, department of gastroenterology, Ankara, Türkiye;* [3]*Ankara university institution of hepatology, Ankara, Türkiye*
Email: idilman@medicine.ankara.edu.tr

Background and aims: Family screening for metabolic dysfunction-associated steatotic liver disease (MASLD) is recommended but is frequently inadequately implemented due to absence of clear

prioritization criteria. This study aimed to assess the prevalence of MASLD among first-degree relatives (FDRs) of patients diagnosed with MASLD and to determine whether index-case characteristics may serve as risk indicators to prioritize screening.
Method: This prospective, cross-sectional single-center study included patients with MASLD as index cases along with their asymptomatic first-degree relatives (FDRs). Hepatic steatosis and liver stiffness were assessed via FibroScan (Transient elastography [TE]). Non-invasive fibrosis markers were calculated concurrently on the day of TE assessment.
Results: A total of 209 individuals were evaluated, comprising 96 index cases and 113 FDRs. The median age 61 years for index cases and 37 years for FDRs. The median body mass index was 33.4 kg/m^2 for index cases and 27.8 kg/m^2 for FDRs. The median FIB-4 index was 1.48 (IQR 1.04–2.62) for index cases and 0.59 (IQR 0.42–0.76) for FDRs. The median APRI score was 0.34 (IQR 0.24–0.75) for index cases and 0.20 (IQR 0.16–0.28) for FDRs. The median CAP scores were 313 dB/m (IQR 288–342) for index cases and 279 dB/m (IQR 231–323) for FDRs. The median Liver Stiffness Measurements (LSMs) were 12.1 kPa (IQR 9.9–21.3) for index cases and 5.6 kPa (IQR 4.3–6.6) for FDRs. The burden of undiagnosed MASLD in FDRs was alarmingly high: 66% of FDRs exhibited hepatic steatosis (CAP ≥ 248 dB/m), and 73% of them had advanced steatosis (CAP ≥ 280 dB/m). Notably, 9.7% of FDRs presented advanced liver fibrosis (stiffness > 8.2 kPa). Multivariable analysis showed that the waist circumference (Odds Ratio [OR] = 1.1 (95% CI: 1.043–1.163); p < 0.001), and significant fibrosis detected by TE (> 22.4 kPa) (OR = 5.8 (95% CI: 1.173–28.467); p = 0.031) in the index case were associated with hepatic steatosis in FDRs. Additionally, the waist circumference was associated with advance fibrosis in FDRs (OR = 1.13 (95% CI: 1.05–1.21); p = 0.001).
Conclusion: FDRs of patients with MASLD demonstrate a significant prevalence of the condition. The risk of MASLD in FDRs positively correlates with their anthropometric measures and the disease severity of the index case. These findings underscore the critical importance of initiating screening within families, as high-risk individuals can be identified using straightforward clinical variables.

THU-090-YI
Missed opportunities to diagnose metabolic dysfunction associated and alcohol associated steatotic liver disease after incidental detection in the emergency department
Qusai Al Zureikat[1], Ahmed El Sabagh[1], Jennifer Tran[1], Hanna Blaney[2]. [1]*MedStar Health/Georgetown University-Washington Hospital Center, Washington, DC, United States;* [2]*Virginia Commonwealth University, Richmond, United States*
Email: qzureikat@gmail.com

Background and aims: Steatotic liver disease (SLD) is frequently identified on abdominal imaging in the emergency department (ED), yet remains under-recognized. We evaluated diagnosis and gastroenterology (GI) or hepatology referral following incidental detection of hepatic steatosis in the ED, comparing metabolic dysfunction-associated steatotic liver disease (MASLD) and alcohol associated liver disease (ALD).
Method: We conducted a retrospective cohort study of adults with detected hepatic steatosis on abdominal imaging obtained during ED encounters between 2010 and 2024 in a large healthcare system. Patients were classified as MASLD or ALD based on documented clinical risk factors, including cardiometabolic factors, history of alcohol-associated diagnosis, and patient-reported alcohol use. Primary outcomes were new documentation of SLD or hepatic steatosis and GI referral or visit within 6 months after the ED encounter. Outcomes were compared using unadjusted analyses and adjusted logistic regression.
Results: Among 19,361 patients with detected hepatic steatosis, 15,415 (79.6%) were classified as MASLD and 2,816 (14.5%) as ALD. A new hepatic steatosis diagnosis was documented in 1.84% of MASLD patients compared with 3.02% of ALD patients (odds ratio 1.66, 95% CI 1.30–2.13; p < 0.001). Patients were rarely seen by gastroenterology, with only 0.59% of patients with MASLD and 0.78% with ALD seen within 6 months of the emergency department visit (p = 0.43). Elevated alanine aminotransferase (ALT) was present in 58.4% of ALD patients versus 38.5% of MASLD patients (p < 0.001), while elevated aspartate aminotransferase (AST) was present in 78.8% versus 25.9%, respectively (p < 0.001). Mean fibrosis four index (FIB-4) values were significantly higher in ALD than MASLD (2.94 vs 1.28; p < 0.001).
Conclusion: Patients with suspected MASLD were less likely than those with suspected ALD to receive a formal SLD diagnosis following incidental steatosis detection. Patients with ALD had higher AST, ALT, and FIB-4 than those with MASLD, potentially driving formal diagnosis. However, incidental hepatic steatosis and SLD remains under-recognized. These findings highlight missed opportunities for early identification and risk stratification of SLD and support systematic approaches to improve follow-up after incidental steatosis detection in the ED.

THU-091-YI
Epicardial adipose tissue as a marker of divergent hepatic and cardiovascular trajectories in MASLD: a prospective study
Francesca Alletto[1], Annalisa Cespiati[1,2], Rosa Lombardi[1,2], Felice Cinque[1,2], Giovanna Oberti[1,2], Daniel Smith[1,2], Erika Fatta[1], Edoardo Pulixi[1], Cristina Bertelli[1], Giuseppina Pisano[1], Anna Ludovica Fracanzani[1,2]. [1]*SC Medicina ad Indirizzo Metabolico, Fondazione IRCCS Cà Granda Ospedale Maggiore Policlinico of Milan, Italy; Department of Pathophysiology and Transplantation, University of Milan, Italy, Milan, Italy;* [2]*Department of Pathophysiology and Transplantation, University of Milan, Italy, Milan, Italy*
Email: francesca.alletto@unimi.it

Background and aims: Epicardial adipose tissue (EAT) is a visceral fat depot associated with cardiovascular (CV) risk and liver fibrosis in metabolic dysfunction-associated liver disease (MASLD). Longitudinal changes in EAT and their relationship with the progression of liver damage, CV disease, and skeletal mass remain unclear. Aim: to assess 5-year changes in EAT and their association with changes in liver damage, CV disease, and body composition in MASLD.
Method: We enrolled 158 MASLD patients (59% male, mean age 54 ± 12 years) from Metabolic Liver Disease outpatient clinic at Policlinico Hospital, Milan. EAT was measured by transthoracic echocardiography. Liver damage was assessed by liver stiffness measurement (LSM) and controlled attenuation parameter (CAP) at Fibroscan. CV damage was defined by increased carotid intima-media thickness (cIMT ≥ 0.9 mm) and/or carotid plaques on ultrasound. Skeletal muscle mass index (SMI) was assessed by bioelectrical impedance analysis. All evaluations were performed at baseline and after 5 years.
Results: At baseline, mean BMI was 29.3 ± 4.6 kg/m^2, 84% had increased waist circumference (WC). Mean EAT was 7.5 ± 2.3/8.3 ± 2.7 mm in men/women. Mean LSM was 4.9 kPa and CAP 298 ± 53 dB/m. After 5 years, BMI decreased (BMI −0.5 kg/m^2), while increased WC rose to 90%. EAT increased in both sexes, more markedly in men (EAT 1.1 vs 0.6 mm). Despite stable LSM and reduced CAP (CAP 13 dB/m), CV damage progressed, with higher prevalence of increased cIMT (27% vs 44%) and carotid plaques (34% vs 56%). SMI increased in both sexes (SMI 0.7 kg/m^2 in men and 0.3 kg/m^2 in women). Patients with increased EAT at follow-up showed smaller BMI reduction (−0.15 vs −1 kg/m^2, p = 0.04) and increased cIMT (33% vs 13%, p = 0.03), with a trend toward more carotid plaques (30% vs 23%, p = 0.07), without differences in liver damage or muscle mass. At multivariate analysis adjusted for sex, age, and metabolic comorbidities, increased EAT remained independently associated with smaller BMI reduction (OR 1.24, 95% CI 1.1–1.5, p = 0.02), increased cIMT (OR 4.2, 95% CI 1.5–11.6, p = 0.005), and carotid plaque (OR 1.7, 95% CI 1.2–3.2, p = 0.02).
Conclusion: In MASLD, a longitudinal increase in EAT is independently associated with progression of subclinical CV damage, despite stable liver damage and improvements in overall adiposity, reflecting

a dysfunctional adiposity phenotype. These findings support divergent CV and hepatic trajectories in MASLD, and highlight EAT as a dynamic biomarker of residual cardiometabolic risk.

THU-092

Prevalence and clinical profile of metabolic dysfunction-associated steatotic liver disease in Saudi adults: the GENESIS study

Saleh A. Alqahtani[1,2], Faisal M Sanai[3], Faisal Abaalkhail[4,5], Shadan Almuhaidib[6], Haifa F Alotaibi[6], Mohammed AlGhamdi[7], Waleed S Alomaim[8], Abdulalrhman A Alnifayei[9], Layan A. Email: drsaleh.a.alqahtani@gmail.com

Background and aims: Metabolic dysfunction-associated steatotic liver disease (MASLD) is a leading cause of chronic liver disease worldwide. Despite the high burden of metabolic risk factors in Saudi Arabia, robust population-level data on MASLD prevalence and cardiometabolic characteristics remain limited. We aimed to determine the prevalence of MASLD among Saudi adults and characterize its cardiometabolic risk profile using standardized clinical, biochemical, and imaging-based evaluations.
Method: GENESIS is the first, large-scale, prospective, population-based cohort study of MASLD in Saudi Arabia. Adults attending primary healthcare centers across three major regions were recruited between March 2024 and June 2025; individuals with known chronic liver diseases other than MASLD were excluded. Participants underwent standardized clinical assessment, laboratory testing, and vibration-controlled transient elastography. MASLD was defined as a controlled attenuation parameter (CAP) ≥ 268 dB/m plus ≥ 1 cardiometabolic risk factor (CMRF). Sensitivity analyses used alternative definitions (CAP ≥ 220 dB/m and MASLD liver fat score [MASLD-LFS]). Significant fibrosis (F2–F4) was defined as liver stiffness ≥ 7.1 kPa.
Results: Among 2,983 participants, hepatic steatosis (CAP ≥ 220 dB/m) was observed in 68.8%, MASLD prevalence was 37.2% (age-adjusted: 34.1%) and was higher in males (43.6% vs. 30.9%). Severe steatosis (CAP ≥ 300 dB/m) was observed in 20.7%, while significant fibrosis was detected in 2.9%. Using alternative definitions, MASLD prevalence was 66.1% with CAP ≥ 220 dB/m and 58.6% with MASLD-LFS. Compared with participants without MASLD, those with MASLD were more often male (58.2% vs. 44.7%) and older (mean age: 46.1 vs. 39.5 years) (all $p < 0.001$), with higher adiposity (median BMI: 31.6 vs. 27.0 kg/m^2; mean waist-to-hip ratio: 0.91 vs. 0.86). MASLD was associated with a greater burden of CMRFs (diabetes: 33.4% vs 12.9%; hypertension: 23.0% vs 10.1%; dyslipidemia: 36.5% vs 20.6%), as well as higher median insulin (13.0 vs 8.1 µU/mL) and C-reactive protein levels (3.5 vs 2.1 mg/L) (all $p < 0.001$). Smoking status, coffee consumption, and liver enzymes did not differ between groups.
Conclusion: MASLD affected more than one-third of adults screened, with hepatic steatosis affecting approximately two-thirds. These findings highlight a major public health challenge and underscore the need for population-based prevention and management strategies in Saudi Arabia.

Email: drsaleh.a.alqahtani@gmail.com

Background and aims: Reproductive hormonal transitions influence metabolic health, but their relationship with metabolic dysfunction-associated steatotic liver disease (MASLD) in women remains incompletely characterized. We examined whether menopausal status and menstrual irregularity are associated with hepatic steatosis and fibrosis severity among women enrolled.
Method: We analyzed women enrolled in the large, nationwide, population-based GENESIS cohort in Saudi Arabia and categorized them by menopausal status (pre- vs post-menopause) and menstrual regularity (regular vs irregular cycles), based on self-reported data. Steatosis severity was defined using controlled attenuation parameter (CAP) thresholds: S2 (269–299 dB/m) and S3 (≥ 300 dB/m). Significant fibrosis was defined as liver stiffness ≥ 7.1 kPa. MASLD was defined as CAP ≥ 268 dB/m plus at least one cardiometabolic risk factor.
Results: Among 766 women, 483 (63.1%) were pre-menopausal (median age 36 years) and 283 (36.9%) post-menopausal (median age 58 years). The post-menopausal group had higher body mass index (BMI) (32.0 vs 28.8 kg/m^2), larger waist circumference (99.1 vs 87.4 cm), and higher prevalence of diabetes (55.1% vs 12.2%) and dyslipidemia (57.2% vs 11.2%) (all $p < 0.001$). MASLD prevalence was

higher in this group (49.8% vs 24.8%, p < 0.001). Moderate (S2) and severe (S3) steatosis were more common (22.3% vs 12.2% and 26.9% vs 12.8%, respectively; both p < 0.001), while significant fibrosis was uncommon but was more frequent (4.6% vs 0.8%, p = 0.008). Among 678 women with available menstrual cycle data, 501 (73.9%) reported regular cycles (median age 37 years) and 177 (26.1%) irregular cycles (median age 38 years). Women with irregular cycles had higher BMI (31.1 vs 28.1 kg/m^2), larger waist circumference (92.0 vs 87.0 cm), and higher dyslipidemia prevalence (23.7% vs 13.2%, p = 0.002). MASLD prevalence was higher among those with irregular cycles (33.3% vs 23.0%, p = 0.009), as was severe steatosis (22.6% vs 11.4%, p < 0.001). Fibrosis prevalence was low and similar between groups (p = 0.081).
Conclusion: In this cohort, menopausal status and menstrual irregularity were associated with greater metabolic burden, higher MASLD prevalence, and more severe steatosis, with modest differences in fibrosis. Reproductive transitions may help identify women at increased MASLD risk and support sex-specific risk assessment and targeted screening strategies.

Email: drsaleh.a.alqahtani@gmail.com

Background and aims: Obesity is a major cardiometabolic risk factor that may exacerbate symptoms and reduce health-related quality of life (HRQoL) in metabolic dysfunction-associated steatotic liver disease (MASLD), a highly prevalent condition associated with increased morbidity. Understanding the impact of obesity on symptom burden and HRQoL in MASLD is essential to guide clinical management and targeted interventions. We aimed to evaluate the impact of obesity on symptom burden and HRQoL in adults with MASLD.
Method: Data from adults (≥ 18 years) with MASLD enrolled in the Saudi Arabia cohort of the Global Liver Registry were analyzed. Participants were stratified by obesity status (with obesity, body mass index [BMI] ≥ 30 kg/m^2; without obesity, BMI < 30 kg/m^2). Demographics, comorbidities, and symptom prevalence, including fatigue, anxiety, and hypertension, were collected using standardized patient-reported questionnaires and clinical records. HRQoL was assessed using the Chronic Liver Disease Questionnaire-MASLD (CLDQ-MASLD; 1–7 Likert scale, higher scores indicate better HRQoL), covering six domains: abdominal symptoms, activity, emotion, fatigue, systemic symptoms, and worry.
Results: Among 1,255 participants (median age, 49 years [interquartile ranges (IQR) 30–59]), 637 (50.8%) had obesity, while 618 (49.2%) did not. Participants with obesity were more frequently female (51.3% vs. 32.8%) and had higher prevalence of fatigue (53.7% vs. 43.0%), anxiety (49.1% vs. 40.6%), and hypertension (36.1% vs. 27.3%). Median CLDQ-MASLD scores were significantly lower among participants with obesity for abdominal symptoms (6.0 [4.3–7.0] vs. 6.3 [4.7–7.0], p = 0.010), activity (6.0 [4.8–7.0] vs. 6.4 [5.4–7.0], p < 0.001), fatigue (5.8 [4.5–6.7] vs. 6.0 [5.0–6.8], p = 0.003), systemic symptoms (6.2 [5.3–6.8] vs. 6.5 [5.7–7.0], p < 0.001), and overall CLDQ-MASLD score (6.0 [5.1–6.6] vs. 6.3 [5.5–6.7], p < 0.001). No statistically significant differences were observed for emotion (6.1 [5.1–6.8] vs. 6.2 [5.3–6.8], p = 0.120) or worry (7.0 [6.7–7.0] vs. 7.0 [6.7–7.0], p = 0.515) domains.
Conclusion: In this real-world MASLD cohort from Saudi Arabia, obesity was associated with a higher symptom burden and lower HRQoL, particularly in abdominal symptoms, activity, and fatigue. These findings underscore the need for targeted interventions, including weight management, symptom-focused therapy, and psychosocial support, to improve patient-centered outcomes in MASLD.

THU-095

Socioeconomic, clinical, and quality of life differences by physical activity status among patients with metabolic dysfunction-associated steatotic liver disease and metabolic dysfunction-associated steatohepatitis in Saudi Arabia

Email: drsaleh.a.alqahtani@gmail.com

Background and aims: Regular physical activity (PA) is a core component of the management of metabolic dysfunction-associated steatotic liver disease and steatohepatitis (MASLD/MASH). However, socioeconomic and environmental factors may influence engagement in exercise. We aimed to examine socioeconomic, clinical, and health-related quality of life (HRQoL) differences according to PA status among patients with MASLD/MASH in Saudi Arabia.
Method: We analyzed data from adults with MASLD/MASH enrolled in the Saudi Arabian cohort of the Global Liver Registry. PA was assessed by self-report and categorized as physically active if participants exercised more than 30 minutes at least three times per week (active); all others were classified as having insufficient PA (non-active). Demographic characteristics, cardiometabolic comorbidities, psychosocial symptoms, socioeconomic indicators (education level and financial difficulty), access to exercise facilities, and HRQoL measured using the Chronic Liver Disease Questionnaire (CLDQ) were compared between active and non-active participants.
Results: A total of 1,264 patients were included, of whom 509 (40.3%) reported being physically active. Median age of active participants was 47 years vs 50 years in the non-active group ($p < 0.001$), and males comprised 63.9% of active participants vs 53.4% of non-active participants ($p < 0.001$). Insufficient PA was more frequent among patients with obesity (53.3% vs. 47.0%, $p = 0.029$), diabetes (48.5% vs. 37.1%, $p < 0.001$), and hypertension (35.5% vs. 26.5%, $p = 0.002$). Non-active participants reported higher prevalence of fatigue (55.5% vs. 37.7%, $p < 0.001$), anxiety (49.4% vs. 38.5%, $p < 0.001$), and depression (21.6% vs. 15.3%, $p = 0.007$). Lower educational attainment (primary education or below: 28.9% vs. 18.5%) and greater financial difficulty (reporting a lot of financial difficulty: 5.6% vs. 2.2%) were more common among non-active participants ($p < 0.001$), as was reduced access to a gym or park (81.9% vs. 94.3%, $p < 0.001$). HRQoL was reduced in non-active participants, with lower overall CLDQ scores (median 5.9 vs. 6.5, $p < 0.001$).
Conclusion: In this Saudi Arabian cohort of adults with MASLD/MASH, insufficient PA was associated with lower socioeconomic status, higher cardiometabolic and psychosocial burden, and reduced HRQoL. Encouraging regular PA, particularly among those with socioeconomic and environmental barriers, may help improve patient-centered outcomes in MASLD/MASH.

Email: drsaleh.a.alqahtani@gmail.com

Background and aims: Metabolic dysfunction-associated steatotic liver disease (MASLD) can occur in individuals with normal body mass index (BMI), referred to as lean MASLD, yet its clinical and metabolic profile remains poorly characterized compared with overweight/obese MASLD. We aimed to compare demographic characteristics, metabolic comorbidities, liver disease severity, and systemic inflammation between lean and overweight/obese MASLD groups in a nationwide Saudi cohort.
Method: We analyzed data from adults with MASLD and complete BMI data from the population-based GENESIS cohort in Saudi Arabia. MASLD was defined by controlled attenuation parameter (CAP) ≥ 268 dB/m, measured by transient elastography plus ≥ 1 cardiometabolic risk factor. Participants were categorized as lean MASLD (BMI < 25 kg/m^2) or overweight/obese MASLD (BMI ≥ 25 kg/m^2). We assessed three domains: (1) demographics and anthropometrics, (2) metabolic comorbidities, and (3) liver-related markers, including liver enzymes (alanine aminotransferase [ALT], aspartate aminotransferase [AST]), noninvasive measures of steatosis (CAP) and fibrosis (liver stiffness measurement [LSM], kPa), and systemic inflammation (C-reactive protein [CRP]).
Results: Among 1,110 adults with MASLD, 54 (4.9%) were classified as lean MASLD and 1,056 (95.1%) as overweight/obese MASLD. Median age was 46 years (interquartile range [IQR] 37–55), with 41.8% female. Compared with overweight/obese MASLD, participants with lean MASLD were predominantly male (74.1% vs 57.4%, $p = 0.016$) and tended to be older (median age 51 vs 46 y, $p = 0.052$). Waist-to-hip ratio was similar between groups ($p = 0.675$). Prevalence of diabetes (37.0% vs 33.2%, $p = 0.557$), hypertension (50.0% vs 46.2%, $p = 0.675$), and dyslipidemia (38.9% vs 36.4%, $p = 0.772$) were comparable between lean and overweight/obese MASLD. Significant fibrosis (LSM ≥ 7.1 kPa) was observed in 4 (7.4%) of lean MASLD vs 61 (5.8%) of overweight/obese MASLD ($p = 0.551$). ALT and AST were similar between groups, while CRP was higher in the overweight/obese MASLD group (median 3.8 vs 1.5 mg/L, $p < 0.001$).
Conclusion: Lean MASLD, predominantly affecting males, exhibits similar steatosis, fibrosis burden, and metabolic comorbidity prevalence compared with overweight/obese MASLD despite lower BMI, whereas systemic inflammation was greater in the overweight/obese group. Recognition of lean MASLD is essential for early diagnosis, risk stratification, and optimized clinical management.

Demographic and metabolic predictors of MASLD progression in Saudi Arabia: a retrospective cross-sectional analysis

Amani Alsadoon[1], Khalid A Alswat, Mohammed Kaouache[2], Wadi B. Alonazi[3]. [1]Liver Disease Research Center, College of Medicine, King Saud University, Riyadh, Saudi Arabia; [2]Department of Mathematics and General Sciences, Prince Sultan University, Riyadh, Saudi Arabia; [3]Health Administration Department, College of Business Administration, King Saud University, Riyadh, Saudi Arabia
Email: amalsadon@ksu.edu.sa

Background and aims: Metabolic dysfunction-associated steatotic liver disease (MASLD) represents a major public health challenge in Saudi Arabia and globally. Data on factors associated with advanced MASLD phenotypes in Middle Eastern populations remain limited. This study aimed to identify demographic and metabolic factors

independently associated with advanced MASLD in a large cohort from Saudi Arabia.
Method: This retrospective cross-sectional study analyzed anonymized data from 780 adults with MASLD enrolled in the Saudi Observatory for Liver Diseases (SOLID) registry at the Liver Disease Research Center, King Saud University. MASH and cirrhosis were defined using FibroScan liver stiffness thresholds (≥7.9 kPa and ≥13.0 kPa, respectively) with elevated aminotransferases as a pragmatic noninvasive surrogate. Multivariable logistic regression identified independent predictors, with models mutually adjusted for demographic and metabolic covariates. Discriminative ability was evaluated using ROC curves.
Results: Among 780 patients with MASLD, 6.5% had cirrhosis and 5.8% met criteria for MASH. Male sex was a consistent predictor of advanced disease, with higher odds of cirrhosis (OR = 2.82; 95% CI: 1.36–5.59; p = 0.003) and MASH (OR = 2.38; 95% CI: 1.24–4.53; p = 0.009) compared with females. Increasing age was independently associated with MASH (OR = 1.04 per year; 95% CI: 1.01–1.08; p = 0.012), but not with cirrhosis after adjustment. Type 2 DM showed an inverse association with cirrhosis (OR = 0.31; 95% CI: 0.16–0.65; p = 0.002), possibly reflecting referral bias or earlier disease detection rather than a protective biological effect. Traditional metabolic risk factors, including BMI, triglycerides, HDL cholesterol, and hypertension, were not significant predictors. These associations attenuated after multivariable adjustment. Model discrimination was acceptable to good, with AUC values of 0.77 for cirrhosis and 0.69 for MASH.
Conclusion: In this Saudi clinical cohort, age and male sex were the principal determinants of advanced MASLD, while conventional metabolic risk factors showed limited independent predictive value after adjustment. The inverse association observed between diabetes and cirrhosis likely reflects diagnostic or referral bias. These findings support the need for demographic-focused risk stratification strategies to improve identification of advanced MASLD in regional clinical practice.

Email: klaswat@ksu.edu.sa

Background and aims: Intermittent fasting is increasingly recognized as a metabolic intervention for liver health; yet, evidence on Ramadan diurnal intermittent fasting (RDIF), a culturally mandated dry fast, remains limited in MASLD. We evaluated the effects of RDIF on hepatic steatosis, liver stiffness, metabolic parameters, and lifestyle behaviors in a real-world MASLD cohort.
Method: This prospective observational study enrolled 79 adults with MASLD (median age 47 years; 58.2% male) who undertook RDIF for at least 21 consecutive days during Ramadan. Assessments were conducted 7 days before Ramadan and at the end of Ramadan, including anthropometrics, liver biochemistry, transient elastography (liver stiffness measurement [LSM] and controlled attenuation parameter [CAP]), lipid and glycaemic profiles, 24-hour dietary recall, and movement behaviors (total, light, and moderate-to-vigorous physical activity and sedentary behavior). The total physical activity and sedentary behavior were used to calculate the Physical Activity Sedentary Time Balance Index (PASTBI).
Results: After RDIF, significant reductions in ALT (from 95.3 to 70.0 U/L; p < 0.001), AST (from 55.5 to 46.3 U/L; p < 0.001), and CAP scores (from 317.0 to 280.5 dB/m; p < 0.001) were observed, while LSM showed a non-significant reduction (from 7.1 to 6.1 kPa; p = 0.054). BMI modestly and non-significantly decreased (from 30.8 to 30.0 kg/m^2; p = 0.096), while waist circumference was significantly reduced (from 103.1 to 97.0 cm; p = 0.002). Favorable lipid changes were observed, including reductions in total cholesterol (from 5.1 to 4.9 mmol/L, p = 0.019), triglycerides (from 1.8 to 1.7 mmol/L, p = 0.031), and LDL cholesterol (from 2.9 to 2.8 mmol/L, p = 0.041), though HDL remained stable (p = 0.217). Light and moderate-to-vigorous physical activity significantly decreased (from 37.1 to 21.4 min/day and from 15.9 to 7.3 min/day, respectively; p < 0.001 for both). The PASTBI significantly decreased (from 15.9 to 7.3; p < 0.001), although sedentary behavior remained unchanged (p =).
Conclusion: This is the first prospective study to demonstrate that RDIF was associated with significant improvements in hepatic aminotransferases, hepatic steatosis, central adiposity, and atherogenic lipid profiles in patients with MASLD, with a borderline reduction in LSM, despite a compromised movement behaviors profile. RDIF may represent a culturally rooted lifestyle intervention with potential therapeutic relevance for MASLD.

THU-102
Glucagon-like peptide-1 receptor localization in lipid droplets and M2-like macrophages in MASH

Wataru Ando[1], Mitsuhiro Sugawara[1], Hiroaki Yokomori[2]. *[1]Kitasato University, School of Pharmacy, Kitamoto city, Japan; [2]Kitasato University, School of Pharmacy, Minato-ku, Tokyo, Japan*
Email: andow@pharm.kitasato-u.ac.jp

Background and aims: Over the past three decades, the incidence of metabolic dysfunction–associated fatty liver disease (MAFLD) has greatly increased and has become a burdensome chronic liver disease worldwide. Type 2 diabetes is bidirectionally related to MAFLD. Glucagon-like peptide-1 receptor (GLP-1R) agonists may improve MAFLD; however, the underlying mechanisms have not been elucidated at the morphological level. Therefore, we investigated the cellular localization of GLP-1R in livers of patients with MAFLD using immunohistochemistry (IHC), immunoelectron microscopy (IEM), and Western blot analysis.
Method: Liver biopsy specimens were obtained from three patients with MASH and were compared with those from four histologically normal controls. IHC and IEM were performed using anti-GLP-1R, CD68, and CD138 antibodies. Western blotting of biopsy-derived protein extracts was conducted to quantify GLP-1R expression levels.
Results: IHC showed that GLP-1R localized to the basolateral membranes of hepatocytes with macrovesicular steatosis and was

expressed in monocytes infiltrating hepatic sinusoids in early MAFLD. In advanced MASH, reaction products indicating GLP-1R expression were predominantly observed in proliferating mononuclear cells surrounding inflammatory areas. IEM revealed small clusters of GLP-1R molecules on the peripheral rims of lipid droplets and on the cytoplasmic leaflets of endoplasmic reticulum membranes and intracellular vesicles. Western blot analysis demonstrated markedly higher GLP-1R protein expression in early MASH samples compared with normal controls. Furthermore, dual expression of GLP-1R with CD68 or CD138 was clearly increased in advanced MASH compared with early-stage disease.
Conclusion: GLP-1R is localized within lipid-associated microdomains of steatotic hepatocytes and alternatively activated (M2-like) macrophages. These findings provide mechanistic insight into liver-specific GLP-1 signaling and may inform future development of GLP-1–based therapeutic strategies for MASH.

Email: angelo.armandi@unito.it

Background and aims: A strong evidence on the role of ethnicity for prognostication in MASLD is lacking. Here, we investigated the incidence of liver-related events (LRE) in Asian and Caucasian patients with MASLD.
Method: A retrospective longitudinal study of patients with MASLD and available liver stiffness measurement (LSM) by vibration-controlled transient elastography (VCTE, Fibroscan) at baseline and follow up. Primary outcome was incidence of composite LRE (hepatocellular carcinoma, decompensating events, liver transplant, liver-related death). We built 1:1 Asian-Caucasian matched cohorts using sex-stratified optimal bipartite matching (Hungarian algorithm) on z-standardized age and baseline LSM, imposing a caliper on the Euclidean distance ($\leq$0.1 SD). Cumulative LRE incidence was estimated by Kaplan-Meier method. Uncertainty was quantified via matched-pair bootstrap (R = 1000), resampling pairs with replacement to obtain pointwise 95% confidence bands and empirical distribution of log-rank p values. We applied the same matching and time-to-event framework within (1) strata of metabolic burden (1, $\geq$2 comorbidities including type 2 diabetes [T2DM], hypertension, obesity) and (2) presence/absence of individual metabolic features.
Results: 13,237 patients were included (11,372 Asians and 1,865 Caucasians). After a median follow up time of 51 [IQR 27–78] months, 586 LRE (4.4%) occurred. In Asians and Caucasians, male sex was 59,1% and 56,9% (p = 0,06), median age was 52,0 [40,0–61,0] and 56,0 [47,0–64,0] years (p < 0.05), and baseline LSM was 5.8 [4.6–7.8] and 8.2 [5.9–12.4] kPa (p < 0.05). Delta LSM over time was similar between Asians and Caucasians (p Welch t-test = 0.925), whilst Caucasians had higher prevalence of T2DM, hypertension, and obesity: 41.6% versus 33%, 55% versus 31.2%, 56.1% versus 44.4% (all p < 0.05). Cumulative LRE incidence was similar in Asians and Caucasians (log-rank p = 0.605). Presence of obesity, T2DM, and hypertension did not affect LRE incidence between the two groups, as well as increasing strata of metabolic burden (all log-rank p > 0.05). At within-group comparison, Asian diabetic patients had higher LRE incidence (log-rank p = 0.03). In the subgroup of patients (n = 2,269) with baseline liver biopsy, Caucasians and Asians with advanced fibrosis (F3-F4 stage: 29.7% in Asians and 36.2% in Caucasians) had similar LRE incidence (log-rank p = 0.861).
Conclusion: Ethnicity does not impact on prognosis in patients with MASLD, with relevant implications in terms of treatment allocation and response.

THU-104-YI

Assessing the impact of demographic, metabolic and liver disease severity factors on physical and mental health component scores among a large Canadian MASLD cohort

Elizabeth Baguley[1], Mark Swain[1,2], Wendy Schaufert[2], Juan G Abraldes[3,4], Abdel Aziz Shaheen[1,2]. *[1]University of Calgary, Calgary, Canada; [2]Alberta Health Services, Calgary, Canada; [3]University of Alberta, Edmonton, Canada; [4]Alberta Health Services, Edmonton, Canada*
Email: elizabeth.baguley@ucalgary.ca

Background and aims: The prevalence of metabolic dysfunction-associated steatotic liver disease (MASLD) is increasing worldwide

and is strongly associated with impaired quality of life. However, few studies have assessed physical and mental health component scores using the 29-item Patient-Reported Outcomes Measurement Instrument Survey (PROMIS-29) quality of life assessment tool, particularly in MASLD-specific cohorts. We aimed to characterize baseline physical and mental health component scores among MASLD patients and identify patient characteristics associated with variation in these scores.
Method: Adult patients attending the Calgary MASLD clinic for a consultation visit between January 2018 and August 2025 were included (n = 1,231). Patients with incomplete PROMIS-29 data (n = 215) or current excessive alcohol use (n = 43; >10 and >15 standard drinks/week for women and men, respectively) were excluded. Physical and mental health component t-scores were derived from the PROMIS-29 domains (i.e., pain interference, depression, physical function, ability to participate in social roles/activities, fatigue, anxiety, sleep disturbance, and a single pain intensity item) using factor scoring coefficients. Wilcoxon rank-sum tests compared t-scores by sex (female vs. male), age (≥65 vs. <65 years), diabetes status, body mass index (BMI) (≥30 vs. <30 kg/m^2) and liver stiffness measurements (LSM) by transient elastography (≥8 kPa vs. <8 kPa).
Results: The cohort median age was 59 years (IQR 49–67), and 58.1% were female. Median physical and mental health component t-scores were 47.5 (IQR 39.7–57.1) and 49.8 (IQR 42.2–56.4), respectively. Compared with males, females reported significantly lower physical (−10.4) and mental (−5.5) health t-scores ($p < 0.001$). Lower physical and mental health t-scores were also observed among patients with diabetes (−3.4 and −2.1, respectively; $p < 0.01$), BMI ≥30 kg/m^2 (−9.7 and −5.4; $p < 0.001$), and LSM ≥ 8 kPa (−4.9 and −3.3; $p < 0.001$). Patients aged ≥65 years reported lower physical health t-scores (−2.5; $p = 0.003$) but had higher mental health t-scores (+1.7; $p = 0.028$) compared to <65 years.
Conclusion: Among MASLD patients, female sex, diabetes, high BMI, and greater LSM are associated with worse physical and mental health, while older age is associated with better mental health despite poorer physical health. These findings underscore the need for tailored interventions that account for differences in sex, metabolic health, liver disease severity, and age to improve quality of life in MASLD.

THU-105
Prediction of dementia-related mortality in metabolic dysfunction-associated steatotic liver disease using survival machine-learning models

Sarpong Boateng[1], Guy Nguefang[2], Basile Njei[3]. [1]*Yale New Haven Health-Temple Medical Center, New Haven, United States;* [2]*Texas Tech University, Lubbock, United States;* [3]*Yale University, New Haven, United States*
Email: sarpong1500@gmail.com

Background and aims: Metabolic dysfunction-associated steatotic liver disease (MASLD) is increasingly recognized as a multisystem disorder with important extrahepatic consequences, including neurodegenerative disease. However, existing liver-focused risk scores have limited ability to identify individuals at risk for dementia-related mortality. We aimed to develop and validate survival-based machine-learning models to predict dementia-related death among adults with MASLD.
Method: We conducted a retrospective cohort study using NHANES III data with linked mortality follow-up. Adults meeting MASLD criteria were included. Dementia-related mortality was defined using National Death Index cause-of-death codes. Penalized Cox regression, random survival forests, and gradient-boosted survival models were developed and internally validated using cross-validation and bootstrap resampling. Model discrimination, calibration, and clinical utility were compared with the fibrosis-4 score using concordance indices, reclassification metrics, and decision-curve analysis.
Results: Among 1,774 adults with MASLD and a median follow-up of 16.1 years, 115 dementia-related deaths occurred (6.5%). Survival machine-learning models outperformed conventional approaches and the fibrosis-4 score for risk prediction. The gradient-boosted survival model demonstrated the greatest clinical utility, achieving substantial improvement in net reclassification and consistently higher net benefit across clinically relevant risk thresholds. Waist circumference, diabetes, body mass index, and age were the most influential predictors. Risk stratification isolated all observed dementia-related deaths within a high-risk subgroup with a mortality rate of 19.4%.
Conclusion: Survival-based machine-learning models improve identification of MASLD patients at high risk for dementia-related mortality, highlighting the dominant role of metabolic factors over liver-specific fibrosis markers. These findings support the potential role of individualized risk stratification to guide surveillance and preventive strategies for extrahepatic complications in MASLD.

THU-106
Sex differences in improvement of metabolic dysfunction-associated steatotic liver disease and cardiorespiratory fitness during a residential lifestyle intervention for youth living with obesity

Maarten Buytaert[1], Maxine Vangampelaere[2], Kristof Vandekerckhove[1], Ilse Coomans[1], Ellen Dupont[3], Sander Lefere[2], Ruth de Bruyne[1]. [1]*Ghent University Hospital, Ghent University, Gent, Belgium;* [2]*Ghent University, Ghent, Belgium;* [3]*Zeepreventorium De Haan, De Haan, Belgium*
Email: maarten.buytaert@ugent.be

Background and aims: Cardiopulmonary exercise testing (CPET) evaluates maximal oxygen consumption during exercise (VO_2peak). In children with obesity, VO_2peak per lean mass is the most reflective of cardiorespiratory fitness. The change in physical fitness and its association with metabolic dysfunction-associated steatotic liver disease (MASLD) during a lifestyle intervention is poorly understood.
Method: Adolescents aged 12–18 years with (severe) obesity receiving a structured, combined lifestyle intervention in a residential setting were prospectively followed for 9–12 months. CPET and DEXA were performed at the start and at 9 months. Baseline MASLD was defined as a CAP value > 248 dB/m on FibroScan; resolution of MASLD as a CAP < 248 dB/m at 6 months post start of the intervention program.
Results: 78 adolescents (40 boys) with a median age of 16 years were followed, with 56 adolescents (35 boys) having baseline MASLD. Of those, 17 boys and 12 girls experienced MASLD resolution. Cardiorespiratory fitness (VO_2peak/lean mass) improved for all adolescents, going from a median of 39.3 to 45.1 ml/min/leankg in boys and from 39.7 to 43.0 ml/min/leankg in girls ($p < 0.001$ for both). Importantly, the underlying changes were different between sexes. In boys with MASLD resolution, lean mass was preserved, contrary to boys without resolution (+ 0.6% vs. −7%, $p = 0.007$). For all boys with baseline MASLD, the absolute VO_2peak value increased (median 2686 to 2820 ml/min, $p = 0.022$ for boys with MASLD resolution and 2302 to 2615 ml/min, $p = 0.005$ for boys without MASLD resolution). To the contrary, girls had a minimal, non-significant change in absolute VO_2peak. In girls with MASLD, lean mass decreased during the lifestyle trajectory, both in girls with and without MASLD resolution (−8% vs. −9%). Only girls without MASLD at baseline preserved their lean mass.
Conclusion: Cardiopulmonary fitness ameliorated during a residential lifestyle trajectory, but underlying physiological changes differed between boys and girls. Preservation of lean mass was associated with MASLD resolution in boys. Maximal oxygen uptake increased in boys during the trajectory, contrary to the girls. Girls with MASLD lose more lean mass compared to those without MASLD. This highlights the importance of lean mass preservation during weight loss

trajectories, with concomitant improvement of maximal oxygen uptake.

THU-107

Stronger association and causal link between visceral adipose tissue and metabolic dysfunction-associated steatotic liver disease in women, particularly after menopause

Yutian Cao[1], Xiqiao Zhou[1]. [1]*Jiangsu Province Hospital of Chinese Medicine, Affiliated Hospital of Nanjing University of Chinese Medicine, Nanjing, China*
Email: zhouxiqiao@njucm.edu.cn

Background and aims: The link between visceral adipose tissue (VAT) and metabolic dysfunction-associated steatotic liver disease (MASLD) is well-established, yet notable sex and menopausal disparities remain poorly understood. We hypothesized that the strength and causality of this association differ significantly by sex and menopausal status.
Method: We conducted: (1) a cross-sectional analysis of 7,596 Chinese adults to examine the association between VAT (quantified as visceral fat area and categorized into quartiles) and MASLD severity (steatosis grades S0-S3), with analyses stratified by sex and menopausal status and adjusted for confounders; (2) Mendelian randomization (MR) analyses were conducted using summary-level genome-wide association study (GWAS) data for MASLD (n = 797,878 Europeans) and sex-specific genetic variants linked to VAT (n = 325,153 Europeans). Two-sample MR tested causality, followed by two-step MR to assess VAT's mediating role between sex hormones and MASLD.
Results: Cross-sectional analyses revealed a markedly stronger VAT-MASLD association in women, which escalated dramatically after menopause. The adjusted risk of severe MASLD was highest in postmenopausal women (Q4 vs. Q1, OR = 39.13), followed by premenopausal women (OR = 9.83) and then men (OR = 2.19) (all P < 0.001). MR analyses confirmed a causal effect of VAT on MASLD exclusively in females (OR_1 = 1.77, OR_2 = 3.42, both P < 0.001) across two independent datasets, with no causal effect observed in males. Two-step MR identified VAT as a key mediator, explaining 34–42% of the effect of bioavailable testosterone (BT) and sex hormone-binding globulin (SHBG) on female MASLD risk.
Conclusion: Our findings demonstrate that VAT accumulation is a potent, causal risk factor for MASLD specifically in women, with risk magnified postmenopausally. These findings underscore the necessity for sex- and menopause-specific risk assessment strategies and highlight the potential of targeting BT or SHBG to prevent and treat MASLD in women.

Email: pcarrillo-ibis@us.es

Background and aims: Weight loss is the mainstay treatment for MASLD but may lead to sarcopenia if muscle mass and quality decline. This study aimed to assess longitudinal changes in muscle composition and their relationship with hepatic outcomes during lifestyle interventions in MASLD.
Method: Forty-nine patients with MASLD were prospectively evaluated at 0, 3, and 6 months. Participants were assigned to a home-based lifestyle advice program performing only cardiorespiratory exercises (CG, n = 24) or a supervised physical activity program combining cardiorespiratory and resistance exercises (SPA, n = 25). Assessments included muscle fat (PDFF of erector spinae by MRI), vastus lateralis quality by echography, determining both echogenicity (mean grayscale value) and stiffness (elastography), also physical performance (6-minute walk test) and BIA. Liver steatosis and fibrosis were evaluated by MRI-PDFF and MRE. Statistical analyses were performed with SPSS 22.0.
Results: At baseline, PDFF of the erector spinae correlated positively with age (r = 0.36, p = 0.03, n = 36), BMI (r = 0.38, p = 0.02, n = 36), liver stiffness (liver MRE, r = 0.61, p < 0.01, n = 36), and inversely with ASM/BMI (r = –0.49, p < 0.01, n = 36) and female sex (r = –0.43, p = 0.01, n = 36). In the multivariate linear model, only age (95% CI [–0.06; 0.44], p = 0.01, n = 36) and BMI (95% CI [0.34; 1.26], p < 0.01, n = 36) remained as predictors of muscle PDFF. Muscle echogenicity was associated with both age 95% CI [0.17; 0.82], p < 0.01, n = 49) and liver stiffness (95% CI [–1.4; –0.4], p < 0.01, n = 49. Muscle stiffness correlated with hepatic PDFF (r = 0.39, p = 0.01, n = 36). At 3 months, the SPA group reduced muscle PDFF (–1.2 ± 3.1% vs +1.0 ± 1.9% in CG; p = 0.03, n = 31) and increased muscle echogenicity (–7.35 ± 10% vs 3.07 ± 15.58% p = 0.01, n = 46) and 6MWT (45.2 ± 29.2 m vs vs 22.2 ± 39.4 m, p = 0.03, n = 45). At 6 months, SPA participants showed a marked reduction (–7.6 ± 16.4 vs 3.4 ± 15.6%, p = 0.03, n = 43) in muscle echogenicity.
Conclusion: Supervised physical activity led to early improvements in muscle quality (reductions in intramuscular fat and echogenicity) and performance. Intramuscular fat accumulation was closely related to age, adiposity, and liver stiffness. Age and BMI and age and liver stiffness are, respectively, predictors of intramuscular fat and echogenicity. These findings highlight the importance of integrating resistance training into lifestyle programs to achieve hepatic improvement while preserving muscle integrity in MASLD.

THU-109

Metabolic dysfunction–associated steatotic liver disease predicts hepatic and cardiovascular complications after kidney transplantation

Lourianne Cavalcante[1], Isabel Veloso Alves Pereira[2,3], Vinay Jahagirdar[4], Arun J. Sanyal[4]. [1]*Federal University of Bahia, Hepatology and Gastroenterology, Salvador, Brazil;* [2]*School of Medicine - University of Sao Paulo - Brazil, Sao Paulo, Brazil;* [3]*Hospital das Clínicas HCFMUSP (Lim 07); Departamento de Gastroenterologia e Nutrologia, Faculdade de Medicina, Universidade de São Paulo, São Paulo, Brazil;* [4]*Stravitz-Sanyal Liver Institute - Virginia Commonwealth, VA, USA, Richmond, United States*
Email: Lourianne@gmail.com

Background and aims: Metabolic dysfunction-associated steatotic liver disease (MASLD) is highly prevalent among patients with chronic kidney disease, particularly those with diabetes and hypertension. Its impact on kidney transplant (KT) recipients remains poorly defined. We aimed to characterize the 5-year pre-transplant phenotype and post-transplant outcomes of KT recipients with MASLD.
Method: We conducted a retrospective cohort study using the TriNetX global federated network. Adult KT recipients were stratified

by MASLD status; those with other chronic liver diseases or prior liver transplantation were excluded. Pre-transplant features were analyzed using odds ratios (OR). Post-transplant outcomes were assessed in a propensity score–matched cohort (247 per group) using Kaplan–Meier survival, Cox proportional hazards, and multivariable logistic regression. Sensitivity analyses included E-values and Number Needed to Harm (NNH).

Results: Among 50,327 KT recipients, 1,679 had MASLD. Pre- kidney transplant, MASLD patients exhibited markedly higher odds of advanced liver disease (fibrosis/cirrhosis OR 11.54, portal hypertension OR 9.35, hepatic encephalopathy OR 12.26) and cardiometabolic comorbidities (diabetes OR 2.44, dyslipidemia OR 3.43, ischemic heart disease OR 2.18). In the matched post-transplant cohort, MASLD was independently associated with increased risks of ascites (adjusted OR 2.39, 95% CI 1.15–5.00, p = 0.0195) and major adverse cardiovascular events (MACE) (adjusted OR 2.14, 95% CI 1.28–3.58, p = 0.0074). No significant associations were observed for graft rejection or hemodialysis. Sensitivity analyses confirmed robustness (E-value 4.07 for ascites; 3.69 for MACE). Clinical impact was substantial, with NNH of 17 for ascites and 8 for MACE. MASLD patients showed a significantly higher prevalence of hepatocellular carcinoma before kidney transplantation (OR 4.39, 95% CI 2.29–8.42), while post-transplant HCC incidence was numerically higher (23.5% vs 18.9%) but not statistically significant (HR 1.39, 95% CI 0.85–2.28); no differences were observed for other malignancies.

Conclusion: MASLD defines a high-risk phenotype among KT candidates, characterized by advanced liver disease and metabolic comorbidities. Post-transplant, MASLD independently predicts hepatic decompensation and cardiovascular events, but not graft-related outcomes. These findings support routine MASLD screening and liver fibrosis risk stratification in KT evaluation, and justify tailored post-transplant surveillance strategies.

Email: thisistaliachan@gmail.com

Background and aims: Metabolic dysfunction associated steatotic liver disease (MASLD) frequently coexists with alcohol-related and viral etiologies in real-world practice, yet the impact of these overlapping etiologies on hepatic and extrahepatic outcomes remains unclear. This study aimed to evaluate etiology-specific risks of hepatic decompensation, hepatocellular carcinoma, and mortality in patients with MASLD.

Method: We performed a multicentre longitudinal cohort study, including 1,120 adults with LSM ≥ 10 kPa and MASLD. Patients were classified into MASLD only, MASLD with alcohol-related etiology or MASLD with chronic viral hepatitis. Hepatic decompensation and all-cause mortality were analysed using Fine-Gray competing-risk regression, while hepatocellular carcinoma was analysed using Cox proportional hazards model. Multivariable models were adjusted for age, gender, BMI, smoking status and liver stiffness. Event rates were expressed as incidence rates per 100 person-years.

Results: Among 1,120 patients, 730 (65.2%) had MASLD alone, 54 (4.8%) had MASLD with alcohol-related liver disease and 336 (30.0%) had MASLD with chronic viral hepatitis. Patients with MASLD and alcohol-related liver disease had higher risk of all-cause mortality (adjusted sHR 3.636, 95% 1.059–12.483; p = 0.040) and hepatic-related mortality compared to MASLD only patients (adjusted sHR 8.517, 95% CI 1.242–58.416; p = 0.029). Patients with MASLD and alcohol-related liver disease also had higher incidence rate of hepatic decompensation (4.753 per 100 person years, HR 1.485, 95% CI 0.696–3.316) compared to patients with MASLD only.

Conclusion: In this real-world MASLD cohort, the presence of alcohol-related liver disease was associated with markedly higher risks of all-cause and hepatic-related mortality compared with MASLD alone, highlighting the prognostic importance of identifying overlapping etiologies in risk stratification and clinical management.

THU-111

Impact of metabolic dysfunction associated steatotic liver disease on hepatocellular carcinoma risk in patients with chronic hepatitis B or chronic hepatitis C: a nationwide cohort study

Young Chang[1], Jinhye Cha[2], Hoyoung Na[2], Julie Lee[2]. *[1]Soonchunhyang University Seoul Hospital, Seoul, Korea, Rep. of South; [2]Gilead Sciences Korea, Seoul, Korea, Rep. of South*
Email: chyoung86@gmail.com

Background and aims: The impact of metabolic dysfunction–associated steatotic liver disease (MASLD) on hepatocellular carcinoma (HCC) and other liver-related outcomes in patients with chronic hepatitis B (CHB) and chronic hepatitis C (CHC) remains unclear. We investigated the association between MASLD and liver-related outcomes using a nationwide cohort.

Method: This retrospective cohort study used the Korean National Health Information Database. Adults newly diagnosed with CHB or CHC between 2009 and 2013 were included if health check-up data enabling MASLD assessment were available within two years. MASLD was defined as hepatic steatosis (Fatty Liver Index ≥60) with at least one cardiometabolic risk factor. A 1:3 frequency matching was performed by index year, age, sex, and hepatitis type. Cox proportional hazards models were used to estimate hazard ratios (HRs) for HCC, decompensated cirrhosis, liver transplantation, and

all-cause mortality, with adjustment for demographic, clinical, and metabolic variables.
Results: Among 187,895 patients with chronic viral hepatitis who met the inclusion criteria, 20,107 (10.7%) had concurrent MASLD at baseline. After matching, 72,496 patients were included in the final analysis (MASLD: 18,124; non-MASLD: 54,372). During up to 10 years of follow-up, patients with MASLD showed a higher incidence of HCC than those without MASLD (3.14 vs. 2.24 per 1,000 person-years). MASLD was associated with higher risks of HCC (adjusted hazard ratio [aHR] 2.59; 95% CI 2.23–3.00), decompensated cirrhosis (aHR 1.94; 95% CI 1.72–2.19), liver transplantation (aHR 3.12; 95% CI 1.64–5.94), and all-cause mortality (aHR 1.31; 95% CI 1.19–1.45). In contrast, metabolic dysfunction was not associated with liver-related outcomes or all-cause mortality in patients without MASLD. Within MASLD as well, individual metabolic risk factors were not associated with increased risks of liver-related outcomes and were associated with lower observed risk.
Conclusion: MASLD was independently associated with increased risks of HCC and adverse liver outcomes among patients with CHB or CHC. Metabolic dysfunction in the absence of MASLD, and individual metabolic risk factors within MASLD, were not associated with additional risk.

THU-115
Metabolic dysfunction-associated steatotic liver disease (MASLD) as predominant aetiology and poorest prognosis in multi-ethnic Singapore cirrhosis cohort

Jarvis Chia Kai An[1], Michael Hao Chen[2], Poh Hui Wee[3], Ryan Ng Jian Han[3], Kai Lim[3], Wei Xuan Tay[3], Kaina Chen[3], Yiying Pei[3], Bochao Jiang[3], Kevin Kim Jun Teh[3], Thinesh Krishnamoorthy[3], Hiang Keat Tan[3], Rahul Kumar[4], Marianne DeRoza[5], Chanda Ho[3], Prema Raj[3], Jason Pik Eu Chang[3]. *[1]Lee Kong Chian School Of Medicine, Singapore, Singapore; [2]Duke-NUS Medical School, Singapore, Singapore; [3]Singapore General Hospital, Singapore, Singapore; [4]Changi General Hospital, Singapore, Singapore; [5]Sengkang General Hospital, Singapore, Singapore*
Email: m220172@e.ntu.edu.sg

Background and aims: The epidemiology of cirrhosis is undergoing a major transition, with metabolic risk factors increasingly replacing viral hepatitis as the predominant aetiologies. The prognostic implications of this transition, and its interaction with dynamic decompensating events, remain incompletely defined. This study aims to evaluate current aetiological trends and identify baseline and time-dependent predictors of mortality in a multi-ethnic Southeast Asian cohort.
Method: We conducted a prospective observational cohort study of 1,195 adults with cirrhosis from the SingHealth Chronic Liver Disease Registry across multiple tertiary hospitals in Singapore. Baseline demographic, clinical variables, and time-varying decompensation events were collected. Survival was analysed using Kaplan-Meier methods, and predictors of mortality were evaluated using baseline and time-dependent Cox proportional hazards models.
Results: Mean age was 60.9 years and 59.1% were male. The most common aetiology was MASLD (39.8%), followed by chronic Hepatitis B (23.5%), and alcohol-related liver disease (10.7%). Over a mean follow-up of 80.5 months, 18.4% died. Survival differed significantly by aetiology (log-rank $p < 0.001$), with the shortest survival in MASLD (median 153 months). Baseline predictors of mortality included Child-Pugh class B/C (hazard ratio HR 2.83), portal vein thrombosis (HR 2.23), hepatocellular carcinoma (HR 2.11), male sex (HR 1.91), diabetes (HR 1.38), and older age (HR 1.07 per year). Chronic Hepatitis B was independently associated with lower mortality (HR 0.53). On time-dependent analysis, incident ascites (HR 3.36), spontaneous bacterial peritonitis (HR 1.75), and hepatic encephalopathy (HR 1.51) were the strongest predictors of death, and MASLD (HR 1.56) remained independently associated with mortality (all $p < 0.05$).
Conclusion: MASLD is currently the predominant phenotype of cirrhosis in Singapore and confers the poorest long-term prognosis. Mortality follows a dynamic, event-driven trajectory, with ascites representing the most critical prognostic turning point.

Email: giada.sebastiani@mcgill.ca

Background and aims: Metabolic dysfunction–associated steatotic liver disease (MASLD) is common in people with HIV (PWH), yet its impact on health-related quality of life (HRQoL) remains poorly defined. We aimed to examine the association between MASLD and both generic and liver-specific HRQoL in PWH.
Method: We conducted a cross-sectional analysis within the Canadian multicentre prospective LIVEr disease in HIV (LIVEHIV) cohort, including consecutive PWH on antiretroviral therapy without viral hepatitis, significant alcohol intake, or advanced chronic liver disease. MASLD was defined as hepatic steatosis (controlled attenuation parameter >248 dB/m) plus ≥1 metabolic comorbidity, and significant liver fibrosis as liver stiffness measurement >8 kPa. HRQoL was assessed using the Short Form (SF)-36 and the Chronic Liver Disease Questionnaire (CLDQ). Adjusted marginal mean differences were estimated using multivariable linear regression. Among participants with MASLD, associations with increasing metabolic comorbidity burden were evaluated.
Results: Among 519 participants (mean age 48 years, 74% male, 89% virologically suppressed), MASLD prevalence was 41%. MASLD was independently associated with worse generic HRQoL, including lower physical functioning (−4.6; 95% CI −9.12 to −0.01) and general health (−4.5; 95% CI −8.58 to −0.48) on the SF-36. Liver-specific HRQoL was more markedly impaired: MASLD was associated with a lower overall CLDQ score (−0.29; 95% CI −0.49 to −0.09), with worse scores in fatigue (−0.36; 95% CI −0.64 to −0.09), systemic symptoms (−0.28; 95% CI −0.50 to −0.07), emotional symptoms (−0.32; 95% CI −0.58 to −0.06), and worry (−0.24; 95% CI −0.46 to −0.02). Among PWH with MASLD, increasing metabolic comorbidity burden was associated with a dose–response decline in physical functioning (−10.6, 95% CI −20.8 to −0.50 for 2–3 comorbidities and −14.8, 95% CI −26.5 to −3.22 for ≥4 vs 0–1), whereas liver-specific HRQoL did not differ substantially across comorbidity strata. Notably, significant fibrosis was associated with worse CLDQ activity (−0.62; 95% CI −1.20 to −0.05) and worry (−0.60; 95% CI −1.15 to −0.05).
Conclusion: In PWH, MASLD is independently associated with impaired HRQoL, particularly fatigue, systemic symptoms, and emotional burden. Accumulation of metabolic comorbidities predominantly affects physical functioning, while significant fibrosis

further worsens activity and worry, underscoring the combined impact of metabolic dysfunction and hepatic fibrosis on patient-reported outcomes.

Background and aims: Metabolic dysfunction-associated steatotic liver disease (MASLD), is often silent yet associated with increased cardiovascular and cerebrovascular risk and progression to cirrhosis and hepatocellular carcinoma. Global MASLD prevalence is 38%, will in Italy is estimated at around 27%.
The aim of this study was to assess the effectiveness of EDs as a screening setting for hidden SLD and to estimate its prevalence among ED attendees.
Method: This prospective multicenter study involved five EDs in Abruzzo, Apulia and Lombardy. Adults (≥18 years) triaged as non-urgent/less-urgent (green/white codes) were enrolled at ED presentation. After consent, participants reported whether they were aware of having hepatic steatosis, then underwent first-line assessment (history, biometric and laboratory parameters, physical examination) and focused abdominal ultrasound.
Results: Overall, 1138 eligible patients were enrolled. Our screening identified SLD in 32.5% of the cohort. In Lombardy, 58% of subjects were found to be steatotic (41% displaying mild SLD) In Abruzzo, prevalence was 34.0% (76.0% mild), with site-specific rates of 42.7% (Avezzano), 28.3% (L'Aquila) and 37.0% (Teramo). In Apulia, liver steatosis was present in 22.1%, with 63.7% mild. Importantly, the most of participants were unaware of hepatic steatosis (overall 87%; Lombardy 70%, Abruzzo 92%, Apulia 98%). These findings indicate that MASLD was largely hidden and mostly unrecognized by patients. Moreover, the observed prevalence exceeded national estimates, with significant differences across regions ($p < 0.05$), possibly reflecting heterogeneous environmental or population-related factors.
Conclusion: In ED attendees, liver steatosis was common, largely unrecognized, and identified through a structured clinical-ultrasound approach, highlighting the Emergency Department as a novel and effective opportunistic screening setting for early detection, particularly of mild disease. Notably, the marked and unexpected differences in liver steatosis prevalence observed across Italian regions suggest relevant geographic heterogeneity and underscore the need for region-specific epidemiological evaluation and tailored preventive strategies.

THU-118-YI

Influence of coexistent steatotic liver disease on outcomes and treatment responses in autoimmune hepatitis or primary biliary cholangitis

Oscar Danielsson[1,2], Markku Nissinen[3], Fredrik Åberg[2]. [1]*University of Helsinki, Helsinki, Finland;* [2]*Helsinki University Central Hospital, Helsinki, Finland;* [3]*Terveystalo Ltd, Helsinki, Finland*
Email: oscar.danielsson@helsinki.fi

Background and aims: Steatotic liver disease (SLD) has reached pandemic proportions, and it poses a threat on the course and prognosis of other liver diseases. We investigated the impact of coexisting SLD on Autoimmune Hepatitis (AIH) or Primary Biliary Cholangitis (PBC).
Method: Diagnostic liver biopsies were gathered for patients with AIH or PBC in the Hospital district of Helsinki and Uusimaa between June 2009 and May 2019. Laboratory tests, entries for morbidity and mortality were analysed through chart review and registry linkage until October 2024. SLD was defined as ≥5% fat in biopsy taken at the point of diagnosis of liver disease. These patients were compared with non-SLD patients. For AIH, complete biochemical remission was defined as normal immunoglobulin G and aminotransferase levels. For PBC, remission was defined as alkaline phosphatase <1.67x upper limit of normal. Differences were analysed by chi-square or Mann-Whitney U test, where appropriate. For cancer incidence, Cox regression was used.
Results: The study consisted of 182 AIH- and 148 PBC-patients. SLD prevalence was 12.1% in AIH and 18.9% in PBC ($p = 0.09$), at the time of diagnosis of liver disease. Mean follow-up was 9.8 years for SLD- and 10.7 years for non-SLD-patients. 26.0% (N = 13) of SLD patients had entry for any kind of cancer during follow-up, while 13.6% (N = 38) of non-SLD patients had entries for cancer, $p = 0.025$. When adjusted for age and sex, SLD patients had a hazard ratio of 1.59 (95% confidence interval 0.85–3.0) for cancer, $p = 0.15$. Mean age was 54.0 (SD 15.8) and 58.7 (SD 10.9) years, for non-SLD- and SLD-patients, respectively, $p = 0.07$. For AIH patients with available biochemical status, complete biochemical remission was achieved in 53.6% and 50.9%, 1 and 5 years after diagnosis, respectively, ($p = 0.59$ and 0.71 for difference between SLD and non-SLD patients, at 1 and 5 years, respectively). Among PBC patients with available data, 68.9% and 80.5% were in remission, at 1 and 5 years after diagnosis, respectively ($p = 0.18$ and 0.93 and for difference between SLD and non-SLD patients, at 1 and 5 years, respectively).
Conclusion: Coexisting SLD did not alter rate of biochemical remission among AIH- or PBC-patients. Incidence of cancer was higher among SLD patients, although not significant when adjusted for age and sex.

THU-119-YI

Association between sex and long-term clinical outcomes in metabolic dysfunction-associated steatotic liver disease

Pojsakorn Danpanichkul[1], Torlap Inkongngam[2], Apichat Kaewdech[3], Karn Wijarnpreecha[4], Donghee Kim[5]. [1]*Department of Internal Medicine, Texas Tech University Healt, Lubbock, United States;* [2]*Chiang Mai University, Chiang Mai, Thailand;* [3]*Prince of Songkla University, Gastroenterology and Hepatology Unit, Division of Internal Medicine, Hatyai, Thailand;* [4]*University of Arizona, Phoenix, United States;* [5]*Stanford university, Palo Alto, United States*
Email: pojsakorndan@gmail.com

Background and aims: MASLD affects 35% of U.S. adults and is linked to liver and cardiovascular sequelae. Sex differences in prevalence and biology are known, yet large, sex-stratified, real-world outcome data are limited. We evaluated whether sex is associated with all-cause mortality, MALO, MACE, other cardiovascular outcomes, and HCC in MASLD.
Method: Using TriNetX (multicenter U.S. EHRs), we identified females and males with MASLD from 2010 to 2019, excluding other liver diseases, AUD, cancer, and pregnancy. Events within 30 days of index were classified as baseline. Outcomes at 5 years included mortality, MALO, MACE, HCC, ischemic heart disease (IHD), thrombotic events, heart failure, inflammatory heart disease, stroke, and arrhythmia. We performed 1:1 nearest-neighbor PSM without replacement using demographics, comorbidities, medications, and laboratories. Cox models estimated HRs with 95% CIs. Subgroups contrasted females <50 and ≥50 years with age-matched males.
Results: Among 397,125 patients (216,875 females; 180,250 males), PSM yielded 152,676 per sex with well-balanced characteristics. Over 5 years, females had lower risks of death (HR 0.76, 95% CI 0.74–0.78), HCC (0.57, 0.51–0.65), MACE (0.89, 0.87–0.91), IHD (0.76, 0.74–0.78), thrombotic events (0.92, 0.87–0.97), and heart failure (0.88, 0.85–0.91). Risks were similar for MALO (1.01, 0.98–1.05), inflammatory heart disease (0.99, 0.94–1.06), and stroke (1.03, 1.00–1.07); arrhythmia was slightly higher in females (1.05, 1.03–1.07). In subgroup analyses, females <50 had lower mortality (0.87, 0.77–0.98) but higher MALO (1.22, 1.09–1.37), stroke (1.33, 1.15–1.54), and

arrhythmia (1.27, 1.20–1.33); females ≥50 had lower mortality (0.77, 0.74–0.80), similar to slightly lower MALO (0.96, 0.92–1.00), lower HCC (0.60, 0.53–0.68), and lower MACE (0.87, 0.85–0.90).
Conclusion: In this multicenter, PSM-adjusted cohort, male sex in MASLD was associated with higher mortality, HCC, and macrovascular events, while arrhythmia was modestly higher in females. Age modifies these associations, supporting sex- and age-specific risk assessment and surveillance in MASLD.

THU-120
MASLD and mental health: association of the liver disease with anxiety, depression and binge eating
Stella De Nicola[1], Arianna Bertazzoni[2], Nicola Pugliese[1,2], Chiara Masetti[1], Davide Polverini[1], Roberto Ceriani[1], Andrea Catena[3], Beatrice Mazzuccato[3], Ana Lleo[1,2], Alessio Aghemo[1,2]. *[1]Humanitas Research Hospital IRCCS, Rozzano, Italy; [2]Humanitas University, Pieve Emanuele, Italy; [3]Humanitas Medical Care, Milan, Italy*
Email: stella.denicola@humanitas.it

Background and aims: Metabolic dysfunction-associated steatotic liver disease (MASLD) prevalence is increasing worldwide alongside other cardiometabolic conditions. Given the known relationship between MASLD and dietary habits, patients with binge eating disorder (BED) may be at increased risk of MASLD. A close connection between metabolic syndrome and mental disorders (binge eating, anxiety, depression) was proved but few studies exist on their association with MASLD. The main aim of this study is to investigate prevalence and distribution of BED, depression and state/trait anxiety in MASLD compared to other liver diseases (HCV-HBV-CBP). The second aim is to evaluate correlation between the scores of questionnaires and liver stiffness measurement (LSM) values in MASLD.
Method: We conducted a prospective single-center study at our tertiary hospital from November 2024 to April 2025. Patients completed four questionnaires (STAI-Y1/STAI-Y2, BDI-II, BES), the scores of which were indicative of the likelihood and severity of anxiety, depression and BED. Exclusion criteria were history of psychiatric disease, malignancy or alcohol consumption. All patients were Italian. Data from questionnaires were analyzed by expert psychologists. Baseline clinical and demographic data and LSM were collected.
Results: A total of 130 patients were included, 65 MASLD and 65 controls. Mean STAI-Y1 and STAI-Y2 were indicative of moderate to severe anxiety (40 and 40 respectively in MASLD; 38 and 38 respectively in non-MASLD), but no statistically significant difference was found. There was no significant difference in mean BDI-II scores (7 vs 5 for MASLD vs non-MASLD), suggesting absence of depressive symptoms. A statistically significant difference was found for binge eating: median BES was 5 (IQR 1–9) in MASLD vs 3 (IQR 0–4) in controls ($p < 0.05$). Probable BED (BES > 26) occurred in 4.6% MASLD vs 0% controls. No correlation was found between binge eating, depression or anxiety and LSM values in MASLD. Higher prevalence of anxiety was observed in both groups compared to general population with anxiety more prevalent in the MASLD than in the control group.
Conclusion: These findings support need for an integrated multidisciplinary care plan for MASLD patients with *possible* or *probable* binge eating, which could be screened with the BES questionnaire. Management of psychiatric conditions can improve adherence to lifestyle and pharmacological interventions, eventually preventing disease progression or relapse.

THU-121
Medical education on MASH delivered through a social media series had strong clinician engagement
Shari Dermer[1], Julie Schrand[1], Danielle Montgomery[1], Naim Alkhouri[2]. *[1]Medscape Education, Newark, United States; [2]Summit Clinical Research, Westlake, United States*
Email: sdermer@medscape.net

Background and aims: Use of social media for professional purposes among healthcare providers (HCPs) reached 91% in 2025[1]. To adapt to changing needs in medical education and address gaps in practice related to the management of metabolic dysfunction-associated steatohepatitis (MASH), Medscape developed and delivered high-impact educational content via verified social media channels to meet clinicians in the spaces that they engage in and trust.
Method: A series of six live 15-minute social media broadcasts were released every other month over the 12-month calendar year of 2025. Each episode was posted on 4 different social media channels that included Twitter (X), Facebook, LinkedIn, and YouTube. Our series entitled *MASH Masters* featured a faculty host and 6 guest faculty and discussed topics such as guideline updates, interdisciplinary management, noninvasive tests, risk-stratification, and liver-directed therapy[2].
Results: There was strong engagement across the 6 episodes in season 1 with a social impact of 645,877 and a video engagement rate of 25%.

- Total social media impressions: 429,544 times that the posts were shown on someone's screen.
- Video engagement rate: 25% of engagements resulted in content being viewed.
- Video views: 213,463 times that people started watching a video.
- Direct engagements: 1479 interactions with the social media posts (eg. likes, comments, shares, clicks).
- Link clicks: 1391 times that links to additional educational content were accessed.

Conclusion: These results demonstrate the potential of social media to address gaps in practice and raise awareness regarding current concepts in managing MASH.

THU-122
Clinical outcomes in compensated cirrhosis due to MASH: results from a population-based indiana cirrhosis cohort
Archita Desai[1], Maaz Arif[1], Eric Orman[1], LaKeisha Boyd[1], Yang Li[1], Eduardo Vilar Gomez[1], Niharika Samala[1], Naga Chalasani[1]. *[1]Indiana University, Indianapolis, United States*
Email: desaiar@iu.edu

Background and aims: Patients with MASH-related compensated cirrhosis face substantial risk of decompensation, yet real-world longitudinal data are limited. We aimed to characterize the cumulative incidence and timing of initial decompensation events in a large, contemporary population-based cohort.
Method: The Indiana Cirrhosis Cohort (ICC) is a digitally-constructed cohort derived from a statewide health information exchange using a validated approach to identify patients with cirrhosis. We identified 10,227 adults with compensated cirrhosis (2017–2020, followed until July 2023), of whom 2,482 had Child Pugh (CP) A MASH cirrhosis. We assessed the time to initial decompensation event (IDE; defined as first occurrence of ascites, hepatic encephalopathy [HE], variceal bleeding [VB], HCC, or multiple concurrent IDEs) and time from IDE to death or liver transplantation (LT) using cumulative incidence (CI) functions and Cox regression models.
Results: The cohort of 2,482 adults with CP A MASH cirrhosis had a mean age 63 ± 12 years, 58% female, and 95% White. Median follow-up was 4.5 years (IQR 3.0–5.9). Type 2 diabetes was present in 57% and coronary artery disease in 23%. CP scores were A5 in 1,664 (67%) and A6 in 818 (33%). These groups had similar characteristics except A6 participants were older, had lower median platelet count (130, IQR 96–182 vs 149, IQR 109–203, $p < 0.001$) and higher median MELD3.0 (12, IQR 10–15 vs 10, IQR 8–12, $p < 0.001$). In the entire CP A cohort,

47% (n = 1,156) experienced an IDE during follow up, with a median time to IDE of 2.0 years (IQR 1.1–3.1). Ascites was the most common IDE (19%), followed by HE (15%), multiple concurrent events (6%), HCC (5%), and VB (2%). The 1- 3- and 5-year CIs of any IDE were 11%, 35%, and 48%, respectively. Among A5 patients, the 1- 3- and 5-year CIs of any IDE were 8%, 29%, and 41%, respectively. Among A6 patients, the 1- 3- and 5-year CIs for any IDE were 16%, 47%, and 61%, respectively. Following an IDE, the 1- 3- and 5-year CIs of death/LT were 33%, 59%, and 71%, respectively, occurring at 2.1 years (IQR 0.6–5.8). Outcomes varied by IDE type; 5-year death/LT CI were: HCC:86%, ascites:75%, HE:65%, and VB:29%.

Conclusion: This contemporary population-based study demonstrates high rates of decompensation for Child Pugh A MASH cirrhosis, with A5 and A6 exhibiting different rates of decompensation. These data underscore the importance of developing therapies for CP A MASH cirrhosis.

THU-123

A head-to-head comparison of MAFLD and MASLD diagnostic criteria in estimating the risk of de novo hepatocellular carcinoma (HCC) occurrence in HCV patients achieving direct-acting antiviral-induced sustained virological response

Fiammetta Di Nardo[1], Marcello Dallio[1], Mario Romeo[1], Carmine Napolitano[1], Paolo Vaia[1], Claudio Basile[1], Giuseppina Martinelli[1], Luigi Vitale[1], Marco Niosi[1], Alessandro Federico[1]. [1]*Hepatogastroenterology Division, Department of Precision Medicine, University of Campania Luigi Vanvitelli, Piazza Miraglia 2, 80138, Naples (Italy), Naples, Italy*
Email: fiammetta.dinardo@studenti.unicampania.it

Background and aims: A higher risk of hepatocellular carcinoma (HCC) has been widely reported in patients with chronic hepatitis C virus (HCV) infection who achieve a sustained virologic response (SVR12) induced by direct-acting antivirals (DAAs), presenting with Steatotic Liver Disease (SLD) and cardiometabolic risk factors (CMRFs) indicative of metabolic dysfunction (MD). Two years after the Delphi consensus, the potential benefits of adopting Metabolic dysfunction-associated Steatotic Liver Disease (MASLD) rather than Metabolic dysfunction-associated Fatty Liver Disease (MAFLD) criteria in defining the disease progression risk remain undefined. The present study compared MASLD and MAFLD criteria in estimating the 5-year risk of de novo HCC occurrence in SLD patients achieving DAAs-induced HCV SVR12.

Method: The anthropometrical, biochemical, clinical, Liver Stiffness Measurement (LSM), and Controlled Attenuation Parameter (CAP) data stored in the "Luigi Vanvitelli" University Hospital Health Documents Digitization Archive of 751 HCV-SVR12-SLD patients (January 2015-May 2020) were included. After properly excluding lean individuals (i.e., Body Mass Index < 25 kg/m^2) and patients with other causes of chronic liver damage (n.101), the MAFLD and MASLD criteria were separately applied, ultimately identifying the following groups: HCV-SVR12-MASLD (n.163), HCV-SVR12-MASLD/MAFLD (n.390), and HCV-SVR12-MAFLD (n.97). HCC occurrence was diagnosed according to the EASL guidelines and retrospectively reported along a 5-year follow-up.

Results: At baseline, no significant clinical differences emerged among the groups, and a similar distribution of LSM-advanced fibrosis (AF) was reported in HCV-SVR12-MASLD and HCV-SVR12-MAFLD [53 (32.51%) vs 34 (35.05%), chi-square, p > 0.05]. Compared to MASLD, MAFLD diagnostic criteria better estimated the risk of HCC [HR: 1.936, C.I. 95%: 1.083–2.375, p:0.035], even after stratifying for AF baseline presence (chi-square, p < 0.0001). Multivariate competing risk analysis (adjusted for sex, age, diabetes, steatosis, SVR achieving time, CAP, and fibrosis severity) revealed diabetes (aHR: 2.051, p:0.001), high-sensitivity-C-reactive protein (aHR: 1.351; p:0.02), and Homeostatic-model-assessment-for-insulin-resistance (aHR: 1.219; p:0.02) as variables significantly associated with this outcome.

Conclusion: MAFLD criteria better estimate the de novo HCC risk in SLD patients achieving DAAs-induced HCV SVR12.

THU-124

Impact of gallstone disease, cholecystectomy and genetic variants on liver steatosis and fibrosis: a prospective, cross-sectional cohort study at a tertiary hepatology centre

Simon Drews[1], Susanne Weber[1], Johannes Lehmann[1], Maurice Michel[1], Jörn M. Schattenberg[1], Marcin Krawczyk[2]. [1]*Department of Medicine II, University Hospital Saarland, Homburg, Germany;* [2]*Department of Gastroenterology, Hepatology and Transplant Medicine, Medical Faculty, University of Duisburg-Essen, Essen, Germany*
Email: simon.drews@freenet.de

Background and aims: Gallstone disease (GD) and steatotic liver disease (SLD) are common and interrelated conditions. Patients with SLD have increased risk of GD, and both share similar exogenous risk factors. We analyse the effects of gallstones and cholecystectomy on liver steatosis and fibrosis, together with the role of genetic determinants of GD and SLD in liver injury.

Method: We prospectively recruited 212 patients (112 women; age range 19–85 years): 73 had gallstones with the gallbladder in situ, 63 had undergone cholecystectomy, and 76 served as controls. GD was verified by abdominal sonography. Hepatic fibrosis and steatosis were quantified using transient elastography (TE) and controlled attenuation parameter (CAP), respectively. The following variants were genotyped with TaqMan assays: *ABCG8* p.D19H, *PNPLA3* p.I148M, *TM6SF2* p.E167 K, *MBOAT7* p.G17E, and *APOE* p.C130R.

Results: Participants had median TE of 7.2 (5.0–17.0) kPa and CAP of 244 (213–279) dB/m. Homozygote frequencies were: *ABCG8* 0.47%, *PNPLA3* 7.08%, *TM6SF2* 0.94%, *MBOAT7* 18.40%, *APOE* 1.42%. The *PNPLA3* polymorphism was associated with higher TE (P = 0.008) and FiB4 (P = 0.01); FiB4 was also increased in carriers of the *ABCG8* variant (P = 0.048). In univariate analyses, patients with GD and those after cholecystectomy were more likely to have TE ≥ 8.1 kPa (P = 0.022). However, in multivariate analyses, fibrosis was significantly (all P < 0.05) associated with older age (OR 1.033, 95%CI 1.009–1.058), diabetes (OR 3.260, 95%CI 1.614–6.584) and the *PNPLA3* variant (OR 1.978, 95%CI: 1.228–3.186), but not with GD or cholecystectomy (P > 0.05). SLD (CAP ≥ 275 dB/m) was positively associated (all P < 0.05) with BMI (OR 1.240, 95%CI 1.132–1.315), *TM6SF2-T-allele* (OR 2.680, 95%CI 1.060–6.779), diabetes (OR 2.602, 95%CI 1.208–5.602) but negatively with *ABCG8* p.D19H (OR 0.139, 95%CI 0.035–0.546).

Conclusion: GD or cholecystectomy might exert minor modulatory effects on liver fibrosis, which however in this setting is – like steatosis – mainly driven by established genetic and exogenous determinants.

THU-125

Dissecting the alternate mediterranean diet score identifies whole grains and red meat as key determinants of fibrosis risk in MASLD

Nicholas Dunn[1], Sheel Patel[1], Luis Antonio Diaz[2], Vatsalya Vatsalya[1], Robert Wong[3], Juan Pablo Arab[4], Shira Zelber[5], Aleksander Krag[6,7], Zobair M. Younossi[8], Maiying Kong[1], Ashwani K. Singal[1]. [1]*University of Louisville, Louisville, United States;* [2]*Division of Gastroenterology and Hepatology, University of California San Diego, San Diego, United States;* [3]*Stanford University, Stanford, United States;* [4]*Division of Gastroenterology, Hepatology, and Nutrition, Department of Internal Medicine, Virginia Commonwealth University School of Medicine, Richmond, United States;* [5]*School of Public Health, University of Haifa, Haifa, Israel;* [6]*Center for Liver Research, Department of Gastroenterology and Hepatology, Odense University Hospital, Odense C, Denmark;* [7]*Institute of Clinical Research, Faculty of Health Science, University of Southern Denmark, Odense M, Denmark;* [8]*The Global NASH Council, Washington, United States*
Email: ashwanisingal.com@gmail.com

Background and aims: Diet is a crucial component in the management in metabolic dysfunction-associated steatotic liver disease (MASLD). However, composite dietary indices may obscure the contribution of individual food components. The Alternate Mediterranean Diet score (aMED) captures key dietary domains linked to metabolic health, but its aggregate score has shown inconsistent associations with MASLD. We aimed to evaluate the association of aMED with MASLD and fibrosis severity and to dissect individual aMED components to identify dietary factors independently associated with steatosis and fibrosis progression.
Method: Adults ≥18 years from NHANES 2017–2023 with valid vibration-controlled transient elastography and ≥1 cardiometabolic risk factor were included. MASLD was defined by CAP ≥248 dB/m. Significant fibrosis, advanced fibrosis, and cirrhosis were defined using liver stiffness ≥8, ≥10, and ≥15 kPa, respectively. Bidirectional stepwise models identified aMED component scores independently associated with each outcome, adjusting for demographic, socioeconomic, behavioral, and dietary confounders. Survey-weighted, multivariable logistic regression analyses were derived.
Results: Among 9,563 participants representing 155 million U.S. adults, MASLD prevalence was 63%, with significant fibrosis in 11%, advanced fibrosis in 6%, and cirrhosis in 3%. Higher aMED was associated with lower odds of MASLD (OR 0.87, 95% CI 0.82–0.92), significant fibrosis (OR 0.85, 0.79–0.92), and advanced fibrosis (OR 0.87, 0.77–0.98), with a borderline association for cirrhosis (OR 0.86, 0.74–1.01; p = 0.059). Independent predictors of MASLD were higher legume (OR 0.89, 0.83–0.95) and fruit intake (OR 0.92, 0.85–0.99). Higher red/processed meat intake increased (OR 1.16–1.17; 95% CI 1.07–1.30), while higher whole grain intake reduced (OR 0.82; 95% CI 0.73–0.93), the odds of significant and advanced fibrosis. Whole grain intake was the sole dietary predictor of cirrhosis (OR 0.79, 0.64–0.96).
Conclusion: Greater adherence to a Mediterranean-style dietary pattern is associated with lower odds of MASLD and fibrosis. Within the aMED score, higher whole-grain intake and lower red/processed meat intake emerged as the principal protective components against fibrosis. These findings support targeted Mediterranean diet recommendations emphasizing increased whole grains and reduced red meat to mitigate fibrosis progression in MASLD. Given the cross-sectional design, longitudinal studies are needed to confirm these associations.

Natural history and predictors of fibrosis progression in metabolic dysfunction-associated steatotic liver disease (MASLD) – Longitudinal cohort study with paired liver biopsies

Fahim Ebrahimi[1], Luigi Terracciano[2,3], Caner Ercan[4], Luigi Tornillo[5,6], Matthias Matter[5], Jürg Vosbeck[5], Elaine Chng[7], Fion Goh[7], Serene Lek[7], Aleksei Suslov[5], Stefan Wieland[5], Nikolai Naoumov[8], Markus Heim[1,5].
[1]University Hospital Basel, Basel, Switzerland; [2]IRCCS Humanitas Research Hospital, Milan, Italy; [3]Humanitas University, Milan, Italy; [4]University of Texas MD Anderson Cancer Center, Houston, United States; [5]University of Basel, Basel, Switzerland; [6]GILAB AG, Allschwil, Switzerland; [7]HistoIndex Pte. Ltd., Singapore, Singapore; [8]University College London, London, United Kingdom
Email: f.ebrahimi@outlook.com

Background and aims: The natural history and long-term liver histologic evolution of untreated metabolic dysfunction-associated steatotic liver disease (MASLD) remain poorly understood. Using a well-characterized longitudinal cohort with paired liver biopsies, we aimed to investigate predictors of fibrosis changes over time in untreated MASLD.
Method: This was a longitudinal cohort study of 48 patients with biopsy-proven MASLD spanning the full fibrosis spectrum (F0-F4) and followed between 2000 and 2025. All patients received lifestyle counseling but no specific pharmacological intervention. Paired liver biopsies were obtained at baseline (BL) and end-of-follow-up (EOF). Liver histology was independently assessed by two pathologists and by second harmonic generation/two-photon excitation fluorescence (SHG/TPEF) microscopy with artificial intelligence-based quantification (qFibrosis®). Progression or regression of liver fibrosis were defined as an increase or decrease of ≥1 qFibrosis stage, respectively. Linear regression analyses were used to assess associations between clinical and laboratory parameters with changes in qFibrosis scores.
Results: Overall, 68.8% were male with a median age of 49 years (IQR 38.0–56.6) and median BMI of 29.7 kg/m^2 (IQR 26.3–32.7). At baseline, 14.6% had type 2 diabetes and 33.3% had histologic evidence of metabolic dysfunction-associated steatohepatitis (MASH). Baseline liver stiffness measurements (LSM), histologic NAS score, and c-reactive protein levels were significantly associated with baseline qFibrosis scores ($P < 0.05$). Over a median follow-up of 8.5 years (IQR 5.5–10.8 years), 18 patients (37.5%) demonstrated fibrosis progression, 19 (39.6%) showed no change, and 11 (22.9%) exhibited fibrosis regression. None of the baseline variables was significantly associated with progression or regression of ≥1 qFibrosis stage. Using the qFibrosis score, in multivariate adjusted linear regression analyses we found that baseline LSM values were significantly associated with an increase in qFibrosis score (regression coefficient: 0.086 (95%CI, 0.028–0.143; $P = 0.004$). Also, an increase in LSM during the follow-up period of ≥5 kPa was associated with an increase in qFibrosis score of 1.77 (95%CI, 0.95–2.59; $P < 0.001$).
Conclusion: In this well-characterized long-term MASLD cohort, baseline liver stiffness measurements and increases in LSM of ≥5 kPa during the follow-up period predicted increases in liver fibrosis according to the quantitative qFibrosis assessment.

THU-127-YI

Non-invasive two-step triage reduces access delays to liver services for people with metabolic dysfunction-associated steatotic liver disease: a tertiary program evaluation

Yasamin Farbod[1], Neha Sharma[1], France Martineau[1], Dana Kablawi[1], Philip Wong[1], Xun Zhao[1], Marc Deschenes[1], Tianyan Chen[1], Sahar Saeed[2], Amine Benmassaoud[1], Giada Sebastiani[1]. *[1]Division of Gastroenterology and Hepatology, Department of Medicine, McGill University, Montreal, Canada; [2]Department of Public Health Sciences, Queen's University, Kingston, Canada*
Email: yasamin.farbod@mail.mcgill.ca

Background and aims: The prevalence of metabolic dysfunction-associated steatotic liver disease (MASLD) is placing increasing strain on hepatology services. Limited access to transient elastography (TE; FibroScan®) and specialist care continues to generate major bottlenecks. In 2021, our tertiary hepatology program implemented a biomarker-guided, TE-confirmed two-step triage pathway to optimize resource allocation, prioritizing high-risk MASLD while safely retaining low-risk patients in primary care. We evaluated the impact of this model on access to TE and hepatology services, referral efficiency, and early detection of advanced fibrosis.
Method: We conducted a quasi-experimental study including all consecutive referrals for liver assessment between 2013 and 2020 (pre-implementation) and 2021–2025 (post-implementation). The triage algorithm used age-adjusted FIB - 4 cut-offs as the first tier (low risk: <1.3 if <65 years or <2.0 if ≥ 65 years), with non-low-risk patients proceeding to TE for fibrosis confirmation. Primary outcomes were time from referral to TE and referral to hepatology consultation. Secondary outcomes included the proportion of patients managed without in-person hepatology assessment, no-show rate, and detection of advanced fibrosis (> F3) within 12 months of referral as a safety indicator.
Results: Among 3,953 patients with MASLD who underwent TE (mean age 62; 73% male), 1,750 (44.3%) were pre- and 2,203 (55.7%) were post-implementation. Following implementation of two-step triage, mean time from referral to TE decreased from 13.2 to 5.5 months (absolute reduction of –7.7 months; relative reduction - 58%). Mean time from referral to hepatology consultation was reduced from 30 to 13.2 months (absolute reduction of –16.8 months; relative

reduction - 56%). The share of referrals managed without hepatology consultation increased from 45% to 80%, while hepatology no-show rates declined from 23% to 15%. As a safety signal, the proportion of patients diagnosed with advanced fibrosis within 12 months of referral doubled from 10% to 20%, consistent with earlier detection of higher-risk patients following triage implementation.
Conclusion: Implementation of a biomarker-guided, TE-confirmed two-step triage pathway reduced access delays and accelerated detection of advanced fibrosis in MASLD patients. These real-world findings provide scalable, cost-neutral evidence to support decongestion of hepatology services and improve access to liver care in population-level MASLD management.

THU-131
Vitamin D insufficiency is associated with liver fibrosis development in people with HIV
Francesca Farina[1,2], Aurgho Datta[1], Jovana Milic[3], Gabrielle Mariano[1], Felice Cinque[1], Giovanni Guaraldi[3], Giada Sebastiani[1]. [1]*Chronic Viral Illness Service, Department of Medicine, McGill University Health Centre, Montreal, Canada;* [2]*San Raffaele Hospital, Milan, Italy;* [3]*Modena HIV Metabolic Clinic, University of Modena and Reggio Emilia, Modena, Italy*
Email: farina.francesca1@hsr.it

Background and aims: Steatotic liver disease is the most common liver disease in people with HIV (PWH), who are also at increased risk of liver fibrosis. Vitamin D (VitD) insufficiency is highly prevalent in PWH and in steatotic liver disease, yet its role in liver fibrosis development remains uncertain.
Method: We conducted a multicentre observational cohort study in PWH from Italy and Canada. Hepatic steatosis was assessed by transient elastography and defined as a controlled attenuation parameter ≥ 275 dB/m, while significant liver fibrosis was defined as liver stiffness measurement ≥ 8 kPa. VitD insufficiency was defined as serum 25-hydroxyvitamin D levels < 50 nmol/L. Cumulative incidence of liver fibrosis was estimated using survival methods. Factors associated with fibrosis were evaluated using multivariable logistic regression and generalized estimating equation models.
Results: A total of 4746 PWH enrolled between 2014 and 2024 were included (mean age 60.2 years; 72% male; mean BMI 25 kg/m^2; 11% with diabetes; 23% with hepatitis C coinfection). At baseline, VitD insufficiency was present in 42% of participants, hepatic steatosis in 19%, and significant fibrosis in 14%. After adjustment for sex, ethnicity, HIV duration, CD4 cell count, diabetes, and parathyroid hormone levels, VitD insufficiency was independently associated with hepatitis C coinfection (adjusted odds ratio [aOR] 1.15, 95% CI 1.02–1.31), BMI (aOR 1.10, 95% CI 1.03–1.08), and hepatic steatosis (aOR 1.71, 95% CI 1.35–2.18). Over a median follow-up of 7 years, the cumulative incidence of significant liver fibrosis was 17%. PWH with VitD insufficiency had a higher cumulative incidence of liver fibrosis than those without VitD insufficiency (19% vs 11%; log-rank p < 0.001). In multivariable longitudinal analyses, VitD insufficiency remained independently associated with liver fibrosis development (aOR 1.44, 95% CI 1.14–1.80), after adjustment for hepatic steatosis, diabetes, obesity, parathyroid hormone levels, CD4 cell count, and HIV duration.
Conclusion: VitD insufficiency is common in PWH and is strongly associated with hepatic steatosis and hepatitis C coinfection. VitD insufficiency is independently associated with the development of significant liver fibrosis, irrespective of metabolic risk factors, suggesting that VitD status may contribute to liver disease progression in this population.

THU-132
Impact of unhealthy diet categories on liver disease outcomes among different steatotic liver disease phenotypes following patient-centered education
Serena Gilmore[1], Janet Chu[1], Amy Shui[1], Catherine Magee[2], Mandana Khalili[1,2]. [1]*University of California, San Francisco, San Francisco, United States;* [2]*Division of Gastroenterology and Hepatology, Zuckerberg San Francisco General Hospital and Trauma Center, San Francisco, United States*
Email: serenagilmore00@gmail.com

Background and aims: Data on dietary composition of Steatotic liver disease (SLD) subgroups [metabolic dysfunction (MASLD), alcohol related (ALD), or both (MetALD)] and its impact on SLD outcomes are limited. We aimed to describe diet composition of SLD subgroups and assess the impact of unhealthy diet categories on ALT, AST, and Fibrosis-4 (FIB-4) after SLD education.
Method: Adults ≥ 18 years (n = 360) with SLD were recruited from hepatology clinics, completed a formal SLD education including dietary/ lifestyle modification, and followed for 24 months. Pre- and post- education surveys included unhealthy food consumption (carbohydrates, fast foods, fried foods, sugar-sweetened beverages, and sweets) and coffee/tea frequency, SLD knowledge, and barriers to healthy eating. Bivariate tests were used to compare the characteristics as well as dietary composition of SLD subgroups. Multivariable linear mixed-effects models were performed for each longitudinal outcome (ALT, AST, FIB-4) for each of the unhealthy food categories and their interaction with time. Models included SLD subgroups, perceived barriers to dietary modifications following education, and covariates with p < 0.1 associations from the unadjusted models.
Results: Demographics were median age 54 years, 59% female, 57% Hispanic, 26% Asian, 52% obese, and 36% had diabetes. SLD subgroups were 59% MASLD, 20% MetALD, and 21% ALD. Proportion of unhealthy food categories consumed significantly differed across SLD subgroups with sugar-sweetened beverage consumption being higher in ALD and MetALD subgroups, sweets higher in MetALD, and fast food consumption higher in ALD compared to MASLD. Onmultivariable analysis, fried food consumption ≥ 6 times/week (vs none) was associated with a greater change in AST (estimate 2.46, 95% CI 1.10–3.82) and ALT (estimate 1.72, 95% CI 0.03–3.40) over time. Drinking < 3 cups of coffee per day (vs none) was associated with an increase in AST over time (estimate 0.76, 95% CI 0.10–1.42) but not FIB-4. There were no significant differences in AST, ALT, or FIB-4 over time with other unhealthy food consumption categories.
Conclusion: Unhealthy diet categories differed among SLD subgroups, including higher sugar-sweetened beverages consumption with increased alcohol use. Fried food consumption contributed significantly to change in AST and ALT over time. These findings suggest that tailored dietary modification, especially limiting fried foods, are important to SLD outcomes.

THU-133
Depression and anxiety levels are higher in obese women than in men in a cohort of MASLD patients
Marta Guariglia[1], Gian Paolo Caviglia[1], Angelo Armandi[1], Eleonora Dileo[1], Francesca Saba[1], Kamela Gjini[1], Maria Lorena Abate[1], Antonella Oliviero[1], Elisabetta Bugianesi[1,2]. [1]*Division of Gastroenterology and Hepatology, Department of Medical Sciences, University of Turin, Turin, Italy;* [2]*Città della Salute e della Scienza—Molinette Hospital, Turin, Italy*
Email: marta.guariglia@unito.it

Background and aims: Obesity is a major determinant of metabolic dysfunction-associated steatotic liver disease (MASLD) and is closely linked to psychiatric disorders, including depression and anxiety. Increasing evidence highlights the interplay between these conditions with sex and age. We aimed to investigate the prevalence and determinants of depression and anxiety in patients with MASLD.
Method: We prospectively enrolled 277 patients with MASLD (age 54 [20–80] years; 157 males/120 females; BMI 29 [18–46] kg/m^2; T2DM: 61 [22.0%]). All patients underwent liver stiffness measurement by FibroScan® 530. Advanced fibrosis was defined according to liver stiffness values ≥8.0 kPa. Depression and anxiety were assessed using the Hospital Anxiety and Depression Scale (HADS), categorized as: 0–7 (normal), 8–10 (borderline), and ≥11 (abnormal).

Results: Overall, 26% of patients showed at least borderline depression (≥8 points) and 28% at least borderline anxiety; notably, 33 patients were already on antidepressant or anxiolytic treatment. Women were more frequently affected than men (depression: 36.7% vs. 17.8%; anxiety: 40.8% vs. 17.9%). In women, depression correlated with BMI (p = 0.18, p = 0.048), and anxiety correlated inversely with age (ρ = –0.20, p = 0.028). The Kruskall-Wallis test, only in women, shows that in females aged ≥50 years, depression levels are higher in patients with a BMI ≥ 30 (p = 0.026). In multivariable logistic regression adjusted for age, BMI, liver stiffness, antidepressants and diabetes, moderate-to-severe depression remained significantly associated with BMI ≥30 (OR = 2.2, 95% CI = 1.02–4.73, p = 0.045).
Conclusion: In patients with MASLD, psychological burden appeared more pronounced among women, with obesity emerging as a key determinant of depression and younger age of anxiety. These findings highlight the importance of systematic psychological assessment, particularly in obese women, to facilitate timely referral and tailored support.

THU-134

Exploring the link between handgrip strength and MASLD

Leen Heyens[1,2,3,4], Anouk Rensink[5], Francesco Innocenti[6], Struyve Mathieu[4], Sven Francque[7,8], Geert Robaeys[1], Ger Koek[2,5] and MASLD research group[1]. *[1]Hasselt University, Faculty of Health and Life Sciences, LCRC, Hasselt, Belgium; [2]Maastricht University, School of Nutrition and Translational Research in Metabolism (NUTRIM), Maastricht, Netherlands; [3]Ziekenhuis Oost-Limburg, dept. Future Health, Genk, Belgium/LCRC(-MHU), Genk, Belgium; [4]Ziekenhuis Oost-Limburg, dept. Gastroenterology, Genk, Belgium; [5]Maastricht University Medical Centre, dept. Gastroenterology and Hepatology, Maastricht, Netherlands; [6]Maastricht University, Care and Public Health Research Institute (CAPHRI), Department of Methodology and Statistics, Maastricht, Netherlands; [7]Antwerp University Hospital, Department of Gastroenterology and Hepatology, Antwerp, Belgium; [8]University of Antwerp, InflaMed Centre of Excellence, Laboratory of Experimental Medicine and Paediatrics, Antwerp, Belgium*
Email: leen.heyens@uhasselt.be

Background and aims: Handgrip strength (HGS) is a surrogate marker for whole-body muscle strength. Metabolic dysfunction-associated steatotic liver disease (MASLD) is closely linked with obesity, insulin resistance, and sarcopenia. This study aimed to investigate the relationship between HGS and markers of liver steatosis and fibrosis in an MASLD population.
Method: Cross-sectional cohort studies were conducted from 2019 to 2023 across primary care practices in Belgium and the Netherlands, and a hospital endocrinology department in Belgium. Presence of fibrosis was defined by a Vibration Controlled Transient Elastography (VCTE™, *i.e.*, liver stiffness) cut-off value of >8 kPa, and steatosis (hence MASLD) by a Controlled Attenuation Parameter (CAP™) cut-off value of >275 dB/m (FibroScan®, Echosens, Paris). HGS was assessed using a hydraulic hand dynamometer (JAMAR, Saehan, Korea) and categorized into low, average, or high based on normative data. Spearman correlation and logistic regression analyses were conducted to assess associations between absolute HGS, bHGS (absolute HGS/BMI), hHGS (absolute HGS/height), VCTE, and CAP.
Results: In this cross-sectional study, 422 participants were included. MASLD was present in 264 (62.5%) of participants, of whom 193 (45.7%) were male and 57 (13.5%) had fibrosis. The median age and BMI were 61[IQR 16] years and 28.1 [IQR 6.2] kg/m^2, respectively. bHGS was significantly lower in the MASLD group (1.0 [IQR 0.6] *vs.* 1.2 [IQR 0.6], p < 0.001), while absolute HGS and hHGS did not differ. bHGS, but not absolute and hHGS, was inversely correlated with CAP (r = –0.149, p = 0.015) in the MASLD group. In women, absolute, bHGS, and hHGS were significantly lower in individuals with fibrosis compared to those without fibrosis. Multivariable logistic regression models adjusted for age, sex, smoking, alcohol, BMI, T2DM, and exercise indicated that there were no statistically significant associations between absolute HGS, bHGS, and hHGS and the presence of steatosis.
Conclusion: bHGS was associated, but not independently, with steatosis severity. Given the intrinsic relationship between BMI and steatosis, bHGS may not reflect an independent muscle–liver link. Absolute HGS and hHGS showed no independent relationship with steatosis or fibrosis in this MASLD cohort. Standardization of HGS normalization methods and larger longitudinal studies are needed to clarify its role in MASLD risk assessment.

THU-135

Association of geriatric nutritional risk index with prognosis in hepatocellular carcinoma patients with and without metabolic dysfunction–associated steatotic liver disease

Chia-Jung Ho[1], Chun-Ting Ho[1,2], Yi-Chen Lin[3], Tsai Shin-Yu[1], Yi-Hsiang Huang[4], Ming-Chih Hou[5], Jaw-Ching Wu[6], Chien-Wei Su[7]. *[1]Taipei Veterans General Hospital, Department of Medicine, Taipei, Taiwan; [2]National Yang Ming Chiao Tung University Yangming Campus, Ph.D. Program of Interdisciplinary Medicine, Taipei, Taiwan; [3]Linkou Chang Gung Memorial Hospital, Department of Medicine, Taoyuan City, Taiwan; [4]Taipei Veterans General Hospital, Department of Medical Research, Taipei, Taiwan; [5]Taipei Veterans General Hospital, Department of Medicine, Taipei, Taiwan, Taipei City, Taiwan; [6]National Yang Ming Chiao Tung University Yangming Campus, Institute of Clinical Medicine, Taipei, Taiwan; [7]Taipei Veterans General Hospital, Division of General Medicine, Department of Medicine, Taipei, Taiwan*
Email: happywish99@gmail.com

Background and aims: Malnutrition adversely affects outcomes in hepatocellular carcinoma (HCC), while metabolic dysfunction–associated steatotic liver disease (MASLD) has emerged as an increasingly prevalent underlying condition. However, the relationship between nutritional status and MASLD and their prognostic impact on HCC patients remain unclear. We aim to evaluate the prognostic role of malnutrition in HCC patients by assessing geriatric nutritional risk index (GNRI) and further stratified by concurrent MASLD status.
Method: We retrospectively analyzed 994 HCC patients who underwent curative resection between 2016 and 2023 at Taipei Veterans General Hospital. Patients were categorized as non-MASLD (n = 544) or MASLD (n = 450) based on non-tumor liver histology. Risk of malnutrition was assessed using the GNRI and classified as major risk (GNRI < 82), moderate risk (GNRI 82 to <92), low risk (GNRI 92 to ≤98), and no risk (GNRI > 98). Overall survival (OS) was the primary endpoint. Survival analyses were performed using Kaplan–Meier and Cox proportional hazards models.
Results: Among the entire cohort, the prevalence of no risk, low, moderate, and major nutritional risk were 79.8%, 13.5%, 5.8%, and 0.9%, respectively. Compared with the non-MASLD group, patients with MASLD had higher body mass index, more cardiometabolic risk factors, lower prevalence of malnutrition risk (GNRI ≤ 98). They also exhibit higher serum albumin, lower aspartate aminotransferase (AST) and alpha-fetoprotein levels, earlier tumor stage, and smaller tumor size. After a median follow-up of 62.9 months, 251 deaths were recorded, with an overall 5-year OS of 73.9%. Patients at risk of malnutrition (GNRI ≤ 98) had significantly poorer 5-year OS than patients without malnutrition risk (GNRI > 98) (77.3% vs. 60.7%, p < 0.001). This association remain consistent in the MASLD and the non-MASLD subgroups. However, in multivariate Cox analysis, GNRI was not an independent predictor for OS. Older age, lower serum albumin, advanced BCLC stage, and higher histology grade independently predicted poorer OS.
Conclusion: HCC patients with MASLD exhibit lower prevalence of malnutrition risk and more favorable tumor characteristics. Malnutrition, assessed by GNRI, was associated with poor OS in both MASLD and non-MASLD subgroups. However, GNRI was not an independent prognostic factor after adjustment, with age, serum

albumin, and tumor burden remaining the key determinant of outcomes.

THU-136

Comparison of demographics, metabolic risk factors and clinical presentation in lean Vs. non-lean metabolic dysfunction-associated steatotic liver disease (L-MASLD Vs. NL-MASLD) in all of US large cohort in the United States

Ke-Qin Hu[1], Yash Deole[1], Argyrios Ziogas[1], Jenny Fang[1], Hoda Anton-Culver[1]. [1]*University of California Irvine, Irvine, United States*
Email: kqhu@uci.edu

Background and aims: The demographics, metabolic risk factors (MRFs) and clinical presentation of lean metabolic dysfunction-associated steatotic liver disease [L-MASLD, i.e., BMI < 23 for Asians and < 25 for non-Asians] remain to be defined. All of US (AOU) program is one of the largest EHR-linked multi-state/multicenter research cohorts in the US, providing a unique value to address these issues. Aim: Compared L-MASLD vs. Non-lean MASLD (NL-MSALD) in their basic demographics, MRFs, clinical presentation using AOU EHR-linked large cohort of cases with MASLD.
Method: A total of 16117 cases with EHR diagnosis of fatty liver but no history of alcohol use, HBV or HCV infection, AIH, PBC, or PSC, were identified as MASLD cases, including 1135 with L-MASLD; 14982, NL-MASLD (NL-MASLD) for the following statistical analyses.
Results: In L-MASLD group, the mean age was 56.39 ± 16.11; 66.5% were females; 59.6%, White; 21.1%, Hispanic; 7.1%, Black; 4.6%, Asian. Compared to NL-MASLD, age 65 (36.7% vs. 24.1%), Asian-ethnicity (4.6% vs. 2.3%), ALP (> 110, 47.3% vs. 42.5%) and GGT (> 60, 9.1% vs. 5.8%) elevations were significantly higher in L-MASLD group; and type-2 diabetes (T2DM, 29.3% vs. 48.6%), hyperlipidemia (HLD, 63.3% vs. 71.6%), hypertension (HTN, 58.0% vs. 73.8%), obstructive sleep apnea (OSA, 14.5% vs. 42.4%), ALT elevation (> 40, 56.9% vs. 62.2%), and cirrhosis (4.5% vs. 6.5%) were significantly lower in L-MASLD group, but hepatocellular carcinoma (HCC, 0.8% vs. 0.4%), coronary artery disease (CAD, 23.0% vs. 22.9%), and myocardial infarction (MI, 9.8% vs. 9.3%) were not significantly different. Multivariable Logistic Regression analysis indicated that the rates of Asian-ethnicity (95% CI 1.39–2.55), age ≥ 65 (95%CI 0.38–0.50), ALP (95%CI 0.59–0.78) and GGT (95%CI 0.42–0.67) elevation were significantly higher; T2DM (95%CI 1.49–1.99), HTN (95%CI 1.48–1.97), OSA (95%CI 3.02–4.27), cirrhosis (95%CI 1.03–1.87), and ALT elevation (95%CI 1.05–1.37), but not HLD (95%CI 0.91–1.22) were significantly lower in L-MASLD.
Conclusion: In AOU multicenter large cohort, L-MASLD group had significantly higher rates in age ≥ 65, Asian-ethnicity. The rates of T2DM, HTN, OSA, and cirrhosis were sig lower in L-MASLD, but 4.5% and 0.8% of MASLD cases had cirrhosis and HCC, and the rates of CAD and MI were comparable in both groups. Our data indicated although L-MASLD may have lower rates of MRFs compared to NL-MASLD, it carries comparable long-term prognosis with NL-MALSD.

THU-137

Role of predominant zone of fibrosis on cardiometabolic biomarkers, MACE, MALO, and new-onset diabetes in people with MASH

Alan L. Hutchison[1], Mary E. Rinella[1]. [1]*The University of Chicago, 5841 S. Maryland Ave, MC 4076 | M410, Chicago, United States*
Email: alan.hutchison@uchicagomedicine.org

Background and aims: Hepatocytes in different zones of the liver have different functions – Zone 1 hepatocytes are critical for gluconeogenesis and beta-oxidation, while Zone 3 hepatocytes specialize in glycolysis and lipogenesis. MASH fibrosis can originate predominantly in either zone, but how this impacts progression of cardiometabolic biomarkers and progression of disease has not been studied. We aim to understand how predominant zone of fibrosis in MASH affects these outcomes.
Method: We obtained the Nonalcoholic Fatty Liver Disease Adult Database 2 data from the NASH Clinical Research Network study through the NIH, approved by UChicago IRB 25–0987. Subjects with fibrosis on liver biopsy and a predominant location of fibrosis of "Fibrosis is more prominent around or between portal areas" or "Fibrosis is more prominent around or between central veins" were included. We compared cardiometabolic biomarkers and outcomes of new major adverse cardiovascular events (MACE), major adverse liver outcomes (MALO), and new-onset diabetes.
Results: All analyses controlled for age, sex, and BMI. For subjects with Stage 1 fibrosis, the HbA1c was lower in subjects with Zone 1 fibrosis than in Zone 3 fibrosis (5.87 vs. 6.18, $p < 0.017$). Likewise, the HOMA-IR was lower in those with Zone 1 fibrosis than in those with Zone 3 fibrosis (7.25 vs. 8.6, $p < 0.045$). Among those with Stage 3 fibrosis the Triglyceride-Glucose Index was lower in Zone 1 fibrosis as compared to Zone 3 fibrosis (8.84 vs. 9.29, $p = 0.015$). When additionally controlling for diabetes diagnosis and hypertension diagnosis, subjects with Zone 3 fibrosis had lower rates of MACE outcomes than those with Zone 1 fibrosis (HR: 0.53, 95% CI: 0.37–0.77, $p < 0.001$). When additionally controlling for diabetes diagnosis, subjects with Zone 3 fibrosis had lower rates of MALO outcomes than those with Zone 1 fibrosis (HR: 0.36, 95% CI: 0.20–0.64, $p < 0.0006$). Subjects with Zone 3 fibrosis had higher rates of new-onset diabetes than those with Zone 1 fibrosis (HR: 1.75, 95% CI: 1.24–2.47, $p < 0.002$).
Conclusion: There were significant differences in metabolic indicators based on predominant zone of fibrosis when controlling for age, sex, and BMI. These results suggest that pre-cirrhotic Zone 1 fibrosis is associated with more cardiometabolically favorable biomarkers than Zone 3 fibrosis and less likely development of new-onset diabetes, but may result in more MACE and MALO than Zone 3 fibrosis.

THU-138

Caloric restriction and lifestyle guidance intensity in placebo arms and histologic improvement in metabolic dysfunction–associated steatohepatitis: systematic review and meta-analysis

Feng Ijung[1], Ming-Lun Yeh[2], Chia-Lun Lee[3], Jee-Fu Huang[2], Ming-Lung Yu[2]. [1]*Institute of Precision Medicine, National Sun Yat-sen University, Kaohsiung, Taiwan;* [2]*Hepatobiliary Division, Department of Internal Medicine, Kaohsiung Medical University Hospital, Kaohsiung, Taiwan;* [3]*The Center for Physical and Health Education, National Sun Yat-sen University, Kaohsiung, Taiwan*
Email: ijfeng@g-mail.nsysu.edu.tw

Background and aims: Lifestyle modification is central to metabolic dysfunction–associated steatotic liver disease (MASLD). We assessed whether more intensive lifestyle advice in placebo arms of randomized trials improves histology and whether weight change accounts for these gains. To probe the lifestyle → weight → NAFLD Activity Score (NAS) pathway, we prespecified meta-analysis and meta-regression, acknowledging that study-level mediation can be insensitive.
Method: We searched PubMed, Embase, and Medline to 30 July 2025 for randomized trials of biopsy-proven metabolic dysfunction–associated steatohepatitis with reported placebo-arm advice and outcomes. Advice was classified as none, general, or structured/detailed for exercise, diet, and caloric restriction. Primary outcomes were steatohepatitis resolution without fibrosis worsening, ≥2-point NAS reduction, and fibrosis change; secondary outcomes included NAS domains and mean changes in NAS, fibrosis, weight, and BMI. Random-effects models synthesized effects; subgroups compared advice intensity. Meta-regression tested study-level associations of weight change and intervention duration with NAS. Study-level

mediation (advice → weight → outcomes) used bootstrap confidence intervals.
Results: Seventy-eight trials (n = 5,820) were included. Across all placebo arms, absolute improvements were observed for resolution (+0.15 [0.12, 0.18]), ≥2-point NAS reduction (+0.22 [0.17, 0.28]), and ≥2-point NAS reduction without fibrosis worsening (+0.26 [0.21, 0.32]). Mean changes indicated overall decreases in NAS (−0.56 [−0.75, −0.38]) and fibrosis (−0.29 [−0.50, −0.08]); ballooning and steatosis also improved. In subgroup comparisons, structured advice outperformed general or none. Advice intensity predicted greater weight loss across exercise and diet categories. In meta-regression, larger weight loss related to greater NAS reduction (≈0.19 NAS points per 1-kg loss), and longer intervention duration tracked with additional NAS improvement. Study-level mediation showed small, imprecise indirect effects via weight, suggesting limited power and heterogeneity rather than absence of the pathway.
Conclusion: In placebo arms, structured lifestyle advice improves NAS, fibrosis, and key domains. Greater weight loss correlate with larger NAS reductions, while study-level mediation was inconclusive. Trials should standardize advice intensity and duration, and care pathways should adopt structured programs targeting sustained weight loss, diet quality, and physical activity.

THU-139
Aberrant neurovascular coupling as an early biomarker of brain involvement in MASLD with high liver stiffness
Jie Li[1], Zhuoru Jiang[2], Qian Chen[2], Wenjing Ni[2], Jun Chen[2]. *[1]Nanjing Drum Tower Hospital, Affiliated Hospital of Medical School, Nanjing University, Nanjing, China; [2]Nanjing Drum Tower Hospital, Affiliated Hospital of Medical School, Nanjing University, Nanjing, China*
Email: lijier@nju.edu.cn

Background and aims: Metabolic dysfunction-associated steatotic liver disease (MASLD) is increasingly recognized as a multisystem disorder affecting the brain. However, the impact of liver fibrosis severity on neurovascular coupling (NVC) remains poorly understood. This study aimed to investigate NVC alterations and their cognitive correlates in MASLD patients stratified by liver stiffness.
Method: A total of 111 MASLD patients were recruited and stratified into low liver stiffness (LLS; n = 58) and high liver stiffness (HLS; n = 53) groups based on magnetic resonance elastography (MRE cutoff≥2.5 kPa). NVC was quantified using the coupling between cerebral blood flow (CBF) and regional homogeneity (ReHo) derived from functional MRI. We analyzed global and voxel-wise CBF/ReHo ratios, seed-based functional connectivity (FC), and their associations with neuropsychological performance. Sensitivity analyses were performed to validate reproducibility against gray matter volume (GMV) atrophy, age, and gender.
Results: Compared to the LLS group, HLS patients exhibited significantly attenuated global CBF-ReHo coupling ($p < 0.001$), independent of GMV changes. Regionally, HLS patients manifested disrupted NVC characterized by increased CBF/ReHo ratios in the left temporal pole (superior temporal gyrus) and right insula. Furthermore, the HLS group displayed reduced functional connectivity between the right insula and the superior temporal gyrus. These neuroimaging aberrations were significantly correlated with poorer performance in executive function (Trail Making Test Part B) and memory domains (Digit Span Backwards, Auditory Verbal Learning Test). Validation analyses using ALFF confirmed the robustness of these NVC impairments.
Conclusion: High liver stiffness in MASLD is associated with significant neurovascular uncoupling and functional disconnectivity in the insular and temporal networks. These alterations are intrinsic functional impairments independent of structural atrophy and are linked to specific cognitive deficits, suggesting that NVC metrics may serve as potential biomarkers for monitoring liver-brain axis dysfunction in severe MASLD.

THU-140
Steatotic liver disease as an upstream risk factor for the development of metabolic syndrome–related disorders: a 7-year health checkup cohort study in Japan
Yoshihiro Kamada[1], Makoto Fujii[1], Hitoshi Nishizawa[1], Shiro Fukuda[1], Iichiro Shimomura[1], Eiji Miyoshi[1]. *[1]Graduate School of Medicine, The University of Osaka, Suita, Japan*
Email: ykamada@sahs.med.osaka-u.ac.jp

Background and aims: Steatotic liver disease (SLD) is regarded as a hepatic manifestation of metabolic syndrome (MetS), but its longitudinal role in the development and regression of MetS-related illnesses remains unclear. This study aimed to elucidate the prospective associations between SLD and the onset and regression of type 2 diabetes (T2D), hypertension, and dyslipidemia in a Japanese community cohort.
Method: We prospectively analyzed 714 Japanese adults (mean age 53.5 years, 73% male) participating in health screening with abdominal ultrasonography at baseline and after 7 years. Individuals with prior liver disease were excluded. Incident and regressed MetS-related diseases during follow-up were identified among participants initially disease-free or with existing disease for each outcome. Multivariate logistic regression assessed baseline predictors, including SLD and obesity (BMI ≥ 25), for both new onset and regression of T2D, hypertension, dyslipidemia, and SLD.
Results: At baseline, 60.9% of subjects were diagnosed with SLD. SLD at baseline was independently associated with higher 7-year incidence of T2D, hypertension, and dyslipidemia (all $p < 0.05$), independent of obesity. Conversely, neither T2D nor hypertension at baseline predicted SLD onset; obesity and dyslipidemia were the only independent predictors of incident SLD. Interestingly, the absence of SLD at baseline was a significant independent factor for the regression of each MetS-related disease over 7 years. In contrast, baseline obesity (BMI ≥ 25) did not contribute to the regression of any MetS-related disorder. Sankey diagram analyses illustrated that the sequence of obesity → SLD → MetS-related diseases prevailed. Subjects whose SLD regressed over 7 years exhibited reduced risk of developing new MetS-related disorders.
Conclusion: SLD is an upstream, obesity-independent risk factor for the emergence of MetS-related diseases in Japanese adults, and its absence or improvement contributes significantly to the regression of each component of MetS. Obesity itself, without SLD, does not contribute to the regression of cardiometabolic comorbidities. Improving SLD may be a pivotal therapeutic target for preventing and ameliorating major metabolic disorders.

HCV exposure modifies MASLD trajectories in people living with HIV: impaired steatosis and persistently elevated liver stiffness despite sustained virologic response
Ahmed Kamel[1], Rahma Mohamed[2], Aya M. Al-sharif[2], Mohamed Nagy[2], Andrew Saweres[2], Lamiaa Al Sehemy[2], Reham Awad Awad[2], Hanan Hamdy[2], Rana Marwan[2], Remon Atef[2], Omar Aboulhamayed[2], Gamal Esmat[2], Ahmed Cordie[2]. *[1]Faculty of Pharmacy, Cairo, Egypt; [2]Faculty of Medicine Qasr El Ainy, Cairo, Egypt*
Email: ahmedm.kamel@pharma.cu.edu.eg

Background and aims: Metabolic dysfunction-associated steatotic liver disease (MASLD) is increasingly prevalent in people living with HIV (PLWH). Whether prior hepatitis C virus (HCV) infection has lasting effects on hepatic steatosis and fibrosis trajectories remains unclear.
Method: This longitudinal cohort study included 442 PLWH with serial transient elastography assessments over up to 36 months in Egypt. PLWH with HBV co-infection or significant alcohol use were excluded. Participants were categorized as HCV-exposed (prior HCV infection with confirmed SVR12 following DAA therapy) or HCV-unexposed. Controlled attenuation parameter (CAP) and liver stiffness measurement (LSM) trajectories were modeled using

linear mixed-effects models with random intercepts. The primary analysis examined three-way interactions between time, HCV exposure status, and baseline MASLD status (CAP ≥248 dB/m), adjusting for age, sex, BMI, diabetes, and CD4 count.
Results: Of 442 PLWH, 54 (12.2%) were HCV-exposed with confirmed SVR12. Baseline characteristics were similar between groups, including MASLD prevalence (27.8% vs 25.8%, p = 0.88). For CAP trajectories, the three-way interaction (time × HCV exposure × baseline MASLD) was significant (p = 0.015). Among patients with baseline MASLD, HCV-unexposed individuals showed steatosis resolution (−1.21 dB/m/month, p < 0.001) while HCV-exposed individuals showed no improvement despite SVR (+0.08 dB/m/month, p = 0.90). Among those without baseline MASLD, HCV-unexposed individuals progressed toward steatosis (+1.42 dB/m/month, p < 0.001) while HCV-exposed showed slower, non-significant progression (+0.71 dB/m/month, p = 0.098). HCV-exposed patients demonstrated persistently higher LSM despite SVR. At baseline, HCV-exposed patients had 11.3% higher LSM without MASLD (p = 0.03) and 17.8% higher with MASLD (p = 0.05). Although both groups improved over time in the MASLD stratum (p = 0.01), HCV-exposed patients remained elevated at 6 months (14.3% higher, p = 0.06) and 12 months (11.0% higher, p = 0.31). The three-way interaction for LSM was not significant (p = 0.86).
Conclusion: Prior HCV infection in PLWH is associated with persistently elevated steatosis and fibrosis despite SVR12. HCV-exposed patients with baseline MASLD fail to achieve steatosis resolution seen in unexposed counterparts—a "metabolic trap" limiting improvement despite viral cure. These patients warrant intensified metabolic surveillance even after successful DAA therapy.

THU-142
Cardiometabolic risk factors and fibrosis in MASLD: comparison between people living with HIV and the general population in Egypt

Ahmed Cordie[1], Rahma Mohamed[2], Ahmed Kamel[3], Gamal Esmat[1]. *[1]Cairo University, Giza, Egypt; [2]Cairo University Hospitals HIV Clinic, Endemic Medicine Department, Cairo University, Cairo, Egypt; [3]Cairo University, Clinical Pharmacy Department, Faculty of Pharmacy, Cairo University, Egypt, Giza, Egypt*
Email: rahmashaheen2007@gmail.com

Background and aims: Metabolic dysfunction-associated steatotic liver disease (MASLD) encompasses diverse cardiometabolic phenotypes that may differ between populations. We compared cardiometabolic risk factor patterns and their association with hepatic fibrosis in people with HIV (PWH) versus non-HIV individuals in Egypt.
Method: This cross-sectional study included adults with MASLD from a general population screening program and an HIV clinic in Cairo. MASLD was defined according to the 2023 multi-society Delphi consensus as steatotic liver disease (controlled attenuation parameter ≥248 dB/m) plus at least one cardiometabolic criterion. Participants with hepatitis B, hepatitis C, or alcohol use were excluded. Significant fibrosis was defined as liver stiffness measurement ≥8 kPa by transient elastography. Multivariable logistic regression assessed factors associated with fibrosis, adjusting for age, sex, and individual cardiometabolic criteria.
Results: Among 417 participants with MASLD (225 non-HIV, 192 PWH), the populations exhibited distinct metabolic phenotypes. Non-HIV individuals demonstrated a glycemic-predominant profile: dysglycemia (FBS ≥100 mg/dL or HbA1c ≥5.7%) was present in 80.0% versus 36.5% of PWH (p < 0.001), and overt diabetes (FBS ≥126 mg/dL or HbA1c ≥6.5%) in 43.1% versus 10.4% (p < 0.001). Conversely, PWH showed higher triglyceride elevation (53.1% vs 40.9%, p = 0.016). PWH qualified for MASLD with fewer criteria, with 45.8% meeting only one or two criteria compared to 24.0% in non-HIV individuals. Despite this lower metabolic burden, fibrosis prevalence was equivalent between groups (14.1% vs 13.8%, p = 1.000). Low HDL cholesterol emerged as the sole independent cardiometabolic predictor of fibrosis overall (OR 1.99, 95% CI 1.06–3.87, p = 0.035) and in non-HIV individuals (OR 2.75, 95% CI 1.05–7.87, p = 0.046), with a similar trend in PWH (OR 2.14, p = 0.091). Age predicted fibrosis in non-HIV individuals (OR 1.05, p = 0.009) but not in PWH.
Conclusion: PWH with MASLD exhibit a lipid-centric metabolic phenotype distinct from the glycemic-predominant pattern in non-HIV individuals, characterized by four-fold lower diabetes prevalence but higher triglyceride abnormalities. Despite qualifying for MASLD with fewer cardiometabolic criteria, PWH achieve equivalent fibrosis rates, suggesting heightened fibrosis susceptibility per metabolic insult. Low HDL cholesterol independently predicts fibrosis across populations, warranting targeted screening strategies.

THU-147
Long-term association between Helicobacter pylori serostatus changes and incident metabolic dysfunction–associated steatotic liver disease

Ji Min Choi[1], Heesun Lee[1], Eun Kyung Choe[1], Hae Yeon Kang[1]. *[1]Seoul National University Hospital, Seoul, Korea, Rep. of South*
Email: haeykang@gmail.com

Background and aims: Metabolic dysfunction–associated steatotic liver disease (MASLD) has become the leading cause of chronic liver disease worldwide. Helicobacter pylori (H. pylori) infection has been implicated in metabolic dysregulation, yet its long-term relationship with MASLD remains unclear. This study aimed to investigate the association between H. pylori serostatus and the development of incident MASLD in the Korean population.
Method: We conducted a retrospective cohort study that included subjects who underwent general health check-ups between 2015 and 2024. H. pylori infection was assessed by serum anti–H. pylori IgG antibody testing, and MASLD was defined by hepatic steatosis with at least one cardiometabolic risk factor. Incident MASLD during follow-up was evaluated according to baseline and longitudinal changes in H. pylori serostatus.
Results: A total of 17,707 individuals without MASLD at baseline were included; of these, 10,682 (60.3%) were H. pylori–seronegative and 7,025 (39.7%) were seropositive. Over a mean follow-up of 4.3 years, the incidence of MASLD was higher in the baseline H. pylori–seropositive group than in the negative group (19.3% vs. 17.7%, p = 0.007). The risk of incident MASLD varied by changes in H. pylori serostatus, being highest in the persistently seropositive (+/+) group, followed by the persistently seronegative (−/−), seroconverted (−/+), and seroreverted (+/−) groups (hazard ratios adjusted for age, sex, smoking, exercise, and body mass index: 1.09, 1.00 [reference], 0.75, and 0.72, respectively).
Conclusion: Baseline H. pylori serostatus and its longitudinal changes were associated with the development of incident MASLD. Consideration of H. pylori serostatus dynamics may provide additional insights into MASLD risk stratification.

Maternal MASLD and timing of early-childhood adiposity: a prospective cohort of over 1,000 mother–child dyads

Cecilia Katzenstein[1], Lauren Alpert[2], Lital Aliasi-Sinai[2], Jacqueline Slobin[1], Nina Rodriguez[1], Jeanette Rios[3], Kim Le[2], Priyanka Singh[2], Keith Sigel[2], Rhoda Sperling[2], Norah Terrault[4], Jaime Chu[2], Tatyana Kushner[5]. *[1]Icahn School of Medicine at Mount Sinai, New York, United States; [2]Mount Sinai Hospital, New York, United States; [3]UCSF Department of Obstetrics, Gynecology, and Reproductive Sciences, San Francisco, United States; [4]University of Southern California Keck School of Medicine, Los Angeles, United States; [5]Weill Cornell Medicine, New York, United States*
Email: cecilia.katzenstein@icahn.mssm.edu

Background and aims: Maternal metabolic dysfunction influences fetal development and early-childhood growth, yet the significance of maternal MASLD is poorly defined. Prior small studies of maternal MASLD focus on offspring adiposity at single timepoints and report

no independent association after adjusting for maternal BMI. Whether MASLD influences the timing of early adiposity, an emerging determinant of long-term cardiometabolic risk, remains unexplored.
Method: We leveraged a prospective cohort at an urban health system to evaluate mother–child dyads with maternal MASLD assessed by ultrasound and/or CAP with concurrent metabolic risk factors. Child anthropometry from 12 to 36 months included repeated BMI and weight-for-length (WFL) measurements; analyses were restricted to children with ≥2 anthropometric measurements to define adiposity timing. The timing of first high adiposity (≥85th percentile) was categorized as early (12–18 months) or late (24–36 months). Multinomial regression models assessed associations between maternal MASLD and adiposity timing, adjusting for pre-pregnancy BMI, gestational age at delivery, infant sex, and birth-weight-for-gestational-age category.
Results: The analytic cohort included 1,055 mother-child dyads, with 40% of mothers having BMI > 30 and 79% having at least one metabolic risk factor. MASLD was present in 18.5% of pregnancies. The mean age was 29.1(± 5.9) and 41% were Hispanic. By 36 months, 87% of children reached BMI/WFL ≥85th percentile at least once between 12 and 36 months. Maternal pre-pregnancy BMI was independently associated with the overall likelihood of high adiposity in the child (adjusted OR per BMI unit 1.05; $p < 0.05$). While maternal MASLD was not associated with overall child adiposity prevalence, in adjusted multinomial models MASLD was associated with a higher predicted probability of early-onset high adiposity at 12–18 months (90.8%) and a lower probability of later onset at 24–36 months (7.2%), compared with pregnancies without SLD (83.3% and 15.1%; p = 0.035).
Conclusion: In a metabolically high-risk cohort with a high prevalence of early-childhood adiposity, maternal MASLD was associated with earlier onset of high adiposity independent of maternal BMI. These findings suggest that maternal MASLD may influence postnatal metabolic programming by altering the timing of adiposity gain rather than adiposity burden alone. Timing-specific effects may represent an important and previously unrecognized pathway linking maternal liver disease to offspring metabolic risk.

THU-149
Impact of endothelial dysfunction on disease progression in patients with MASLD and microalbuminuria

Hijran Khidirova[1], Nermin Musayeva[1]. [1]*Azerbaijan Medical University, Baku, Azerbaijan*
Email: dr.musayevanarmin37@gmail.com

Background and aims: MASLD is a common chronic liver disease, generally associated with obesity, insulin resistance, and metabolic syndrome. Recent evidence suggests that endothelial dysfunction may play an important role in disease progression by contributing to liver inflammation, fibrosis, and increased cardiovascular risk. Biomarkers such as Endocan, ADMA, hs-CRP, and IL-6 may provide further information about vascular and inflammatory changes in MASLD. This study aimed to find the association between endothelial dysfunction and liver disease severity, and to evaluate the predictive value of traditional and novel non-invasive biomarkers in MASLD patients.
Method: The study enrolled 180 patients with ultrasound-confirmed MASLD, divided into two groups based on UACR: 84 patients with microalbuminuria and 96 without. Cllinical and laboratory analysis, metabolic parameters, and steatosis grading, FIB-4, and MASLD Fibrosis Score. Endocan, ADMA, hs-CRP, IL-6. Statistical analyses used Student's t-test or Mann–Whitney U test for group comparisons, Pearson or Spearman correlation for associations, and multivariate regression to identify independent predictors of fibrosis.
Results: Patients with microalbuminuria exhibited significantly elevated FIB-4 scores (1.9 ± 0.6 vs 1.2 ± 0.5, p < 0.001), and higher ultrasound steatosis grades (p < 0.01) compared to patients without microalbuminuria. Endocan (3.8 ± 1.2 vs 2.4 ± 0.8 ng/mL, p < 0.001) and ADMA (0.72 ± 0.15 vs 0.55 ± 0.10 μmol/L, p < 0.001), were elevated in the microalbuminuria group. İnflamatory markers hs-CRP (5.2 ± 2.0 vs 3.1 ± 1.5 mg/L, p = 0.001) and IL-6 (6.5 ± 2.3 vs 4.0 ± 1.7 pg/mL, p < 0.001), were significantly higher. Multivariate regression revealed that microalbuminuria and elevated Endocan levels independently predicted higher fibrosis scores (β = 0.42, p < 0.001 and β = 0.31, p = 0.004, respectively) Correlation analyses demonstrated strong positive associations between endothelial biomarkers and liver disease severity, including steatosis grade and FIB-4 scores.
Conclusion: Endocan, ADMA, and inflammatory mediators, represent endothelial dysfunction and are associated with more advanced liver disease in MASLD and microalbuminuric patients. Results support the role of non-invasive biomarkers in the identification of subjects at risk of progression and may contribute to improved monitoring strategies when combined with traditional clinical assessments.

Risk stratification of chronic kidney disease in adults using noninvasive fibrosis tests based on the american diabetes association algorithm

Chan-Young Jung[1], Hye Won Lee[1], Jung Il Lee[1], Han Ah Lee[2], Seung Up Kim[1]. [1]*Yonsei University College of Medicine, Seoul, Korea, Rep. of South;* [2]*Chung-Ang University, Seoul, Korea, Rep. of South*
Email: ksukorea@yuhs.ac

Background and aims: Although the American Diabetes Association (ADA) recently established a diagnostic algorithm for the early detection of liver fibrosis among high-risk individuals, its implications for chronic kidney disease (CKD) risk stratification remain unclear. We investigated whether the ADA diagnostic algorithm can effectively stratify CKD risk in individuals with high risk of future cirrhosis.
Method: This was a retrospective cohort study of 9,264 adults without pre-existing CKD who underwent vibration-controlled transient elastography from April 2006 to October 2018. Participants were categorized into three groups: 1) no metabolic criteria; 2) low risk (FIB-4 < 1.3 or 1.3–2.67 with liver stiffness [LS] <8kPa); and 3) high risk (FIB-4 > 2.67, or 1.3–2.67 with LS ≥ 8kPa). The primary outcome was incident CKD, defined by estimated glomerular filtration rate (eGFR)<60 mL/min/1.73 m^2 or proteinuria (≥1+) on two consecutive tests. Secondary outcomes included ≥25% eGFR decline on two visits and 3- and 5-year CKD risk.
Results: During a mean follow-up of 3.7 years, 440 (4.7%) patients developed incident CKD. When stratified by ADA algorithms, multivariable Cox models revealed a 1.55–fold (95% confidence interval [CI], 1.11–2.17) higher risk of incident CKD in the high-risk group, compared to those with no metabolic abnormalities. The high-risk group also had a 2.59–fold higher risk (95% CI, 2.06–3.26) of a 25% eGFR decline (mean follow-up 3.5 years) and a 1.48–fold (95% CI, 1.00–2.18) higher 5-year CKD risk, compared to those with no metabolic abnormalities.
Conclusion: The two-step algorithms proposed by the ADA can effectively stratify CKD risk in individuals with a high risk of future cirrhosis.

Email: florian.koutny@stpoelten.lknoe.at

Background and aims: Metabolic dysfunction–associated steatotic liver disease (MASLD) is a growing global health problem and is linked to both liver disease and cardiometabolic risk. However, although standard frequentist analyses suggest a link with coronary disease, the size of this association after full adjustment for cardiovascular risk factors often remains uncertain. In this study we use Bayesian models with different priors to evaluate both the strength of the association and the robustness of the findings.
Method: We included 1,427 participants from the Paracelsus 10,000 study who had MASLD diagnosed by ultrasound. Coronary artery calcification (Agatston score > 0) was measured using cardiac CT. We ran Poisson regression models (both frequentist and Bayesian), adjusting for cardiovascular risk factors in three steps: (1) unadjusted, (2) adjusted for SCORE2, and (3) fully adjusted for age, sex, metabolic syndrome, and smoking status. We used three different prior distributions (non-informative, pessimistic, and skeptical). Results are reported as posterior medians with a 95% highest posterior density (HPD) interval, and as probabilities for IRR > 1 (any positive effect), IRR > 1.10 (at least 10% higher risk), and IRR > 1.20 (at least 20% higher risk).
Results: Frequentist Poisson regression showed a strong unadjusted association between MASLD and coronary calcification (IRR 1.64, p < 0.001), which remained significant after SCORE2 adjustment (IRR 1.15, p = 0.034) but attenuated and became non-significant after full adjustment (IRR 1.13, p = 0.079). Bayesian models confirmed a clear unadjusted positive effect (non-informative prior: IRR 1.65, 95% HPD 1.38–1.92; P[IRR > 1] = 100%). After full adjustment, there was still a 29% probability of a strong effect (IRR > 1.20). Under a skeptical prior, evidence weakened after adjustment (P[IRR > 1] = 99% unadjusted; 78.4% after SCORE2; 69.9% fully adjusted; IRR 1.03, 95% HPD 0.93–1.13), with low probability of clinically relevant effects (P[IRR > 1.10] = 10.9%; P[IRR > 1.20] = 0.2%).
Conclusion: MASLD is associated with coronary artery calcification, even after accounting for cardiovascular risk factors. However, the Bayesian results indicate that much of this association is driven by age, sex, and metabolic factors, and that a large effect (>20% higher risk) is unlikely after full adjustment. Overall, MASLD seems to be linked to a higher cardiometabolic risk profile and subclinical atherosclerosis, while its additional independent effect appears small.

THU-154

Impact of liver biopsy on patients' readiness to participate in metabolic-dysfunction associated steatotic liver disease drug trials

Piotr Krzeski[1], Yan Su[2], Ping Xu[2], Nicholas Donahue[2], Jenson Ruiz Garcia[3], Kelly Millhaem[2], Phillippa Miranda[2]. *[1]Medpace, Warsaw, Poland; [2]Medpace, Cincinnati, United States; [3]Medpace, London, United Kingdom*
Email: p.krzeski@medpace.com

Background and aims: Surrogate endpoints based on liver biopsy are currently required by regulators in clinical trials for accelerated approval of novel therapies in metabolic dysfunction-associated steatotic liver disease (MASLD). While the requirement for the liver biopsy (typically at baseline and end of treatment) is likely to negatively affect patients' readiness to participate in a drug trial because of its perceived risks and discomforts, the impact remains largely unquantified. Our aim was to estimate the impact of liver biopsy requirement on patients' readiness to participate in MASLD drug trials using screening rates (rates of signing informed consent forms) as a quantitative marker.
Method: We selected early phase (1b through 2b) MASLD trials run at 10 or more US sites which screened at least 100 patients, with or without mandatory biopsy at screening at our institution. We analyzed descriptively and calculated the screening rate ratio with a negative binominal regression model using mandatory biopsy status at screening (with vs without) as the main factor, and investigational product formulation (IP, oral vs injectable) and year of the study as covariates and an offset for time of enrollment to adjust for the varying enrollment durations among sites/studies.
Results: We identified 19 trials (12 with and 7 without mandatory biopsy run at cumulative 444 and 169 US sites, respectively). Two trials in the group without mandatory biopsy were excluded as their screening rates exceeded preidentified outlier criteria. The mean screening rates were 1.72 and 3.03 patients per site per month in trials with and without mandatory biopsy at screening, respectively, with the mean screening rate ratio = 1.77 with 95% CI (1.50, 2.09) and p < 0.0001. No statistically significant impact of IP formulation or year of study on the screening rate was found.
Conclusion: MASLD patients are approximately twice as likely to accept participation in clinical trials without mandatory liver biopsy compared to trials with the requirement, with potentially significant time and cost implications on the trials' execution.

THU-155

Association between biomarkers of subclinical cardiovascular disease and metabolic dysfunction-associated steatotic liver disease

Morgane L'Henaff[1], Jeanne Hersant[1,2], Marine Roux[2], Frédéric Gagnadoux[1,2], Patrice Rodien[1,2], Christophe Aubé[1,2], Isabelle Fouchard[1,2], Loic Bière[1,2], Frédéric Oberti[1,2], Adrien Lannes[1,2], Jerome Boursier[1,2]. *[1]Angers university Hospital, Angers university, Angers, France; [2]Angers university, Angers university Hospital, Angers, France*
Email: jeboursier@chu-angers.fr

Background and aims: Cardiovascular disease (CVD) is the leading cause of mortality in patients with metabolic dysfunction-associated steatotic liver disease (MASLD). Meta-analyses have suggested an independent association between MASLD and early atherosclerosis, but the association with the severity of the liver disease remains debated. Furthermore, the estimation of 10-year cardiovascular risk with SCORE2 has been scarcely investigated in MASLD. We aimed to evaluate the association between the severity of MASLD and biomarkers for subclinical atherosclerosis, as well as with SCORE2.
Method: A total of 452 patients were included from 3 departments in our institution: Hepatology (MASLD), Diabetology (metabolic syndrome), and Pneumology (sleep apnoea syndrome). All patients had MRI-PDFF and FibroScan examinations. Liver steatosis was defined by

liver fat fraction ⩾5%, and liver fibrosis was categorized into 3 groups: mild (< 8 kPa), intermediate (8–12 kPa), advanced (>12 kPa). Subclinical atherosclerosis was evaluated with carotid intima-media thickness (CIMT), pulse wave velocity (PWV), and heart rate-adjusted augmentation index (@75AIx). 10-year cardiovascular risk was estimated using the SCORE2 and its adaptations (SCORE2-OP and SCORE2-Diabetes).
Results: There were 5 subgroups of patients: 21 controls (no liver steatosis and no other cardiometabolic risk factor than overweight/obesity); 135 metabolic patients (metabolic risk factors but no steatosis); and 296 patients with steatosis of whom 210 had mild, 50 intermediate, and 36 advanced liver fibrosis. CIMT and PWV were not associated with liver steatosis or fibrosis severity in multivariate analyses adjusted for age, sex, cardiovascular history, alcohol consumption, smoking, and the 5 cardiometabolic risk factors. @75AIx was not associated with steatosis but was paradoxically inversely associated with fibrosis severity ($p < 0.05$). SCORE2 was lower in control patients and was independently associated with metabolic and MASLD groups. However, there was no significant difference in SCORE2 results among the metabolic, mild MASLD, intermediate MASLD, and advanced MASLD groups.
Conclusion: In this well-phenotyped cohort (MRI PDFF, FibroScan), the biomarkers for subclinical atherosclerosis and the 10-year estimated cardiovascular risk do not correlate with MASLD severity. This suggests that cardiovascular risk assessment should be considered for all patients with MASLD, regardless of the severity of their liver disease.

THU-156
Clinical predictors of increased liver stiffness over time in metabolic dysfunction-associated steatotic liver disease: a prospective real-life study

Stéphanie André-Dumont[1,2], Joyce Scholtens[1], Nicolas Lanthier[1,2]. *[1]Service d'Hépato-gastroentérologie, Cliniques universitaires Saint-Luc, Brussels, Belgium; [2]Laboratory of Gastroenterology and Hepatology, Institut de Recherche Expérimentale et Clinique, Université catholique de Louvain, Brussels, Belgium*
Email: nicolas.lanthier@saintluc.uclouvain.be

Background and aims: Static measurements of liver stiffness (LS) assessed by transient elastography are mainly used in routine practice to evaluate MASLD, whereas dynamic data are lacking. Here, we wanted to evaluate LS dynamics to reflect the evolution of MASLD.
Method: Patients with MASLD assessed with standardised serial LS from baseline diagnostic and at one- and three-year follow-ups (FU) were prospectively included. They were classified as progressors (PRO, ≥ 20% LS increase compared to baseline), stable (STB, <20% of LS variations) and improvers (IMP, ≥ 20% LS decrease compared to baseline).
Results: 192 patients diagnosed with MASLD were included. At baseline, 57% were F0-F1, 38% F2-F3 and 5% F4. 36% were treated for type 2 diabetes. Initial management included lifestyle advice (74%), dietitian support (8%), interventional clinical trial (7%), bariatric surgery (6%) and glucagon-like peptide-1 receptor agonist (GLP1-RA, 3%). After one year (n = 192), 30% were IMP, 47% were STB and 23% were PRO. IMP at one-year were characterised at baseline by a higher body mass index (IMP, median, 32.0 vs. STB, 30.5 vs. PRO, 30.9 kg/m^2; $p = 0.027$), a larger waist circumference (115 vs. 107 vs. 107 cm; $p = 0.002$) and a higher LS (8.9 vs. 6.3 vs. 5.0 kPa; $p < 0.001$). Moreover, IMP had a greater reduction than PRO in body weight (BW, −5 vs. 0%; $p < 0.001$), alanine aminotransferase (−34 vs. −8%; $p = 0.004$), gamma-glutamyl transferase (−25 vs. −5%; $p = 0.032$) and controlled attenuation parameter (−7 vs. −2%; $p = 0.045$). In multivariate logistic regression, after adjustment for sex and BMI, higher baseline age (OR = 1.052; $p = 0.012$) and ALT (OR = 1.027; $p < 0.006$), and increase in BW (OR = 1.107; $p = 0.019$) and ALT (OR = 1.012; $p = 0.025$) were independent predictors of being PRO after one year of FU. After three years (n = 134), the proportion of patients in the three groups remained similar (IMP 34%; STB 42%; PRO 25%) with comparable characteristics.
Conclusion: This is the first prospective data on standardised longitudinal LS in real-life conditions within a MASLD cohort. Screening for advanced fibrosis leads to effective and sustainable lifestyle advice with a positive impact on the severity of liver disease. While around 40% of patients remain stable at one and three years, with normal baseline LS, older patients with low LS, elevated ALT who gain weight and increase their ALT levels over time should be monitored.

THU-158
Are current MASLD alcohol thresholds appropriate for all patients? The role of metabolic vulnerability

Rosa Lombardi[1], Felice Cinque[1], Annalisa Cespiati[1], Edoardo Pulixi[1], Francesca Alletto[1], Daniel Smith[1], Erika Fatta[1], Cristina Bertelli[1], Gabriele Maffi[1], Anna Ludovica Fracanzani[1]. *[1]Fondazione IRCCS Ca' Granda Ospedale Maggiore Policlinico di Milano, University of Milan, Milan, Italy*
Email: rosalombardi@hotmail.it

Background and aims: In patients with steatotic liver disease (SLD) fixed alcohol intake thresholds have been set to define metabolic dysfunction–associated steatotic liver disease (MASLD) and metabolic-associated alcohol-related liver disease (Met-ALD). Individual susceptibility to alcohol-related liver damage may vary according to metabolic and biological vulnerability. We aimed to evaluate whether the association between alcohol intake and liver stiffness differs across age, sex, metabolic comorbidities and genetic background.
Method: We analyzed a cohort of 1,099 adults with SLD (66% males, mean age 51 ± 12 ys), (1034 MASLD; 60 Met-ALD). Alcohol intake was assessed as a continuous variable (g/week). Liver damage was evaluated by liver stiffness measurement (LSM) by Fibroscan. Multivariable linear regression models were used to assess the association between alcohol and LSM, adjusting for age, sex, obesity, diabetes, and PNPLA3 genotype. Interaction terms were included to test effect modification by all covariates. Additional analyses were performed restricting the population to patients classified as MASLD.
Results: In the overall cohort, alcohol intake was independently associated with higher liver stiffness ($B = 0.005$, $p = 0.045$), with a significant interaction by obesity ($B = 0.015$, p for interaction 0.007) and by PNPLA3 genotype ($B = -0.013$, p for interaction = 0.019), indicating a weaker alcohol–LSM association among PNPLA3 carriers. A significant interaction between alcohol intake and sex was also detected, with alcohol-related increases in liver stiffness observed in women but not in men ($B = 0.025$, p for interaction = 0.003). In MASLD patients, alcohol intake was associated with increased LSM even within current MASLD alcohol thresholds ($B = 0.009$, $p = 0.045$). A significant interaction between alcohol intake and obesity was observed (B for interaction = 0.023, $p = 0.019$), indicating a steeper increase in liver stiffness with increasing alcohol consumption in obese individuals. No significant interaction was observed with age categories or diabetes after interaction testing.
Conclusion: Alcohol-related liver damage in SLD is associated with liver damage even at alcohol intake levels currently considered compatible with MASLD and seems to be strongly influenced by metabolic vulnerability and sex. These findings challenge the use of uniform alcohol thresholds and support a more individualized, risk-based approach to alcohol consumption recommendations in MASLD.

THU-159

Brief alcohol counseling in steatotic liver disease: a single-center observational study of six-month changes in alcohol use, noninvasive liver metrics, and quality of life

Erica Nicola Lynch[1], Armando Curto[1], Michele Tanturli[1], Rocco Iamello[1], Gabriele Bianchi[1], Tommaso Mello[1], Tommaso Innocenti[1], Gabriele Dragoni[1], Andrea Galli[1]. *[1]University of Florence, Department of Experimental and Clinical Biomedical Sciences "Mario Serio", Florence, Italy*
Email: ericanicola.lynch@unifi.it

Background and aims: Steatotic liver disease (SLD) is the leading cause of chronic liver disease. NAFLD has been renamed metabolic dysfunction–associated SLD (MASLD); SLD also includes MASLD with moderate alcohol intake (MetALD) and alcohol-related liver disease (ALD). Alcohol and metabolic risk factors synergistically worsen outcomes, so MASLD guidance may not apply to MetALD. We aim To quantify alcohol use in SLD, describe MASLD/MetALD/ALD distribution, and evaluate a structured brief alcohol-counseling program on alcohol intake, quality of life, and non-invasive liver indices.
Method: Single-center observational study (Careggi University Hospital, Florence). Adults with imaging- or biopsy-confirmed MASLD were enrolled (May 2024–May 2025). Alcohol intake (units/day, days/week, binge) and AUDIT were recorded with liver stiffness and CAP and key scores (FIB-4, FAST, NFS). Patients reporting >1 unit on >1 day/week and consenting received 10–15 min structured counseling with reinforcement at ~3 and 6 months. Quality of life was assessed with SF-LDQOL.
Results: Ninety-two patients were included (60.1 ± 13.4 years; 62% men; BMI 29.6 ± 4.35 kg/m^2): MASLD 84.8%, MetALD 12.0%, ALD 3.3%. Alcohol use was reported by 56.5%, mostly low–moderate (1.57 units/day; 1.9 days/week; binge 6.5%; AUDIT 2.73). Baseline: stiffness 8.94 kPa; CAP 296 dB/m; FIB-4 1.14; FAST 0.32; NFS −1.59. Twenty-seven initiated counseling; 22 completed ~6-month follow-up with reductions in alcohol use (3.57 to 1.52 units/day; 5.00 to 2.15 days/week; weekly max 6.07 to 2.68; all $p < 0.001$), AUDIT (7.62 to 3.86; $p < 0.001$), and binge episodes (14.8% to 3.8%); 36.4% achieved abstinence. CAP decreased 281.9 to 246.1 dB/m (−12.7%; $p = 0.002$), FAST improved 0.28 to 0.18 ($p = 0.02$), and stiffness trended down 7.29 to 5.91 kPa ($p = 0.12$). SF-LDQOL improved 148.5 to 153.1 ($p = 0.045$); CAP reduction was significant in MASLD and MetALD but not ALD.
Conclusion: Brief structured alcohol counseling significantly reduced alcohol intake and improved CAP, FAST and quality of life at ~6 months, with greatest benefits in MetALD. Despite small sample size, single-center design and no controls, results support integrating brief alcohol interventions into routine SLD care and validating them in larger controlled multicenter studies.

THU-163

The pseudo-normalization trap in metabolic dysfunction-associated steatotic liver disease: hypolipidemia (low density lipoprotein level < 95 mg/dl) predicts all-cause mortality in a real world cohort

Aysel Mammadyarzade[1], Elvan Isik[2], Ilker Turan[2], Fulya Günsar[2], Zeki Karasu[2], Ulus Akarca[2]. *[1]Ege University, Medical Faculty, Department of Internal Medicine, Izmir, Türkiye; [2]Ege University, Medical Faculty, Department of Gastroenterology, Izmir, Türkiye*
Email: ulusakarca@gmail.com

Background and aims: Dyslipidemia is a key feature of Metabolic Dysfunction-Associated Steatotic Liver Disease (MASLD), and guidelines universally recommend lipid management. However, in advanced disease, declining lipids often reflect impaired synthetic function, a phenomenon known as "reverse epidemiology." We aimed to investigate whether this "pseudo-normalization" of Low-Density Lipoprotein (LDL) serves as an independent predictor of mortality in a real-world MASLD cohort.
Method: We analyzed a longitudinal real-world cohort of 995 patients with MASLD followed for a mean of 3.9 years. Patients were stratified by baseline LDL levels. The primary outcome was all-cause mortality or liver transplantation. Survival was analyzed using Kaplan-Meier curves and multivariate Cox proportional hazards models. To isolate the prognostic value of lipids from metabolic profile, the multivariate model was adjusted for demographics (age, sex), metabolic control (fasting blood glucose), and liver injury (ALT).
Results: During follow-up, 111 mortality events occurred (11.2%). A striking inverse dose-response relationship was observed between LDL and survival. Patients in the lowest LDL quartile (< 95 mg/dL) had the highest mortality rate (19.1%), whereas those in the highest quartile (> 146 mg/dL) had the lowest (3.4%) (Log-rank $p < 0.0001$). In multivariate analysis, low LDL (< 95 mg/dL) remained a significant independent predictor of mortality (Hazard Ratio: 1.86, 95% CI: 1.19–2.90, $p = 0.006$), even after adjusting for age, sex, fasting glucose, and ALT. While age ($p < 0.001$) and glucose ($p < 0.001$) were also predictive, low LDL carried a distinct risk burden independent of these metabolic factors. Mechanistically, this high-risk phenotype was linked to disease severity; patients in the lowest LDL quartile had significantly higher baseline FIB-4 scores compared to the highest quartile (Median: 1.32 vs. 0.97, $p < 0.001$), despite similar age profiles.
Conclusion: This real-world study confirms a "Lipid Paradox" in MASLD: spontaneous hypolipidemia signals a high-risk phenotype. Importantly, this risk is independent of age, diabetes, and liver inflammation. Clinicians should be wary of the "pseudo-normalization trap": in MASLD, low LDL levels should not be interpreted as metabolic success but as a robust "red flag" for poor outcomes.

Email: jampuero-ibis@us.es

Background and aims: A recent international consensus redefined obesity (Rubino et al., *Lancet* 2025), moving beyond BMI as the sole reference metric. The Body Roundness Index (BRI), which better reflects central adiposity and inflammation, may more accurately capture obesity-related risk. This study aimed to assess the utility of BRI in metabolic-associated steatotic liver disease (MASLD) and its association with clinical and prognostic parameters.
Method: We included 1352 MASLD patients from the HEPAMET registry with available data to calculate BMI (weight, height) and BRI (height, waist). BMI was categorized as overweight (>25), obesity (>30), and severe obesity (>40). BRI was stratified into quintiles (Zhang et al., *JAMA* 2024). Histological, biochemical, and metabolic parameters were analyzed; follow-up was available for 720 patients.
Results: Mean age was 52.3 ± 12.5 years; 45.7% were men. MASH was present in 39.8%, and fibrosis stages were F0 33%, F1 28%, F2 12.8%, F3 15.5%, F4 8.7%. Mean BMI was 34.9 ± 8.4 (obesity 68.7%), and mean BRI 7.56 ± 2.7 (≥5.46 in 77%). BMI was not associated with MASH (p = 0.23) or fibrosis (p = 0.81). In contrast, BRI correlated with both MASH (Q1 11.5%, Q2 25.8%, Q3 38.4%, Q4 41.3%, Q5 42.9%; p = 0.001) and fibrosis (F0 7.31 ± 3 vs. F1 7.48 ± 2.6 vs. F2 7.47 ± 2.5 vs. F3 7.92 ± 2.3 vs. F4 8.01 ± 2.6; p = 0.023). Independently, BRI predicted advanced fibrosis [OR 1.08 (95% CI 1.02–1.14); p = 0.015], along with age, AST, GGT, platelets, diabetes, and hypertension. During follow-up, BRI was higher in patients who developed cirrhosis (7.77 ± 2.3 vs 6.86 ± 2.1; p = 0.005) or died (7.69 ± 2.6 vs 6.95 ± 2.2; p = 0.031). A non-significant trend was observed for hepatic decompensation (p = 0.223), possibly due to the small number of events (21/720). In multivariate analysis, BRI independently predicted progression to cirrhosis [HR 1.23 (95% CI 1.08–1.41); p = 0.002], together with ALP, GGT, platelets, and hypertension. BRI also predicted mortality [HR 1.17 (95% CI 1.02–1.33); p = 0.025], along with age and platelet count.
Conclusion: BRI is an independent predictor of advanced fibrosis, cirrhosis progression, and mortality in MASLD, providing superior prognostic accuracy than BMI.

THU-165

The impact of metabolic dysfunction–associated steatotic liver disease in patients with biopsy proven drug induced liver injury

Iulia Minciuna[1], Mihai Zaharia[2], Tudor Cosma[1], Ana Maria Fit[1], Ioana Rusu[3], Oana Nicoara-Farcau[1], Corina Radu[1], Buzias Maria[1], Horia Ștefănescu[2], Bogdan Procopet[1]. [1]Regional Institute of Gastroenterology and Hepatology "O. Fodor," University of Medicine and Pharmacy "Iuliu Hatieganu," Cluj-Napoca, Cluj-Napoca, Romania; [2]Regional Institute of Gastroenterology and Hepatology "O. Fodor," Cluj-Napoca, Romania; [3]Department of Pathology, Regional Institute of Gastroenterology and Hepatology "O. Fodor", Cluj-Napoca, Romania
Email: Iuliabreaban@yahoo.com

Background and aims: Drug-induced liver injury (DILI) is a heterogeneous condition whose biochemical and histological features may overlap with metabolic dysfunction–associated steatotic liver disease (MASLD), now the most prevalent chronic liver disease worldwide. As coexistence of MASLD and DILI becomes increasingly common, their interaction remains insufficiently characterized. The aim of this study was to assess the prevalence of MASLD features in biopsy-proven DILI and their association with liver injury patterns, histology, and clinical outcomes.
Method: We retrospectively analyzed patients evaluated for suspected DILI at a tertiary center between 2015 and 2025. Patients with available liver biopsy were included and classified as pure DILI or DILI with MASLD features. Clinical, biochemical, and histological data were collected. DILI causality was assessed using RUCAM, and injury patterns were defined by standard criteria.
Results: Among 100 patients with biopsy-confirmed DILI, cholestatic injury was the most common pattern (58.6%). Hepatocellular injury occurred more frequently in pure DILI (26.3% vs 13.1%), whereas mixed injury predominated in MASLD+DILI (32.8% vs 7.9%, p = 0.026). According to RUCAM, DILI was rated as probable or very probable in 83.9% of cases. Controlled attenuation parameter values were higher in MASLD+DILI (245 vs 169 dB/m, p = 0.036), while liver stiffness (6.5 vs 9.8 kPa, p = 0.2) and HVPG (median 5 kPa in both groups) were comparable. Histologically, cholestasis was observed in 86.7% of biopsies, and fibrosis was mild in most cases (F0–F1 >90%). Eosinophilic infiltration was more frequent in MASLD+DILI (84.4% vs 64.3%, p = 0.048), with no association with serum eosinophilia. Laboratory analyses showed that only pure hepatocellular and cholestatic patterns correlated with inflammation (r = 0.20, p = 0.044) and histological cholestasis (r = 0.28, p = 0.004), respectively; GPT >5 × ULN was associated with moderate-to-severe lobular inflammation (r = 0.28, p = 0.005). Hospitalization duration (median 12 days) and the need to for liver transplantation (1.7% vs 2.6%, p = 0.7) did not significantly differ between patients with and without MASLD.
Conclusion: MASLD is frequently observed in patients with biopsy-proven DILI and is associated with differences in liver injury patterns and histological features, including a higher prevalence of mixed injury and eosinophilic infiltration. However, the presence of MASLD does not appear to adversely affect fibrosis severity or short-term clinical outcomes.

THU-166

The prevalence of microvascular lesions in metabolic-associated steatotic liver disease patients without cirrhosis

Iulia Minciuna[1], Ana Maria Fit[2], Ioana Rusu[2], Oana Nicoara-Farcau[3], Corina Radu[3], Cristian Moldovan[4], Cristina Adela Iuga[5], Andreea Fodor[3], Tudor Cosma[1], Buzias Maria[1], Horia Ștefănescu[3], Bogdan Procopet[1]. *[1]Regional Institute of Gastroenterology and Hepatology "O. Email: Iuliabreaban@yahoo.com

Background and aims: Although portal hypertension is traditionally considered a late complication of advanced fibrosis, growing evidence indicates that it may develop early in metabolic-associated steatotic liver disease (MASLD), even in the absence of cirrhosis, likely driven by porto-sinusoidal microvascular injury involving endothelial dysfunction, platelet activation, and neutrophil extracellular trap (NET)–associated immunothrombosis. This study aimed to determine the prevalence of portosinusoidal vascular disorder (PSVD)-type microvascular lesions in MASLD patients without cirrhosis and to assess NET presence across disease stages.
Method: In this retrospective study, all adult patients with MASLD who underwent liver biopsy between 2015 and 2024 were included. Biopsies were blindly re-evaluated for fibrosis stage, steatohepatitis activity, and PSVD-related microvascular lesions. In 32 biopsies, NET area and score were assessed by confocal immunofluorescence microscopy.
Results: We identified 75 biopsy-proven, non-cirrhotic MASLD patients with a median age of 54 years, predominantly female, a median liver stiffness of 9.5 kPa (3.3–42), and a median HVPG of 5 mmHg (2–16). Clinical signs of portal hypertension were observed in 46.7% of patients, including splenomegaly (32.8%), esophageal varices (8.8%), portosystemic collaterals (14.7%), and ascites (8%). Moderate-to-severe steatosis was observed in 69.8%, lobular and portal inflammation in 75% and 82.9%, respectively, while 34.2% met criteria for MASH and 85.5% had early-stage fibrosis (F0–F1). Nonspecific microvascular lesions were present in 89.5% of biopsies and specific PSVD-type lesions in 68.4%, with perisinusoidal fibrosis (65.8%) and architectural disturbances (60.5%) being the most frequent nonspecific findings, and obliterative venopathy (65.8%) the predominant specific lesion. Specific lesions were most frequent in F0–F1 fibrosis, whereas nonspecific ones were present in all F2–F3 cases. Steatosis severity did not influence lesion distribution. NET area increased significantly with fibrosis stage and was higher in patients with perisinusoidal fibrosis and portal hypertension. Overall, 80.3% of MASLD patients fulfilled PSVD diagnostic criteria.
Conclusion: Microvascular histological lesions are highly prevalent in MASLD, highlighting the need for increased vigilance in identifying associated vascular changes with potential prognostic implications. NET burden correlates with perisinusoidal fibrosis and signs of portal hypertension.

THU-167

Weathering due to accelerated biological aging among younger patients with metabolic dysfunction-associated steatotic liver disease (MASLD)

Andrew Moon[1], A. Sidney Barritt Iv[1], Chelsea Anderson[1], Jana Phillips[1], Cathrine Hoyo[2], Cynthia Moylan[3], Joellen Schildkraut[4], Melissa Troester[1]. *[1]University of North Carolina, Chapel Hill, NC, United States; [2]NC State University, Raleigh, United States; [3]Duke University, Durham, United States; [4]Emory University, Atlanta, United States*
Email: andrew.moon@unchealth.unc.edu

Background and aims: Premature aging due to environmental, social, and economic stressors, known as weathering, is associated with systemic inflammation, obesity, diabetes, hypertension, and decreased longevity. Weathering, which can be estimated with simple blood tests, may lead to early-onset metabolic dysfunction-associated steatotic liver disease (MASLD). Intervening in early aging processes might prevent or improve conditions like MASLD by slowing cellular deterioration. This study compares weathering between (1) MASLD and non-MASLD patients and (2) MASLD patients with and without advanced chronic liver disease (ACLD).
Method: This was a cross-sectional study including patients age 18–40 years with MASLD (defined by treating hepatologist) and non-MASLD controls seen in GI/hepatology clinic. ACLD was defined as F3/4 fibrosis on biopsy or transient elastography (LSM ≥ 15 kPa). We collected clinical data and labs at the time of enrollment and calculated weathering (chronological minus biological age). Biological age was estimated using the Klemera–Doubal method, which combines seven clinical biomarkers (albumin, alkaline phosphatase, creatinine, C-reactive protein, hemoglobin A1c, systolic blood pressure, and total cholesterol) in a weighted equation using coefficients derived from population-based NHANES data. Group differences in weathering (negative values corresponding to accelerated aging) were assessed using general linear models adjusted for age and sex.
Results: We enrolled 81 patients: 40 non-MASLD (60% F; 25% cryptogenic CLD, 20% viral hepatitis, 25% miscellaneous CLD, 30% no CLD; 13% cirrhosis), 36 MASLD without ACLD (50% F), and 5 with MASLD with ACLD (20% F). Mean chronological ages were 30, 32, and 28 years and biological ages were 34, 46, and 57, respectively. MASLD patients showed more weathering than non-MASLD, with an adjusted mean difference of −11.5 (95% CI: −18.5, −4.5, p = 0.001). There were no statistically significant differences in weathering between MASLD with ACLD and MASLD without ACLD (−13.0, 95% CI: −32.8, 6.7, p = 0.196).
Conclusion: Younger adults with MASLD exhibited greater weathering than those without MASLD. Numerically greater weathering was seen in MASLD with ACLD compared to MASLD without ACLD but this difference was not statistically significant, likely due to a small sample size in the ACLD group. Addressing contributors to weathering including chronic stress and exposure to environmental toxins could reduce the growing burden of MASLD in younger populations.

THU-170

VAT–MASLD–Sarcopenia cascade: metabolic metamorphosis from anabolism to catabolism and its therapeutic implications in liver disease

Astushi Nakamura[1], Takeshi Ichikawa[2]. *[1]Koukan clinic, kawasaki, Japan; [2]Nippon Koukan, Kawasaki, Japan*
Email: naka.a@mac.com

Background and aims: The increasing prevalence of obesity and MASLD necessitates establishing optimal nutritional strategies for sarcopenic obesity(SO) in chronic liver disease(CLD). This study addressed this challenge using a multimodal MRI analysis that simultaneously quantifies liver stiffness(LS), hepatic fat content (PDFF), muscle area, and visceral adipose tissue(VAT) area.
Method: We conducted a single-center retrospective study of 860 patients with CLD. Patients were classified according to etiology into a MASLD group (n = 275) and a non-MASLD group (n = 585). LS (kPa) was used to stratify disease stage, and the pathophysiology and prognosis of SP and SO were evaluated cross-sectionally. SP was defined as low muscle mass on MRI and classified as SO when coexisting with obesity (BMI ≥ 25 kg/m^2). Mesenteric VAT drains directly into the portal system, influencing hepatic metabolism and serving as a strong risk factor for CVD. In this study, VAT area was

quantified at the level of the superior mesenteric artery using MRI. In addition, a longitudinal analysis of 170 obese CLD patients (without HCC) was performed to assess correlations between the annual changes (Δ/year) of these parameters.

Results: SP and SO were observed in 28% and 8% of patients, respectively, and were both associated with disease progression. Among patients with decompensated cirrhosis in the MASLD group, the prevalence of SO reached 50%. In a longitudinal analysis of obese CLD patients (mean 39 months), the prevalence of SO significantly increased($p < 0.01$). Sub-analysis showed that in F0–2 stage, changes in VAT correlated with hepatic status (ΔPDFF, ΔALT, ΔLS), whereas improvement in hepatic fat was paradoxically associated with muscle loss ($\rho = 0.567$, $p < 0.01$). In contrast, in F3–4 stage, changes in ALBI score and ΔPDFF; "burning-out" were independent determinants of muscle loss (both $p < 0.05$). In the prognostic analysis of ACLD (LS ≥ 3 kPa), SP (alone or with SO) was associated with poorer survival compared with non-SP (regardless of obesity status) (HR 2.27, $p = 0.025$).

Conclusion: This study proposes a novel VAT–MASLD–Sarcopenia Cascade model. In the early anabolic phase, VAT acts as the main driver of hepatic injury, whereas in the late catabolic phase, impaired hepatic reserve and burning-out lead to promoting SP, and worsening prognosis. Therefore, therapeutic strategies should be tailored to this metabolic metamorphosis: VAT reduction in the early phase (dual risk: MASH + CVD), and active energy repletion and SP-targeted management in the late phase.

THU-171

The journey of MASLD: the implementation gap between guidelines and primary care in linkage to care

Joo Hyun Oh[1], Hyo Young Lee[2], Sang Bong Ahn[3], Mimi Kim[4], Bo-Kyeong Kang[4], Chul-min Lee[4], Jihyun An[2], Ha Il Kim[2], Eun Chul Jang[5], Jeong-Yeon Cho[6], Hye-Lin Kim[7], Eileen Yoon[2], Dae Won Jun[2]. *[1]Department of Internal Medicine, CHA University College of Medicine, Seongnam, Korea, Rep. of South; [2]Department of Internal Medicine, Hanyang University College of Medicine, Seoul, Korea, Rep. of South; [3]Department of Internal Medicine, Nowon Eulji Medical Center, Eulji University, Seoul, Korea, Rep. of South; [4]Department of Radiology, Hanyang University College of Medicine, Seoul, Korea, Rep. of South; [5]Department of Occupational and Environmental Medicine, College of Medicine, Soonchunhyang University, Chunan, Korea, Rep. of South; [6]Department of Pharmacotherapy, University of Utah College of Pharmacy, Salt Lake, United States; [7]College of Pharmacy, Sahmyook University, Seoul, Korea, Rep. of South*
Email: noshin@hanyang.ac.kr

Background and aims: Although it is well known that most individuals with steatotic liver disease (SLD) do not successfully transition to linkage to care, evidence remains limited regarding how SLD is initially diagnosed and how individuals are subsequently managed after becoming aware of the condition. We aimed to investigate the journey of individuals with SLD and to evaluate the extent of guideline implementation in the general population.

Method: A nationwide, telephone-based survey was conducted among Korean adults aged ≥19 years (n = 3,891). Participants were asked whether they had a prior diagnosis of SLD and, if so, where they were first diagnosed. Linkage to care was defined as receiving follow-up evaluation or clinical care within the medical system after the diagnosis. The at-risk group was defined as individuals with type 2 diabetes, repeated elevations in liver enzymes, or obesity with additional cardiometabolic risk factors.

Results: The self-reported prevalence of SLD was 25.7%. Most respondents (79.9%) were incidentally diagnosed during health check-ups. Overall, 57.2% of individuals with SLD (572/1,000) were linked to care, and 14.9% (85/572) of those linked underwent liver fibrosis assessment. In total, 61.9% (619/1,000) met criteria for the at-risk group, of whom 54.9% (340/619) achieved linkage-to-care and only 12.1% (75/619) received liver fibrosis assessment. Among linked individuals, 66.6% received care in primary clinics, where fibrosis testing rates were markedly lower (2.4%) than in referral centers (16.2%). he most common reason for not seeking care was the belief that SLD was not a serious condition. The rates of successful linkage to care were 58.5%, 52.1%, and 58.7%, and the proportions undergoing liver fibrosis assessment were 11.6%, 12.6%, and 8.7% in the MASLD, MetALD, and ALD groups, respectively.

Conclusion: Most SLD individuals are incidentally diagnosed during medical check-ups. Although awareness of having SLD is relatively high, implementation of guideline—particularly liver fibrosis assessment among at-risk individuals—remains insufficient even after linkage to care.

THU-172

Eligibility for resmetirom or semaglutide therapy in a real-life Greek cohort of patients with metabolic associated steatotic liver disease

Margarita Papatheodoridi[1], Antonia Neonaki[1], Alexandra Argyrou[1], Stratigoula Sakellariou[2], Panagiota Ioannidou[1], Dimitrios Karagiannakis[1], Evangelos Cholongitas[1], Ioannis Vlachogiannakos[1], George Papatheodoridis[1]. *[1]1st Academic Department of Gastroenterology, General Hospital of Athens "Laiko", Medical School of National & Kapodistrian University of Athens, Athens, Greece; [2]1st Department of Pathology, Medical School of National & Kapodistrian University of Athens, General Hospital of Athens "Laiko", Athens, Greece*
Email: gepapath@med.uoa.gr

Background and aims: Pharmacological therapies for metabolic associated steatotic liver disease (MASLD) including resmetirom and semaglutide have been recently approved. Yet, the proportion of real-world patients eligible for these treatments remains uncertain. We evaluated the proportion and clinical relevance of MASLD patients fulfilling the eligibility criteria proposed in the 2025 AASLD guidance.

Method: Adult patients with MASLD attending our tertiary liver outpatient clinics between 2008 and 2024 were included if they had ³1 liver stiffness (LS) measurement and/or liver biopsy. Patients consuming alcohol >20/30 g/week (females/males) or with any other cause of liver injury were excluded. Demographics, comorbidities and clinical outcomes were recorded. Based in the 2025 AASLD guidance, treatment eligibility was defined as metabolic-associated steatohepatitis and/or stage F2–F3 on histology and/or LS 8–15 kPa and advanced liver disease was defined as LS > 15 kPa and/or presence of cirrhosis.

Results: In total, 777 MASLD patients were included (males 54%, mean age 62 ± 14 years, BMI < 25 kg/m^2: 10%, 25–30: 39%, >30: 51%). Diabetes, hypertension, cardiovascular disease and dyslipidemia were present in 26%, 35%, 8% and 35%, respectively. Of the 777 patients, 158 (20.3%) met treatment eligibility criteria, while 523 (67.3%) had only steatosis and/or LS < 8 kPa and 96 (12.4%) had advanced liver disease. Of the 158 treatment eligible patients, 40 (25.6%) had diabetes, 85 (58.6%) had BMI > 30 and 14 (8.9%) BMI < 25. None of the 158 treatment-eligible patients died or developed liver cancer, but 4 (3.3%) patients developed liver decompensation (2 ascites, 1 variceal bleeding, 1 encephalopathy) during follow-up. In the 681 patients without advanced liver disease, treatment eligibility was significantly associated with greater BMI [OR per kg/m^2: 1.01 (95%CI: 1.00–1.03), P = 0.011], diabetes [OR: 2.29 (1.53–3.43), P < 0.001], hypertension [OR: 1.89 (1.31–2.73), P < 0.001] and dyslipidemia [OR: 2.26 (1.57–3.24), P < 0.001]. In multivariable analysis, treatment eligibility was independently associated with greater BMI [OR per kg/m^2: 1.02 (1.00–1.03), P = 0.014], diabetes [OR: 1.77 (1.10–2.82), P = 0.017] and dyslipidemia [OR: 2.05 (1.36–3.09), P < 0.001].

Conclusion: The recent AASLD treatment indications for resmetirom or semaglutide are fulfilled by approximately one fifth of MASLD patients seen at Greek tertiary liver centers, who are at risk for liver decompensation in the near future.

Estimated glomerular filtration rate and urine albumin-creatinine ratio trajectories in young adulthood and midlife metabolic-dysfunction associated steatotic liver disease: the coronary artery risk development in young adults study

Seong Park[1], Rachel Orbuch[1], Laura Colangelo[1], Ankeet Bhatt[2], Mercedes Carnethon[1], Lisa VanWagner[3]. [1]*Northwestern University Feinberg School of Medicine, Chicago, United States;* [2]*Kaiser Permanente San Francisco Medical Center, Oakland, United States;* [3]*University of Texas Southwestern Medical Center at Dallas, Dallas, United States*
Email: seong.park@northwestern.edu

Background and aims: Metabolic-dysfunction associated steatotic liver disease (MASLD) is associated with an increased risk of chronic kidney disease (CKD). We aim to assess the relationship between long-term patterns of estimated glomerular filtration rate (eGFR) and urine albumin-creatinine ratio (UACR) patterns during early adulthood and the prevalence of MASLD in midlife.
Method: Participants (28–40 years at Year 10, 1995–1996) of the CARDIA study who had liver fat assessed by non-contrast computed tomography (CT) at Year 25 (Y25, 2010–11) and eGFR and UACR measured at ≥ 1 exam at Year 10, 15, 20 or 25 were included. MASLD was defined as CT liver attenuation < 51 Hounsfield units after excluding other causes of liver fat. Participants were stratified into quartiles for baseline eGFR and UACR. Group-based trajectory modeling was used to create eGFR and UACR trajectories and joint eGFR-UACR trajectory groups from Y10 through Y25. Logistic regression models assessed associations of Y10 eGFR and UACR, and trajectory groups with Y25 MASLD prevalence.
Results: Of 2229 study participants, Y25 MASLD prevalence was 24% (n = 536). Only 10 (0.5%) participants had UACR > 300 mg/g at Y10. Median UACR at Y10 was 2.2, 3.3, 4.9, and 10.2 mg/dL in quartiles 1 to 4, respectively. In a joint model with eGFR, only higher UACR quartiles were associated with increased Y25 MASLD prevalence (OR = 1; OR = 1.3 [95% CI: 0.98–1.74]; OR = 1.48 [95% CI: 1.11–1.98]; and OR = 1.43 [95% CI: 1.06–1.91] for quartiles 1 to 4, respectively). Two eGFR (high decreasing vs. low decreasing) and two UACR (high increasing vs. low stable) trajectories were identified. Individuals in the stable, low UACR trajectory group had lower odds of Y25 MASLD (OR = 0.56 [95% CI: 0.41–0.78]) compared with individuals in increasing, higher UACR trajectory group. In a joint model, only high eGFR-increasing UACR trajectory group was significantly associated with Y25 MASLD (OR = 1.82 [95% CI: 1.21–2.73]) compared to high eGFR-stable UACR trajectory group. Baseline eGFR quartiles and eGFR trajectories were not associated with Y25 MASLD.
Conclusion: Higher, though mostly normal UACR in young adulthood and rising UACR trajectories throughout early adulthood are associated with higher MASLD prevalence in midlife. Monitoring UACR levels in early adulthood may help identify individuals at risk of MASLD in midlife.

THU-174

Quantitative digital pathology reveals distinct fibrosis zonal patterns among subtypes of steatotic liver disease

Jeong Hwan Park[1], Gi-Ae Kim[2], Heejoon Jang[3], Yukti Choudhury[4], Julian Lee[4], Elaine Chng[4], Won Kim[3]. [1]*Department of Pathology, SMG-SNU Boramae Medical Center, Seoul National University College of Medicine, Seoul, South Korea, Seoul, Korea, Rep. of South;* [2]*Division of Gastroenterology and Hepatology, Department of Internal Medicine, College of Medicine, Kyung Hee University Hospital, Kyung Hee University, Seoul, South Korea, Seoul, Korea, Rep. of South;* [3]*Divisions of Gastroenterology and Hepatology, Department of Internal Medicine, SMG-SNU Boramae Medical Center, Seoul, South Korea; Department of Internal Medicine, Seoul National University College of Medicine, Seoul, South Korea, Seoul, Korea, Rep. of South;* [4]*HistoIndex Pte. Ltd., Singapore, Singapore*
Email: ruvit21@snu.ac.kr

Background and aims: Steatotic liver disease (SLD) subtypes have differing etiologies and include metabolic dysfunction-associated steatotic liver disease (MASLD), metabolic dysfunction and alcohol-associated liver disease (MetALD), and alcohol-associated liver disease (ALD). These entities share overlapping histopathologic features with overall fibrosis stage being the strongest predictor of liver-related outcomes. However, the conventional fibrosis staging system is semi-quantitative and constrained in its evaluation of any etiology-specific differences. We aimed to evaluate etiology-specific fibrosis distribution using a quantitative digital pathology approach.
Method: From the Boramae Hospital cohort, 88 liver biopsies from three SLD subtypes (28 MASLD, 30 MetALD, and 30 ALD) were selected based on histopathologic findings and demographics, stratified by NASH CRN fibrosis stages (F0-F4). Unstained biopsy sections were imaged by HistoIndex's second harmonic generation/two-photon excitation fluorescence (SHG/TPEF) microscopy for the quantification of qFibrosis continuous values, amount of SHG-detected collagen in biopsies overall (%SHG) and collagen amount in five specific hepatic zones - portal, periportal, zone 2, pericentral, and central vein. These measures were compared in the three disease groups across fibrosis stages.
Results: Correlation between NASH CRN fibrosis stages and qFibrosis values was strongest in MASLD (Spearman's $\rho = 0.91$), followed by ALD ($\rho = 0.81$) and MetALD ($\rho = 0.72$). While qFibrosis values did not differ significantly between disease groups at the same fibrosis stage, overall collagen amount (%SHG) and zonal collagen amounts showed etiology-specific differences. At F3, %SHG was significantly higher in ALD than in MASLD ($p < 0.05$). In the periportal zone, collagen proportion was significantly higher in ALD compared to MetALD at F1 ($p < 0.05$), and was higher in both MetALD and ALD than in MASLD at F4 (both $p < 0.01$). In zone 2, collagen proportion was higher in ALD than in MetALD at F1 ($p < 0.05$) and higher than in MASLD at F4 ($p < 0.05$).
Conclusion: Quantitative digital pathology and zone-specific fibrosis analysis identifies distinct etiology-specific collagen burden and zonal fibrosis patterns among MASLD, MetALD and ALD, despite identical conventional fibrosis stages. These findings underscore the limits of the conventional staging system and support the value of etiology-adapted quantitative fibrosis assessment.

THU-175

Dynamic transitions in steatotic liver disease subtypes and risk of liver-related events: a nationwide cohort study

Yewan Park[1], Jooyi Jung[2], Seungbong Han[2], Gi-Ae Kim[1]. [1]*Kyung Hee University Hospital, Seoul, Korea, Rep. of South;* [2]*Korea university, Seoul, Korea, Rep. of South*
Email: antiankle@naver.com

Background and aims: Steatotic liver disease (SLD) is a dynamic condition, yet most studies rely on single-time-point assessments, leaving the prognostic impact of its subtype transitions unclear. This study aimed to investigate the association between SLD subtype transitions and the risk of long-term liver-related events (LREs).
Method: From the Korean National Health Insurance Service database, adults who underwent national health checkups in both 2015 and 2017 were recruited. SLD subtypes included metabolic dysfunction–associated SLD (MASLD), metabolic dysfunction–associated alcohol-associated SLD (MetALD), and alcohol-associated liver disease (ALD). Transitions were classified into stable, regression, and progression. LREs included incident liver cirrhosis, hepatocellular carcinoma, liver transplantation, and liver-related mortality. Subdistribution hazard ratios (sHRs) were estimated using Fine–Gray competing-risk models.
Results: Among 1,988,878 individuals, 21.7% transitioned over two years: 11.3% progressed, whereas 10.4% regressed. Across all SLD subtypes, the progression group showed an increased risk of LREs compared with the stable group (sHR, 1.33; 95% confidence interval [CI], 1.28–1.39), whereas the regression group showed attenuated risk

(sHR, 0.86; 95% CI, 0.83–0.88). The findings were consistent within each SLD subtype of no SLD, MASLD, MetALD, and ALD. Sensitivity analyses stratified by sex, body mass index, and fatty liver index thresholds of >60 demonstrated comparable findings.
Conclusion: We found that progression to more advanced SLD subtypes was associated with increased risks of LREs, whereas regression to less advanced subtypes or no SLD was associated with substantial risk reduction. The findings can contribute to communicating the necessity of improving SLD subtypes through lifestyle modification, such as reducing alcohol intake or improving metabolic risk factors.

THU-179
Ethnic differences in non-invasive tests, disease severity, and liver-related outcomes in a diverse Canadian population with metabolic dysfunction-associated steatotic liver disease
Andre Jeyarajan[1], Chinmay Bera[2], Ravikiran Sindhuvalada Karnam[3], Natalie Simonian[4], Maxwell Tong[4], Leila Amiri[4], Nashla Hamdan[4], Keyur Patel[4]. *[1]University of Toronto, Department of Medicine, Toronto, Canada; [2]University of Arkansas for Medical Sciences, Division of Gastroenterology and Hepatology, Little Rock, United States; [3]Narayana Health City, Bengaluru, India; [4]University Health Network, University of Toronto, Division of Gastroenterology and Hepatology, Toronto, Canada*
Email: a.jeyarajan@mail.utoronto.ca

Background and aims: Non-invasive tests (NITs) are recommended to identify Metabolic dysfunction-associated steatotic liver disease (MASLD) patients with advanced MASLD fibrosis (F3–4). Although there are racial/ethnic disparities in MASLD severity, NITs were validated in predominantly White populations. Our aims were to (1) characterize the performance of NITs in predicting advanced fibrosis and (2) describe the severity of MASLD and liver-related outcomes based on race/ethnicity.
Method: Retrospective, observational cohort study at a single Canadian tertiary-care centre. We included patients with biopsy-proven MASLD from 1995 to 2025. NITs evaluated were FIB-4, NFS, liver stiffness measurement (LSM), Agile 3+, and MAFLD fibrosis score (MFS) at validated thresholds. Liver-related outcomes included hepatic decompensation, hepatocellular carcinoma (HCC), and liver transplant (LT).
Results: Our cohort of 817 patients included 434 (53.1%) White, 90 (11%) South Asian, 88 (10.8%) East Asian, 94 (11.5%) Southeast Asian, 61 (7.5%) Latin American, and 50 (6.1%) Other (27 Black, 22 Middle Eastern, one Indigenous). Advanced fibrosis (≥F3) prevalence was 31.8% (East Asians) to 56% (Whites). For NITs, AUROC range for F3–4 were 0.79–0.85 for Whites, 0.74–0.92 for South Asians, 0.79–0.87 for East Asians, 0.75–0.91 for Southeast Asians, 0.80–0.86 for Latin Americans, and 0.80–0.87 for Others. FIB-4 had higher diagnostic performance for F3–4 in Southeast Asians compared to Whites (AUROC: 0.89 vs. 0.79, $p = 0.01$); other NITs were not significant. On multivariable regression analysis, East Asian ethnicity was a negative predictor of advanced fibrosis/cirrhosis at baseline. During follow-up over mean 5.0 ± 5.1 years, 98/759 patients at risk developed hepatic decompensation with the rate per 100 person-years highest for Whites (3.25) and Latin Americans (3.16) and lowest for East Asians (0.75). 38/806 patients at risk developed HCC, with incidence highest for Latin Americans and lowest for East Asian and Others. 49/817 of patients underwent LT, with incidence highest for South Asians and lowest for Southeast Asians. On multivariable Cox regression analysis, East ($p = 0.05$) and Southeast Asians ($p = 0.01$) had lower risks of hepatic decompensation compared to Whites.
Conclusion: NIT performance for predicting MASLD F3–4 was similar across ethnic groups. Latin Americans had high rates of hepatic decompensation and HCC development during follow-up, while East and Southeast Asians had the lowest risks of hepatic decompensation.

THU-180
Health related quality of life in steatotic liver disease patients over time: impact of extra-hepatic comorbidities
Katrina Pekarska[1], Ian Rowe[1], Richard Parker[1]. *[1]Leeds Teaching Hospitals NHS Trust, University of Leeds, Leeds, United Kingdom*
Email: katrina.pekarska@gmail.com

Background and aims: Health-related quality of life (HRQL) is increasingly recognised as an important patient-reported outcome in steatotic liver disease (SLD). Previous studies have shown reduced HRQL in SLD, driven not only by liver fibrosis but also by metabolic and psychosocial factors, highlighting the need to characterise how SLD impacts patients over time. We investigated patient reported HRQL and changes over time.
Method: We conducted a single-centre observational cohort study of adults with SLD managed through a UK primary care assessment pathway. The EQ-5D-5L questionnaire was administered at baseline following clinical assessment/brief intervention and repeated by telephone at 6 months. Data on demographics, comorbidities, alcohol intake, and non-invasive fibrosis measures were collected. EQ-5D index values were derived using the England value set.
Results: A total of 116 patients completed EQ-5D-5L at baseline and at six months. Mean age was 56 ± 13 years, 68% were male, 72% were obese (BMI≥30), 34% had diabetes, the median Charlson comorbidity index was 2 (IQR 1–4). Most participants had MASLD (n = 92), with 12 MetALD and 12 ALD. There was no significant change in mean EQ-5D index over time (0.81 ± 0.23 vs 0.84 ± 0.22; mean difference 0.028 ± 0.154, p = 0.11). Median EQ-VAS (visual analogue scale) increased from 73 (IQR 60–80) to 75 (IQR 68.8–85.0), p = 0.039. The median within-patient change was +4.5 points (IQR −5 to +10) and 35% experienced a clinically meaningful improvement (≥10 points). There were no differences in baseline HRQL between SLD subtypes. In univariable analyses, musculoskeletal (MSK) conditions (β = −0.29, p < 0.001) and anxiety/depression (β = −0.17, p = 0.020) were associated with lower baseline EQ-5D index. In multivariable analyses adjusting for age, sex, BMI, and liver stiffness (kPa), MSK conditions remained independently associated with lower EQ-5D index (β = −0.26, p < 0.001). Liver stiffness showed a weak, non-significant association with EQ-5D index at follow-up (β = −0.002 per kPa, p = 0.093). After adjustment for baseline HRQL, no variables independently predicted change in EQ-5D index over time.
Conclusion: HRQL is moderately impaired in patients with SLD and remained largely stable over six months. Extra-hepatic comorbidities, particularly MSK and anxiety/depression, are the main drivers of reduced HRQL, highlighting the need for holistic care alongside liver-directed management. Treatments addressing extra-hepatic conditions may therefore be of greatest benefit.

THU-181
Significant hepatic fibrosis identified by serologic scores is associated with a higher risk of advanced colorectal neoplasia: a case-control study
Lucia Pinzon Uribe[1], Davinia Sacramento Luis[1], Inmaculada Alonso Abreu[1], Jesus Barreto Davila[1], Carla Amaral[1], Dalia Morales[1], Felicitas Diaz-Flores[1], Onofre Alarcon[1], Alejandro Jiménez Sosa[1], Manuel Hernández-Guerra[1,2]. *[1]Hospital Universitario de Canarias, La Laguna, Spain; [2]Universidad de La Laguna, La Laguna, Spain*
Email: mhernand@ull.edu.es

Background and aims: Metabolic dysfunction–associated steatotic liver disease (MASLD), present in up to 80% of patients with metabolic syndrome (MS), has been independently associated with the development of advanced neoplasia (AN), including colorectal cancer (CRC) and advanced adenoma (AA). Both risk factors are also closely linked to the progression of hepatic fibrosis. However, no studies have specifically examined the relationship between liver fibrosis and the presence of AN.

Method: We conducted a retrospective case–control study including all patients undergoing colonoscopy during May from 2003 to 2024. Cases had AN, and two age- and sex-matched controls without AN were randomly selected from the same month. Demographic data, tobacco and significant alcohol intake (≥30 g/day in men and ≥20 g/day in women), MetS-related clinical variables, laboratory parameters for APRI and FIB-4, and imaging findings (ultrasound/CT) were collected. Patients with high-risk conditions for AN (family history of CRC, prior AN, or inflammatory bowel disease) or with chronic liver diseases unrelated to MASLD were excluded. Statistical analysis included bivariate comparisons and multivariable logistic regression to identify independent associations with AN including the study period.
Results: A total of 2,611 subjects were included: 548 AN cases (mean age 68.1 ± 12.5 years; 67.7% males) and 2,063 controls (62.5 ± 15.4; 55.8%). After matching, cases (n = 548) and controls (n = 1,369) showed similar rates of aspirin use, hypertension, diabetes, dyslipidemia, and Charlson comorbidity index ≥3. Cases had higher alcohol consumption (32.6% vs 27.7%, p = 0.019), smoking prevalence (43.7% vs 37.5%, p = 0.007), and ≥2 MetS components (49.4% vs 40%, p = 0.005). APRI>0.5 (16.5% vs 5.7%) and FIB-4 > 1.3 (54% vs 44.7% were more frequent in cases (all p < 0.001), consistently across the study period. In multivariable analysis, significant hepatic fibrosis and smoking were independently associated with AN. No temporal interaction was observed between fibrosis indices and AN. Among patients with imaging-confirmed hepatic steatosis (n = 194), cases had higher rates of APRI>0.5 (28.8% vs 10.4%, p = 0.049) and FIB-4 > 1.3 (40% vs 30.2%, p = 0.063).
Conclusion: Significant hepatic fibrosis estimated by non-invasive scores is independently associated with a higher risk of AN. Identifying fibrosis in individuals with metabolic risk factors and/or MASLD may improve risk stratification and guide targeted CRC screening strategies.

THU-182
The relationship between endothelial dysfunction, insulin resistance, and metabolic associated steatotic liver diseases

Kateryna Pivtorak[1], Oleksandr Ivanchuk[1], Mykola Fedzhaga[1], Natalya Pivtorak[1]. [1]*National Pirogov Memorial Medical University, Vinnytsia, Ukraine*
Email: ekaterina.pivtorak@yahoo.com.ua

Background and aims: Metabolic dysfunction associated steatotic liver disease (MASLD) is currently recognized as a significant risk factor for the development of liver cirrhosis, diabetes mellitus, and cardiovascular disease. Cardiovascular complications in MASLD aggravate disease progression and worsen patient prognosis. In recent years, increasing attention has been paid to intercellular interactions and endothelial dysfunction (ED) as key mechanisms of vascular injury in MASLD; however, ED remains insufficiently studied. This study aimed to assess the association between insulin resistance, the severity of liver fibrosis, and ED in patients with MASLD.
Method: 262 patients were examined. Levels of inflammatory mediators, endothelin-1 (ET-1), and von Willebrand factor (vWF) activity were measured. Carotid artery intima–media thickness, presence of atherosclerotic plaques and stenosis, and the HOMA-IR index were assessed. The adiponectin-to-leptin ratio was expressed as log A/L. Liver fibrosis was evaluated using transient elastography. All patients underwent ECG and echocardiographic examinations.
Results: Correlation analysis demonstrated a strong positive association between HOMA-IR and leptin levels (r = 0.8; p = 0.00166), as well as inverse correlations between HOMA-IR and adiponectin (r = −0.66; p = 0.0033) and log A/L index (r = −0.71; p < 0.001). A decrease in adiponectin accompanied by an increase in leptin was associated with worsening insulin resistance. In obese patients, C-reactive protein levels correlated positively with HOMA-IR (r = 0.58; p = 0.05), blood glucose (r = 0.44; p = 0.0045), and insulin levels (r = 0.66; p = 0.0001). Obese patients with MASLD exhibited impaired endothelium-dependent vasodilation, indicating endothelial dysfunction. Concentrations of proinflammatory cytokines (TNF-α and IL-6) in MASLD patients were 3–7 times higher than in obese individuals without MASLD. Plasma ET-1 levels showed a strong positive correlation with cardiovascular risk and cognitive impairment. Inflammatory mediators (TNF-α, IL-1, IL-6) and C-reactive protein and fibrinogen were closely associated with obesity severity, ET-1 and vWF levels, and insulin resistance, serving as predictors of cardiovascular risk.
Conclusion: MASLD development is closely linked to endothelial dysfunction, elevated leptin and systemic inflammatory markers, and reduced adiponectin levels, highlighting their combined role in increased cardiovascular risk in patients with MASLD.

THU-183
Similar hepatic outcomes in type 1 and type 2 diabetes among adults with MASLD: A U.S. propensity-matched multi-institutional cohort study

Renan Prado[1]. [1]*Cleveland Clinic Foundation, Cleveland, United States*
Email: prador2@ccf.org

Background and aims: Metabolic dysfunction–associated steatotic liver disease (MASLD) is closely linked to diabetes, yet the hepatic risk associated with type 1 diabetes (T1DM) remains poorly defined compared with type 2 diabetes (T2DM). We compared long-term liver-related outcomes between adults with MASLD and T1DM versus T2DM using a large multicenter cohort.
Method: We performed a retrospective cohort study using a federated U.S. electronic health record network including academic and community healthcare systems. Adults with MASLD were identified using validated diagnostic codes during a two-year enrollment window. Patients with pre-existing hepatic fibrosis or cirrhosis were excluded to ensure comparable baseline liver status. Individuals were stratified by diabetes phenotype (type 1 vs type 2). To minimize confounding, 1:1 propensity score matching was conducted using a set of covariates, including age, sex, race/ethnicity, hypertension, body mass index, glycemic control (HbA1c), lipid profile, renal function, and key laboratory markers of liver disease severity and MELD-Na components (albumin, bilirubin, INR, sodium, platelets, AST, ALT). Adequate covariate balance was achieved across all matched variables (standardized mean differences <0.10). Outcomes were assessed ≥90 days after index to reduce reverse causality. Patients were followed with a median follow-up of approximately four years.
Results: After propensity score matching, 7,619 MASLD patients with T1DM were well balanced with 7,619 patients with T2DM across all matched demographic, metabolic, and liver-related variables. Liver-specific outcomes were comparable between groups, including cirrhosis (HR 1.03, 95% CI 0.95–1.13; $p = 0.44$), hepatocellular carcinoma (HR 1.15, 95% CI 0.88–1.50; $p = 0.30$), variceal bleeding (HR 1.00, 95% CI 0.86–1.16; $p = 0.99$), ascites (HR 1.10, 95% CI 0.99–1.23; $p = 0.07$), and liver transplantation (HR 1.23, 95% CI 0.97–1.56; $p = 0.10$), with overlapping time-to-event curves.
In contrast, T1DM was associated with a modest but statistically significant increase in all-cause mortality (HR 1.09, 95% CI 1.00–1.19; $p = 0.049$) and in the composite major adverse liver outcome (HR 1.09, 95% CI 1.00–1.18; $p = 0.05$), although absolute risk differences were small.
Conclusion: In this large, real-world propensity-matched cohort, adults with MASLD demonstrated comparable longterm liver-specific outcomes irrespective of diabetes phenotype after rigorous adjustment for metabolic and liver-related factors.

THU-184

Characterization of cardiac electrophysiological subtypes in metabolic dysfunction-associated steatotic liver disease

Jiang Bai[1,2], Shanghao Liu[1,2], Bicheng Ye[1,2], Yilin Zhang[1,2], Yang Bu[3], Jing Wang[4], Gao-Jun Teng[5], Xiaolong Qi[1,2]. *[1]Liver Disease Center of Integrated Traditional Chinese and Western Medicine, Department of Radiology, Zhongda Hospital, Medical School, Southeast University, Nurturing Center of Jiangsu Province for State Laboratory of AI Imaging & Interventional Radiology (Southeast University), Nanjing, China, Basic Medicine Research and Innovation Center of Ministry of Education, Zhongda Hospital, Southeast University; State Key Laboratory of Digital Medical Engineering, Nanjing, China, Nanjing, China; [2]Basic Medicine Research and Innovation Center of Ministry of Education, Zhongda Hospital, Southeast University, State Key Laboratory of Digital Medical Engineering, Nanjing, China, Nanjing, China; [3]Department of hepatobiliary surgery, General Hospital of Ningxia Medical University, Yinchuan, 750004 Ningxia, China, Ningxia, China; [4]Scientific research department, General Hospital of Ningxia Medical University, Yinchuan, 750004 Ningxia, China, Ningxia, China; [5]Zhongda Hospital, Southeast University, Nanjing, China, Nanjing, China*
Email: qixiaolong@vip.163.com

Background and aims: The potential utility of routinely acquired electrocardiographic (ECG) parameters for risk stratification within Metabolic dysfunction-associated steatotic liver disease (MASLD) remains unexplored. This study aimed to identify cardiac electrophysiological subtypes of MASLD using ECG data and to evaluate their associated clinical outcomes.

Method: We analyzed data from 8,848 adults across two independent cohorts: a cross-sectional cohort from China (n = 487) for subtype discovery and a prospective longitudinal cohort from the UK Biobank (n = 8,361) for validation and outcome analysis. Eight ECG parameters were selected for cluster analysis: ventricular rate, P-wave duration, PQ interval, QRS duration, QTc interval, P axis, R axis, and T axis. Unsupervised clustering was performed using the partitioning around medoids (PAM) algorithm. The derived subtypes were subsequently examined for associations with incident chronic liver disease (CLD) and cardiovascular disease (CVD) in the UK Biobank cohort using Cox proportional hazards models. CLD were defined according to the following ICD-10 codes: C22.0, I85.0, I85.9, K70, K72.1, K72.9, K73, K74.0, K74.1, K74.2, K74.6, K76.0, K76.6, K76.7, K76.8, K76.9, Z94.4. CVD were defined using ICD-10 codes I20–I25, I60–I64, I69, and G45.

Results: PAM clustering based on the eight ECG variables delineated six distinct phenotypic clusters. The solution demonstrated acceptable internal validity (mean silhouette coefficient = 0.118; Calinski-Harabasz index = 53) and stability (mean Jaccard similarity = 0.58 ± 0.1). Cluster 6, characterized by prolonged P-wave duration and PQ interval, exhibited a significantly lower risk for incident CLD over a median 13.7-year follow-up (HR 0.59, 95% CI 0.39–0.91, p = 0.017) but a concurrently higher risk for CVD (HR 1.40, 95% CI 1.07–1.83, p = 0.014) compared to other clusters. Cluster 2, defined by elevated T- and R-axis amplitudes, was associated with increased CVD incidence (HR 1.40, 95% CI 1.06–1.86, p = 0.018). Similarly, Cluster 3, characterized by prolonged QRS duration, was linked to higher CVD risk (HR 1.46, 95% CI 1.11–1.92, p = 0.007).

Conclusion: ECG-based phenotyping identifies specific high-risk MASLD subtypes with divergent prognostic profiles. These findings highlight the potential of routine ECG parameters as a simple, non-invasive tool for risk stratification in MASLD, to facilitate targeted monitoring and personalized management.

Heterogeneous vulnerability pathways in metabolic dysfunction-associated steatotic liver disease (MASLD): adiposity vs. genetic susceptibility

Mariana Ramírez-Mejía[1,2], Samuel Canizales-Quinteros[3], Hugo Villamil-Ramírez[3], Guadalupe Ponciano-Rodriguez[4], Nahum Méndez-Sánchez[2,4]. *[1]Plan of Combined Studies in Medicine (PECEM-MD/PhD), Faculty of Medicine, National Autonomous University of Mexico, Mexico City, Mexico; [2]Liver Research Unit, Medica Sur Clinic & Foundation, Mexico City, Mexico; [3]Unidad de Genómica de Poblaciones Aplicada a la Salud, Facultad de Química, Universidad Nacional Autónoma de México (UNAM)/Instituto Nacional de Medicina Genómica (INMEGEN), Mexico City, Mexico; [4]Faculty of Medicine, National Autonomous University of Mexico, Mexico City, Mexico*
Email: nmendez@medicasur.org.mx

Background and aims: Metabolic dysfunction-associated steatotic liver disease (MASLD) arises from heterogeneous pathways involving adiposity, lifestyle factors and biological vulnerability. While overweight/obesity-related MASLD is largely adiposity-driven, lean MASLD may reflect a distinct vulnerability profile. We aimed to evaluate the independent contribution of adiposity, lifestyle, cardiometabolic factors, and genetic susceptibility to MASLD and to assess how their relevance varies among lean individuals and those with overweight/obesity.

Method: We evaluated 468 adults (276 men and 192 women; mean age 46.7 ± 9.0 years) who underwent clinical and biochemical evaluation, dietary intake assessment, physical activity quantification and PNPLA3 rs738409 genotyping (G allele carriers vs. non-carriers). Associations with MASLD were examined using multivariable logistic regression in the overall population and stratified by adiposity status.

Results: In the overall population, MASLD was primarily associated with adiposity, with body mass index showing a strong and consistent association (OR 1.59; 95% CI 1.39–1.86; p < 0.001). 76.9% of participants were PNPLA3 rs738409 G-allele carriers, and carriage remained independently associated with MASLD after full adjustment (OR 3.28; 95% CI 1.42–7.97; p = 0.007). Physical activity showed a modest inverse association, whereas total energy intake, macronutrient composition, and diabetes were not independently associated. Hypertension showed a positive but non-significant trend. Among lean individuals, MASLD was mainly determined by genetic susceptibility, with PNPLA3 rs738409 as the principal independent factor (OR 4.60; 95% CI 1.15–25.29; p = 0.047), while lifestyle and cardiometabolic variables were not independently associated. In contrast, among individuals with overweight/obesity, MASLD reflected a risk profile dominated by adiposity, within which genetic susceptibility remained relevant (OR 3.06; 95% CI 1.12–8.56; p = 0.029). In this group, physical activity exerted a significant protective effect and hypertension emerged as a strong marker of metabolic burden, while diet composition did not independently influence risk.

Conclusion: MASLD reflects different combinations of risk factors, with adiposity as the main determinant. Genetic susceptibility predominates in lean individuals, while in individuals with overweight/obesity risk integrates adiposity, persistent genetic vulnerability and physical activity, supporting the need to move beyond uniform risk frameworks.

THU-186-YI

Distinct cardiometabolic profiles drive divergent HCC risk trajectories in advanced fibrosis-affected MASLD patients

Mario Romeo[1], Marcello Dallio[1], Fiammetta Di Nardo[1], Carmine Napolitano[1], Paolo Vaia[1], Claudio Basile[1], Luigi Di Puorto[1], Giuseppina Martinelli[1], Marco Niosi[1], Alessandro Federico[1]. *[1]Hepatogastroenterology Division, Department of Precision Medicine, University of Campania Luigi Vanvitelli, Piazza Miraglia 2, 80138, Naples (Italy), Naples, Italy*
Email: marioromeo@virgilio.it

Background and aims: Metabolic dysfunction (MD)-associated steatotic liver disease (MASLD) is defined by steatotic liver disease (SLD) in the presence of at least one cardiometabolic risk factor (CMRF)—obesity, type 2 diabetes, dyslipidemia, or hypertension—in the absence of alternative causes. MASLD may progress to steatohepatitis (MASH) and advanced fibrosis (AF), significantly increasing the risk of hepatocellular carcinoma (HCC). While cardiovascular risk is known to escalate with MD severity, the impact of cumulative CMRF burden on HCC development remains poorly characterized. This study aimed to assess differential HCC risk and timing by stratifying MASLD-AF patients according to distinct CMRF combinations.
Method: Biochemical, clinical, and Liver Stiffness (LSM) data from 1921 SLD individuals, archived in the Health Documents Digitization Repository of the "Luigi Vanvitelli" University Hospital (January 2010–Oct 2020), were retrospectively analyzed to identify subjects fulfilling EASL-proposed MASLD criteria and exhibiting LSM-AF. A non-redundant permutation of CMRFs—obesity (Obe), dysglycaemia or type 2 diabetes (Gly), dyslipidemia (Lip), and elevated blood pressure (Press)—was applied, yielding 4 groups with 15 distinct MD profiles: Group 1) One CMRF (n:311) [1a: Obe (n:130); 1b: Gly (n:40); 1c: Lip (n:91); 1d: Press (n:50)]; Group 2) Two CMRFs (n:840) [2a: Obe-Gly (n: 140); 2b: Obe-Lip (n:120); 2c: Obe-Press (n:150); 2d: Gly-Lip (n:130); 2e: Gly-Press (n:140); 2f: Lip-Press (n:160)]; Group 3) Three CMRFs (n:680) [3a: Obe-Gly-Lip (n:190); 3b: Obe-Lip-Press (n:170); 3c: Obe-Gly-Press (n:140); 3d: Gly-Lip-Press (n:180)]; Group 4) Four CMRFs (Obe-Gly-Lip-Press) (n:90). HCC diagnosis and staging (BCLC) were retrospectively recorded over a 5-year follow-up.
Results: Patients with ≥3 CMRFs exhibited significantly higher HCC risk [HR: 3.12, p:0.001]. Within this subgroup, Gly-Lip-Press, Obe-Gly-Lip [HR: 1.129, p:0.034], and Obe-Gly-Lip-Press [HR: 2.21, p:0.002] showed progressively increasing 5-year HCC incidence and decreasing median time to occurrence (48.2 vs 41.3 vs 28.1 months; $p < 0.0001$) (Fig. 2). Notably, the BCLC-C stage at diagnosis was more frequent in Obe-Gly-Lip (31%) compared to other Group 3 profiles (<10%; $p < 0.0001$).
Conclusion: CMRF-based stratification reveals substantial heterogeneity in HCC risk among MASLD-AF patients, supporting the implementation of personalized surveillance strategies taking into account the metabolic burden.

THU-187
Investigating the role of the IL-17/23 Pathway in MASLD progression

Giuseppe Rusignuolo[1], Annika Keitel[1], Lara Kelsch[1], Thomas Wiggers[2], Morten Karsdal[2], Diana Julie Leeming[2], Nils Venhoff[3], Ute Woelfle[4], Christoph Schempp[4], Tobias Boettler[1].
[1]Uniklinik Freiburg, Department of Hepatology, Gastroenterology, Endocrinology, and Infectious Diseases, Freiburg im Breisgau, Germany; [2]Nordic bioscience, Biomarkers & research, Herlev, Denmark; [3]Uniklinik Freiburg, Department of Rheumatology and Clinical Immunology, Freiburg, Germany; [4]Uniklinik Freiburg, Department of Dermatology, Freiburg, Germany
Email: giuseppe.rusignuolo@uniklinik-freiburg.de

Background and aims: Progression of MASLD is driven by inflammatory and fibrogenic pathways that are incompletely understood. Increasing evidence implicates the IL-17/23 axis in hepatic inflammation and fibrosis. Biologic inhibitors of this pathway are widely used in psoriasis. This study aimed to evaluate the impact of IL-17/23 inhibition on MASLD using non-invasive fibrosis, steatosis, and immunological markers.
Method: In this prospective, single-center observational cohort study, patients with psoriasis or pso-arthritis receiving biologic therapy targeting either the IL-17/23 axis or TNF were followed for 6–12 months. Assessments were performed at baseline (t0) and follow-up (t2). Liver fibrosis and steatosis were evaluated by transient elastography with liver stiffness measurement (LSM) and controlled attenuation parameter (CAP), Fibrosis-4 score (FIB-4), and serum biomarkers including cytokeratin-18 (CK18) and type III procollagen N-terminal propeptide (Pro-C3). Immunological profiling included Th17/T regulatory cell ratios in peripheral blood mononuclear cells and inflammatory cytokines (IL-6, IL-22, leptin). The primary endpoint was change in LSM; secondary endpoints were changes in the other parameters measured.
Results: Of 56 enrolled patients, 38 were included in the final analysis: Group A, IL-17/23 inhibitor–naïve patients initiating IL-17/23 blockade (n = 9); Group B, TNF inhibitor–naïve patients (n = 6); and Group C, long-term IL-17/23–treated patients (n = 23). Longitudinal changes (t2–t0) were compared using the Mann–Whitney U test. Group A showed a significantly greater improvement in LSM compared with Group B ($p = 0.025$). No significant differences were observed for the secondary endpoints Pro-C3, CK18, IL-6, IL-22, leptin, CAP, FIB-4, and Th17/Treg ratio at group level. However, consistent trends favoring Group A were observed across multiple markers. A subset of patients initiating IL-17/23 inhibition demonstrated concordant improvement in LSM, fibrosis markers (Pro-C3, CK18), and inflammatory markers (Th17/Treg ratio, IL-6).
Conclusion: Initiation of IL-17/23 inhibition was associated with significant improvement in liver stiffness compared with TNF inhibition, supporting a role of the IL-17/23 axis in MASLD-related fibrogenesis. Improvements in additional non-invasive fibrosis and immune markers in a subgroup of patients suggest an immune-driven, treatment-responsive phenotype. Larger prospective studies with longer follow-up and histological validation are needed to confirm these findings.

THU-188
Age-related clinical features of metabolic dysfunction associated steatotic liver disease in a real-world cohort

Ryotaro Sakamori[1], Yutaro Abe[1], Sumiko Yoshida[2], Atsumasa Komori[3], Kiyoshi Furuta[4], Keisuke Ario[5], Kana Hirooka[6], Kazuhiro Sugi[7], Motoyuki Kohjima[8], Atsushi Naganuma[9], Takayoshi Suga[10], Shiro Yokohama[11], Shintaro Takaki[12], Minoru Tomizawa[13], Yoko Nakamura[14], Tsutomu Yamashita[15], Hiroshi Yatsuhashi[3].

Email: sakamori.ryotaro.bp@mail.hosp.go.jp

Background and aims: Although epidemiological studies on steatotic liver disease (SLD) using health checkup or administrative data are abundant, evidence from real-world clinical practice remains limited, particularly in Asian populations. Because cardiometabolic risk factors such as diabetes mellitus, hypertension, and dyslipidemia change with aging, it is unclear whether elderly and non-elderly patients with metabolic dysfunction associated steatotic liver disease (MASLD) should be managed similarly. This study aimed to clarify age-specific clinical characteristics and outcomes of MASLD in a Japanese real-world cohort.
Method: A prospective registry of patients with SLD was conducted across 31 National Hospital Organization hospitals in Japan. Patients were stratified by age using 65 years as the cutoff, and metabolic factors, fibrosis markers, and clinical outcomes were compared between elderly and non-elderly patients.
Results: Among 410 registered patients, 375 were analyzed, of whom 329 (87.7%) met the diagnostic criteria for MASLD. The non-elderly

group (younger than 65 years) included 178 patients, and the elderly group (65 years or older) included 151 patients. Male predominance was observed in the non-elderly group, whereas female predominance was observed in the elderly group. Patients meeting the body mass index criterion were more frequent in the non-elderly group, while hypertension was more frequent in the elderly group; other cardiometabolic risk factors and related treatments were comparable. Platelet count, aspartate aminotransferase, alanine aminotransferase, and total cholesterol levels were lower in the elderly group. Fibrosis markers, including hyaluronic acid, Mac-2 binding protein glycosylation isomer, and the fibrosis 3 index, were higher in the elderly group, and approximately 10% of patients were suspected to have advanced liver fibrosis. Alanine aminotransferase levels decreased over 1 year, with a greater reduction in the non-elderly group. The cumulative incidence of malignancies, cardiovascular events, and liver-related events was 0.8% at 6 months, 2.8% at 12 months, and 4.6% at 18 months, with a trend toward higher incidence in the elderly group.
Conclusion: In this Japanese real-world cohort, elderly and non-elderly patients with MASLD showed distinct cardiometabolic and fibrosis-related characteristics. The higher prevalence of advanced liver fibrosis and increased clinical events in elderly patients suggest that age-specific management strategies may be required.

THU-189

Ultrasound-assessed skeletal muscle quality is associated with functional and metabolic impairment in metabolic dysfunction-associated steatotic liver disease

Anna Sheptulina[1], Elvira Mamutova[1], Julia Golubeva[1], Karina Gladun[2], Elena Grigorenko[2], Natalia Mitkovskaya[2], Oxana Drapkina[1]. *[1]National Medical Research Center for Therapy and Preventive Medicine, Moscow, Russian Federation; [2]State Institution "Republican Scientific and Practical Center 'Cardiology'", Minsk, Belarus*
Email: sheptulina.anna@gmail.com

Background and aims: Skeletal muscle mass (SMM) and function play an important role in the pathogenesis of metabolic dysfunction–associated steatotic liver disease (MASLD). However, commonly used body composition assessment methods, such as bioelectrical impedance analysis and dual-energy X-ray absorptiometry (DXA), quantify SMM but do not reflect muscle quality, including fat infiltration and stiffness (myosteatosis). In contrast, ultrasound (US) examination of skeletal muscles is a rapid, bedside-applicable method that allows assessment of both quantitative and qualitative muscle characteristics. This study aimed to evaluate the association between US-derived qualitative muscle parameters, body composition, and muscle function in patients with MASLD.
Method: A total of 366 patients with MASLD were included. MASLD was diagnosed based on US evidence of steatosis, exclusion of other liver disease etiologies, and the presence of at least one cardiometabolic risk factor. US assessment of the right rectus femoris (RFM) and vastus intermedius muscles (VIM) included grayscale imaging, shear wave elastography, and compression elastography to evaluate muscle echogenicity (Heckmatt scale) and stiffness. Body composition was assessed using DXA. Relative grip strength (rGS) was calculated as GS divided by body mass index (BMI). Muscle function was evaluated via the 4-meter walk test (4MWT).
Results: The median age was 57 years (nterquartile range [IQR]: 47–63.5); 62.9% of patients were female. All patients overweight or obese, had arterial hypertension and dyslipidemia. Decreased SMM was observed in 75 (20.5%) patients. Higher RFM and VIM echogenicity (grades III–IV) was associated with higher BMI and waist circumference ($p < 0.001$ for both), increased fat mass and body fat percentage ($p = 0.009$ for both), longer 4MWT time ($p < 0.001$), and lower rGS ($p < 0.001$). Grade IV echogenicity was additionally associated with lower high-density lipoprotein cholesterol (HDL-C) levels ($p < 0.001$) and higher uric acid levels ($p = 0.004$). Patients with predominantly soft areas on muscle elastograms had lower SMM ($p = 0.047$), while RFM stiffness was higher in patients with decreased SMM ($p = 0.009$).
Conclusion: Ultrasound-derived qualitative muscle parameters are closely associated with body composition, muscle function, and metabolic abnormalities in MASLD. Muscle ultrasound may serve as a practical, non-invasive tool for identifying impaired muscle quality and early sarcopenic changes beyond conventional anthropometric assessment.

THU-190

Decreased skeletal muscle mass is associated with an adverse metabolic profile in patients with metabolic dysfunction-associated steatotic liver disease

Anna Sheptulina[1], Elvira Mamutova[1], Julia Golubeva[1], Karina Gladun[2], Elena Grigorenko[2], Natalia Mitkovskaya[2], Oxana Drapkina[1]. *[1]National Medical Research Center for Therapy and Preventive Medicine, Moscow, Russian Federation; [2]State Institution "Republican Scientific and Practical Center 'Cardiology'", Minsk, Belarus*
Email: sheptulina.anna@gmail.com

Background and aims: Increasing evidence suggests the association between skeletal muscles and metabolic dysfunction–associated steatotic liver disease (MASLD), indicating that deterioration of metabolic state may negatively impact skeletal muscle mass (SMM), strength, and function. The aim of the present study was to evaluate the assosiation between biochemical metabolic parameters and SMM in patints with MASLD.
Method: A total of 366 patients with MASLD were enrolled in the study. The diagnosis of MASLD was established based on ultrasonographic evidence of hepatic steatosis, exclusion of other causes of liver disease according to laboratory evaluation, and the presence of at least one cardiometabolic risk factor. Body composition was evaluated using dual-energy X-ray absorptiometry (DXA) (Lunar iDXA, GE Healthcare, USA). Decreased skeletal muscle mass was defined as an appendicular skeletal muscle mass–to–body mass ratio (ASMM/M) <23.47% in women and <28.27% in men.
Results: The median age of the cohort was 57 years (interquartile range [IQR]: 47–63.5 years), with women comprising 62.9% of the study population. The median body mass index (BMI) was 31.8 kg/m^2 (IQR: 28.7–34.9). All participants had obesity, arterial hypertension, and dyslipidemia. Decreased SMM was identified in 75 (20.5%) patients. Compared with MASLD patients with preserved SMM, those with decreased SMM exhibited higher serum uric acid ($p = 0.001$), triglycerides ($p = 0.031$), and gamma-glutamyl transferase activity ($p = 0.029$), along with lower HDL-cholesterol levels ($p = 0.005$). Patients with decreased SMM also demonstrated higher systolic and diastolic blood pressure ($p = 0.001$ and $p = 0.008$, respectively), as well as higher BMI and waist circumference ($p < 0.001$ for both).
Conclusion: In patients with MASLD, decreased skeletal muscle mass is common and is associated with an adverse metabolic profile, including dyslipidemia, hyperuricemia, elevated liver enzymes, and higher blood pressure. These findings support the concept of a close interaction between metabolic dysfunction and skeletal muscle impairment in MASLD and highlight the importance of assessing muscle mass as part of comprehensive cardiometabolic risk stratification in this population.

Assessment of maternal and fetal outcomes of pregnancy in metabolic associated fatty liver disease, a prospective cohort study

Hend Shousha[1], Mira Atef[1], Wafaa El-Akel[1], Naglaa Zayed Zayed[1], Sara Raouf[1], Ayman Hany[2], Ayman Yosry[1], Sherif Hamdy[1]. *[1]Endemic medicine department, Faculty of medicine, Cairo University, Cairo, Egypt; [2]Obstetrics and gynecology department, Cairo University, Cairo, Egypt*
Email: hendshousha@yahoo.com

Background and aims: Pregnancy is a pro-inflammatory, pro-thrombotic, insulin-resistant, and hyperlipidemic state. This study intends to evaluate the impact of Metabolic-associated Fatty Liver Disease (MAFLD) on Pregnancy outcomes.

Method: This cohort study involved pregnant women in the third trimester recruited from the obstetrics department, Faculty of medicine, Cairo University, conducted from June 2023 to June 2024. Baseline demographics, pre-pregnancy body mass index (BMI), comorbidities, acoustic radiation force impulse (ARFI) and Transient elastography were performed assessing liver stiffness and controlled attenuation parameter (CAP). Pregnancy outcome was assessed.
Results: Out of 192 pregnant females, prevalence of MAFLD was 84 (44%). There was no significant difference in age between MAFLD and non-MAFLD groups. Gestational DM was more prevalent in the MAFLD group 16(19%) vs 10(9.3%) p 0.049. Pre-pregnancy BMI was significantly higher in MAFLD group (30.37 ± 3.39 vs 26.16 ± 3.67, p < 0.01), CAP was significantly higher in MAFLD group (274.52 ± 17.92 vs 212.90 ± 38.59, p < 0.01 and the mean ARFI of the liver 0.99 ± 0.26 vs 0.92 ± 0.20, p 0.047. Neonatal jaundice was more prevalent in the MAFLD group 58 (69%) vs 38(35%) p < 0.01. Neonates large for gestational age was observed in MAFLD group 13(15.7%) versus 6 (5.6%) p 0.021. No significant difference between the groups regarding preeclampsia, gestational hypertension, pre and post-partum hemorrhage, mode of delivery, preterm, stillbirth, neonatal ICU admission, low for gestational age. In the MAFLD group, significant correlation was observed between pre-pregnancy BMI and CAP. Bilirubin and alkaline phosphatase exhibited an inverse correlation with steatosis grade in the MAFLD group (r = –0.25, –0.24; P = 0.02 and 0.03, respectively). Triglycerides had a strong correlation with CAP and steatosis grade in the MAFLD group (r = 0.28, P = 0.02) and (r = 0.29, P = 0.01), respectively. Most of non-MAFLD group (72%) had no maternal events p 0.04. 50% of MAFLD group neonates had at least one fetal event p < 0.01. MAFLD group had either unfavorable fetal outcome or both unfavorable maternal and fetal p < 0.01. On consolidating outcome groups 91% of MAFLD group had unfavorable outcome p < 0.01. On applying multivariate binary logistic regression, in which unfavorable outcome is the dependent factor, presence of MAFLD is the only significant predictor for unfavorable outcome (P < 0.01, OR 4.25, 95% CI 1.8–10).
Conclusion: MAFLD is associated with unfavorable pregnancy outcomes.

THU-195
Phase angle cut-off values can reliably predict malnutrition in non-cirrhotic and cirrhotic MASLD patients: PhAT-LD study

Aditi Singh [1], Omkar Rudra[1], Uma Kanal[1], Shiv Kumar Sarin[1]. [1]*Institute of liver and biliary sciences, New Delhi, India*
Email: aditi.yogendra98@gmail.com

Background and aims: Malnutrition and sarcopenia are common yet under-recognized in metabolic dysfunction–associated steatotic liver disease (MASLD) and are associated with adverse outcomes. Nutritional assessment in MASLD is challenging due to altered body composition and fluid shifts. Phase angle (PhA), derived from bioelectrical impedance analysis (BIA), is a promising non-invasive marker of nutritional status, but validated cut-offs in MASLD are lacking. This study evaluated the utility of PhA for identifying malnutrition across the MASLD disease spectrum.
Method: This retrospective cross-sectional study included adults with MASLD and MASLD-related cirrhosis diagnosed using standard clinical criteria. Nutritional assessment comprised anthropometry, biochemical parameters, functional tests (handgrip strength, Liver Frailty Index, 6-minute walk test), and BIA-derived body composition analysis. Malnutrition was defined using Global Leadership Initiative on Malnutrition (GLIM) criteria. The cohort was divided into derivation (70%) and validation (30%) sets with stratified disease-stage representation. Receiver operating characteristic analysis was used to determine optimal PhA cut-offs.
Results: A total of 660 patients were analyzed: 118 with non-cirrhotic MASLD, 264 with compensated cirrhosis, and 278 with decompensated cirrhosis. Median age increased with disease severity (p < 0.001). Functional capacity declined progressively, with reduced handgrip strength, shorter 6-minute walk distance, and higher frailty scores across stages (all p < 0.001). PhA decreased stepwise from non-cirrhotic MASLD to compensated and decompensated cirrhosis (p < 0.001). GLIM-defined malnutrition was present in 51.1% overall and was highest in decompensated cirrhosis (65.1%, p < 0.001). PhA showed good diagnostic accuracy for malnutrition (AUC 0.81). Optimal PhA cut-offs were 5.05 for non-cirrhotic MASLD (AUC 0.81), 4.35 for decompensated cirrhosis (AUC 0.80), and 4.65 overall, yielding 76.8% sensitivity and 73.1% specificity. At this threshold, malnutrition was concordantly identified by both GLIM and PhA in 76.8% of patients, while 26.9% were classified as malnourished by PhA alone.
Conclusion: Phase angle is a reliable, non-invasive screening tool for detecting malnutrition in MASLD patients. The use of disease stage–specific and overall cut-offs improves nutritional risk stratification across the entire MASLD spectrum.

THU-196
Association of steatotic liver disease with pregnancy outcomes: a systematic review and meta-analysis of 74.8 million pregnant individuals

Jacqueline Slobin[1], Nina Rodriguez[1], Cecilia Katzenstein[1], Nadejda Capatina[2], Caroline Ovadia[3], Tatyana Kushner[4]. [1]*Icahn School of Medicine at Mount Sinai, New York, United States;* [2]*Guys & Saint Thomas Nhs Foundation Trust, London, United Kingdom;* [3]*University of Edinburgh, Scotland, United Kingdom;* [4]*Weill Cornell Medicine, New York, United States*
Email: jacqueline.slobin@icahn.mssm.edu

Background and aims: The prevalence of steatotic liver disease (SLD) in pregnancy has tripled over the past decade, affecting up to 18% of pregnant individuals. Prior studies report varied associations between SLD and adverse pregnancy outcomes (APOs).
Method: We conducted a systematic review and meta-analysis querying PubMed, Embase, and Web of Science for studies reporting APOs in individuals with SLD. Two independent reviewers screened titles and abstracts, full texts, and extracted data. Pooled prevalence and odds ratios (ORs) with 95% confidence intervals (CI) were calculated using random-effects models in Stata 19.
Results: Twenty-nine studies with 74.8 million pregnant individuals and 95,547 SLD cases were included. In 17 studies reporting prevalence, the pooled prevalence of SLD was 16% (95% CI, 12–20%). SLD was diagnosed by imaging (15), ICD codes (5), Hepatic Steatosis Index (5), Fatty Liver Index (1), and biopsy (1). Studies were conducted in Asia (17), North America (5), Europe (4), Australia (2), and Africa (1).
SLD was associated with gestational diabetes mellitus (OR 2.93, 95% CI, 2.42–3.52; n = 26), preeclampsia (OR 2.72, 95% CI 1.79–4.13; n = 10), gestational hypertension (OR 2.24, 95% CI 1.75–2.88; n = 7), and a composite of hypertensive disorders of pregnancy (OR 3.44, 95% CI 2.70–4.38; n = 10). Pregnant individuals with SLD were more likely to undergo cesarean birth (OR 1.84, 95% CI 1.52–2.22; n = 14) and experience postpartum hemorrhage (OR 1.64, 95% CI 1.09–2.46; n = 6). SLD was also associated with increased odds of preterm birth (<37 weeks; OR 1.89, 95% CI 1.62–2.20; n = 17), with a stronger association with very preterm birth (<32 weeks; OR 3.79, 95% CI 2.22–6.46; n = 4). In subgroup analyses of studies that diagnosed SLD using ultrasound and Fibroscan, associations with preeclampsia and postpartum hemorrhage were no longer significant, but associations with other outcomes persisted. Heterogeneity across studies was high (I^2 = 48–98%) but decreased after stratification by diagnostic method and country.
Conclusion: SLD in pregnancy was associated with increased risk of several APOs, highlighting the importance of screening, risk stratification and medical management of individuals with SLD. However, there was variability in strength of associations by SLD diagnostic modality and marked heterogeneity across studies, complicating risk interpretation. Future directions will focus on

conducting an individual participant data meta-analysis to better identify patients with SLD at risk of APOs.

THU-197

Metabolic comorbidities differentially shape dysfunctional adiposity phenotypes in MASLD

Daniel Smith[1,2], Annalisa Cespiati[1,2], Rosa Lombardi[1,2], Felice Cinque[1,2], Erika Fatta[1], Edoardo Pulixi[1], Daniela Bignamini[1], Giovanna Oberti[1], Anna Ludovica Fracanzani[1,2]. *[1]SC Medicina ad Indirizzo Metabolico, Fondazione IRCCS Cà Granda Ospedale Maggiore Policlinico, Milan, Ita, Milano, Italy; [2]Department of Pathophysiology and Transplantation, University of Milan, Italy, Milano, Italy*
Email: annalisa.cespiati@unimi.it

Background and aims: Metabolic dysfunction-associated steatotic liver disease (MASLD) is defined by liver steatosis in the presence of metabolic comorbidities. Dysfunctional adiposity, rather than adiposity alone, plays a key role in metabolic impairment. While metabolic comorbidities are risk factors for MASLD progression, their differential impact on dysfunctional adiposity remains unclear. Aim: to evaluate the distinct associations between major metabolic comorbidities and markers of dysfunctional adiposity in MASLD.
Method: We enrolled 505 MASLD patients (mean age 50 ± 12 years, 65% male) from tertiary Metabolic Liver center. Dysfunctional adiposity was assessed by epicardial adipose tissue (EAT) measured by echocardiography, and adipose tissue index (ATI, mass/height2) assessed by bioimpedance analysis. Waist circumference (WC) was considered a marker of central adiposity.
Results: Mean BMI was 28.9 ± 4.6, with 84% increased WC. Hypertension was present in 36%, dyslipidemia in 56%, diabetes in 12%, insulin-resistance (IR) in 65%. Dyslipidemia was associated with lower ATI (9.4 ± 3.9 vs 10.2 vs 4.4 kg/m^2, p = 0.04) but higher EAT (8.3 ± 2.8 vs 7.8 ± 2.7 mm, p = 0.04), without difference in WC. Hypertension was associated with higher WC (89 vs 80%, p = 0.01), ATI (10.9 ± 4.2 vs 9.1 ± 4, p = 0.001), and EAT (8.5 ± 2.8 vs7.9 ± 2.7 mm, p = 0.03). Diabetes and IR were both associated with increased WC (diabetes 95 vs 82%, p = 0.008; IR 92 vs 64%, p = 0.001) and ATI (diabetes: 12.2 ± 4.6 vs 9.4 ± 4, p = 0.001; IR: 10.5 ± 4.1 vs 7.9 ± 3.7 p = 0.001), but not with EAT. At multivariate analysis adjusted for age, sex, drugs, dyslipidemia remained independently associated with lower ATI (b = –0.5, 95%CI – 0.88 to – 0.13, p = 0.008), while its association with EAT was lost after adjustment for statin use (p = 0.81), which was independently associated with higher EAT (b = 0.49, 95%CI 0.2–0.8, p = 0.004). Hypertension was independently associated with higher ATI (b = 1.3, 95%CI 0.3–2.3, p = 0.009), as for diabetes (b = 1.9, 95%CI 0.9–2.9, p = 0.0003), and IR (b = 1.18, 95%CI 0.8–1.6, p = 0.001). Only IR remained associated with increased WC (OR 6.8, 95%CI 3.6–13.1, p = 0.001). No metabolic comorbidity showed an independent association with EAT after full adjustment.
Conclusion: Metabolic comorbidities showed distinct associations with markers of dysfunctional adiposity in MASLD. While ATI captured metabolically driven adiposity, EAT reflects a cardiovascular-oriented phenotype, supporting heterogeneous cardiometabolic trajectories in MASLD and the need for marker- specific risk stratification.

THU-198

Development of metabolic dysfunction-associated steatotic liver disease in patients with cryptogenic steatotic liver disease

Won Sohn[1], Hyunwoo Oh[1], Kyoung A Ko[1], Jae Yoon Jeong[2], Ju-Yeon Cho[3], Jung Hee Kim[4], Yong Kyun Cho[1], Yoosoo Chang[1], Seungho Ryu[1]. *[1]Kangbuk Samsung Hospital, Sungkyunkwan University School of Medicine, Seoul, Korea, Rep. of South; [2]Ewha Womans University, Seoul, Korea, Rep. of South; [3]Saint Louis University, Seoul, Korea, Rep. of South; [4]Hallym University Dongtan Sacred Heart Hospital, Seoul, Korea, Rep. of South*
Email: hand0827@naver.com

Background and aims: This study aimed to examine the development of metabolic dysfunction-associated steatotic liver disease (MASLD) in cryptogenic steatotic liver disease (SLD). We investigated the role of homeostatic model assessment of insulin resistance (HOMA-IR) and high-sensitivity C-reactive protein (hs-CRP) in cryptogenic SLD.
Method: A total of 102,431 individuals, consisting of 3,630 patients with cryptogenic SLD and 98,801 individuals without SLD and cardiometabolic factors (non-SLD group), were included in this study. The definition of MASLD was a sonographic presence of hepatic steatosis with at least one of cardiometabolic factors. The risk of MASLD development in cryptogenic SLD was assessed by comparing non-SLD group. We also assessed the risk of MASLD according to the presence of HOMA-IR and hs-CRP.
Results: The mean age was 33.7 years and 27.4% was male sex. During 6.2 years of median follow-up period, 12,580 patients with MASLD developed. Over 60% of cryptogenic SLD patients developed MASLD. The incidence rate of MASLD was significantly higher in cryptogenic MASLD than in non-SLD group (173.3/103 person-year vs. 15.8/103 person-year, p < 0.001). The risk of MASLD development was higher in cryptogenic SLD than non-SLD group (multivariable-adjusted hazard ratio [HR] 6.09, 95% confidence interval [CI] 5.80–6.39). Additionally, we analyzed the development of MASLD between non-SLD group, cryptogenic SLD with low HOMA-IR (≤2.5) and low hs-CRP (≤2 mg/L), and cryptogenic SLD with high HOMA-IR (>2.5) or high hs-CRP (>2 mg/L). Compared to non-SLD group, the risk of MASLD significantly increased in cryptogenic SLD patients with low HOMA-IR and low hs-CRP (multivariable-adjusted HR 5.59, 95% CI 5.29–5.90), and those patients with high HOMA-IR or high hs-CRP (multivariable-adjusted HR 7.87, 95% CI 6.98–8.86).
Conclusion: Cryptogenic SLD patients, particularly those with elevated HOMA-IR or hs-CRP, have an increased risk of developing MASLD. Cryptogenic SLD may represent a transitional state, and incorporating HOMA-IR or hs-CRP assessment could improve risk stratification and early identification of patients likely to progress to MASLD.

Hormonal replacement therapy as a preventive measure in post-menopausal women with metabolic dysfunction–associated steatohepatitis

Norah Terrault[1], Jennifer Dodge[1], Laura Wilson[2], Arun J. Sanyal[3], Brent A. Neuschwander-Tetri[4], Ayako Suzuki[5]. *[1]University of Southern California, Los Angeles, United States; [2]John Hopkins Universisty, Baltimore, United States; [3]Virginia Commonwealth University, Richmond, United States; [4]St.Louis University, St. Louis, United States; [5]Duke University, Durham, United States*
Email: terrault@usc.edu

Background and aims: Cross-sectional studies suggest a link between estrogen deficiency and more advanced fibrosis and hormone replacement therapy (HRT) has been associated with less severe fibrosis in metabolic dysfunction-associated steatohepatitis (MASH); however, prospective data linking HRT exposure to longitudinal fibrosis progression using validated noninvasive tests are lacking.
Method: Women in the multicenter NASH CRN cohort with longitudinal data on HRT use (primary exposure) and liver stiffness measures (LSM) by VTCE exam (IQR/median ≤0.3) were included. Using multinominal logistic regression, relative risk ratios (RRR) for the association of demographic and clinical variables with 30% worsening or 30% improvement of LSM from baseline were estimated, selecting a multivariable female-specific model based on AIC reduction.
Results: 734 women were included: median age 56 y, 67.8% post-menopausal with 14.7% on HRT (ever), 68.9% PNPLA3 GG/CG (n = 513 tested), 48.0% low alcohol intake (>0–7 drinks/wk), 38.7%/36.5% prediabetes/T2DM, median BMI 34.2 kg/m2, 65.9% on anti-

hypertensives, 51.0% T2DM medications (8.9% on GLP1A) and 45.5% lipid meds at baseline. Of 2475 VTCE exams, the median (IQR) was 2 (1–3) per person over 2.3 (1.4–4.4) yrs follow-up. Baseline LSM was 8.1 (5.7–13.1) and median/IQR was 0.16 (0.11–0.22) with a change in LSM from baseline worsened or improved by 30% or more in 13.1% (N = 324) and 18.6% (N = 461), respectively (rest within 30% of baseline). A final model of 10 variables achieved optimal AIC values to predict worsening and improvement ≥30%: LSM at baseline, time between LSM measures, albumin, HDL, BMI, T2DM, platelet count, alkaline phosphatase (ALP), AST:ALT ratio and HRT use. Specifically, ALP was associated with worsening of LSM (RRR 1.05 per 10 units [95% CI:1.01–1.10]) and improvement (RRR 0.94 per 10 units [0.89–0.99]); ALP was not elevated in those with HRT use. Post-menopausal HRT was associated with lower risk of worsening LSM (RRR 0.63, [0.38–1.04]) but not improving LSM (RRR 1.01, [0.62–1.65]).
Conclusion: Female-specific models for prognostication offer value in a personalized medicine era. Amongst a predominantly middle-aged cohort of women with MASLD, ALP emerged as a novel marker associated with fibrosis progression/regression and HRT associated with lower risk of worsening fibrosis in post-menopausal women. This prospective demonstration of HRT's association with LSM change supports a call for randomized studies of HRT in women with MASH.

Association between osteoporosis and the severity of steatotic liver disease
Léa Terrien[1], Jerome Boursier[1], Marine Roux[2], Frédéric Oberti[3], Isabelle Fouchard[3], Adrien Lannes[3], Celine Rolland[3], Damien Combes[3], Christophe Aubé[1], Anita Paisant[1], Béatrice Bouvard[1]. *[1]Angers University, Angers University Hospital, Angers, France; [2]Angers University, Angers, France; [3]Angers University Hospital, Angers University, Angers, France*
Email: jeboursier@chu-angers.fr

Background and aims: Osteoporosis, which remains underdiagnosed, shares common risk factors with steatotic liver diseases (SLD) but the relationship between these two conditions is still being debated. Although the current gold standard for diagnosing osteoporosis is dual-energy X-ray absorptiometry, computed tomography has emerged as an accurate alternative method (PMID 23588747).We aimed to evaluate the association between osteoporosis, as determined by bone mineral density measurement on CT scan (BMD-CT), and the severity of SLD.
Method: We included 330 patients with biopsy-proven SLD in our Hepatology Department. Vertebral BMD was retrospectively assessed using L1 attenuation on thoracic or abdominal CT scans performed within ±2 years of liver biopsy. A high osteoporosis risk was defined by BMD-CT < 110 Hounsfield units (HU). Advanced fibrosis was defined by fibrosis stage F3–4 on liver biopsy. Liver stiffness measurement with FibroScan and the specialized blood test FibroMeterV2G were both available for all patients.
Results: 146 patients (44%) had BMD-CT defined osteoporosis, and 48% had advanced fibrosis. Patients with advanced fibrosis had lower BMD-CT than those without: 109 HU [IQR: 92–139] vs 123 HU [IQR: 96–151], p = 0.026. Age, alcohol consumption and advanced fibrosis were independently associated with BMD-CT osteoporosis in multivariate analysis. The prevalence of BMD-CT osteoporosis across the subgroups was: 23% (if age < 65, and both no/light alcohol ≤ 70 g/week and F0–2 fibrosis), 35–39% (age < 65, and moderate/high alcohol > 70 g/week or F3–4 fibrosis), 59% (age < 65, and both moderate/high alcohol and F3–4 fibrosis), 62–67% (age ≥ 65, whatever alcohol or fibrosis). In multivariate analyses where non-invasive tests replaced histology, FibroMeterV2G was independently associated with BMD-CT osteoporosis, whereas liver stiffness was not. Age (< 65 vs ≥ 65), alcohol consumption (no/light vs moderate/high) and FibroMeter2G (≤ 0.445 vs > 0.445) stratified patients in three groups where the prevalence of BMD-CT osteoporosis was: 19%, 45–52%, and 67–68%.
Conclusion: In addition to age and alcohol consumption, advanced fibrosis is associated with BMD-CT osteoporosis in patients with SLD. Osteoporosis should be screened according to these risk factors, to improve the holistic management of steatotic liver diseases.

THU-203
"Lean" MASLD in the elderly living at high altitude: an underestimated cardiometabolic risk
Nurgul Toktogulova[1]. *[1]Kyrgyz State Medical Academy named after I.K. Akhunbaev (KSMA), Hospital therapy, Bishkek, Kyrgyz Republic*
Email: t.nur30@mail.ru

Background and aims: Metabolically associated steatotic liver disease (MASLD) is a systemic cardiometabolic disorder in which cardiovascular complications are the leading cause of mortality. In elderly patients, metabolic dysfunction is exacerbated by sarcopenia, chronic low-grade inflammation, and reduced adaptive capacity. Residence at mid- to high-altitude, associated with chronic hypobaric hypoxia, represents an additional and insufficiently studied modifying factor.
Method: An open comparative study included 733 ethnic Asians living in low- and mid-altitude regions, comprising healthy controls, patients with MASLD, and those with MASLD and type 2 diabetes. Anthropometry, body composition, metabolic and liver parameters, metabolic syndrome components, and comorbidities were assessed. In a subgroup (n = 50), inflammatory cytokines (TNF-α, IL-4) and the cytokine index were analyzed, and liver fibrosis risk was evaluated. Statistical analysis was performed using SPSS.
Results: Elderly residents of mid-altitude regions with MASLD demonstrated a more pronounced accumulation of cardiometabolic risk factors: the presence of three or more components of metabolic syndrome was significantly more frequent compared with younger individuals. Waist circumference exceeded threshold values in 72.5% of elderly patients. A substantial proportion of cases represented the "lean" MASLD phenotype (BMI < 23 kg/m^2), particularly among men, and was associated with increased fat mass combined with reduced skeletal muscle mass, consistent with a sarcopenic phenotype. Residents of mid-altitude areas exhibited lower levels of fasting glucose, HbA1c, alanine aminotransferase (ALT), and total cholesterol, which may reflect metabolic adaptation to hypoxic conditions. However, levels of TNF-α and IL-4 were elevated regardless of BMI, and inflammatory activity as well as the cytokine index increased with advancing liver fibrosis. Visceral obesity, assessed by waist circumference rather than BMI, showed significant correlations with cytokine profile, ALT levels, and fibrosis indices.
Conclusion: MASLD in elderly individuals living at mid-altitude is characterized by a combination of substantial cardiometabolic burden, chronic inflammation, and a high prevalence of the "lean" phenotype associated with sarcopenia. Residential altitude acts as an independent determinant of an adverse metabolic and inflammatory MASLD phenotype, underscoring the need for a personalized, age- and geography-oriented approach to diagnosis and management.

THU-204
Phosphatidylethanol reductions are associated with clinically meaningful improvements in blood pressure and lipid profile among patients with steatotic liver disease
Nikolaj Torp[1], Stine Johansen[1], Katrine Tholstrup Bech[1,2], Helle Schnefeld[1,2], Markus Maagaard[1,2], Ellen Lyngbeck Jensen[1,2], Mette Lehmann Andersen[1,3], Charlotte Mary Gjøl[1], Gunilla Calov[1], Ida Villesen[1], Johanne Kragh Hansen[1], Katrine Thorhauge[1], Camilla Dalby Hansen[1], Maria Fogt[1], Ea Kyed[1], Kathrine Sejer Sørensen[1], Anine Andersen[1], Peter Andersen[1], Marianne Bergmann[4], Maja Thiele[1,2], Mads Israelsen[1,2], Aleksander Krag[1,2]. *[1]Centre for Liver Research, Department of*

Gastroenterology and Hepatology, Odense University Hospital, Odense, Denmark; [2]Department of Clinical Research, University of Southern Denmark, Odense, Denmark; [3]Department of Gastroenterology and Hepatology, Herlev Hospital, Herlev, Denmark; [4]Department of Biochemistry and Immunology, Lillebaelt Hospital, University Hospital of Southern Denmark, Vejle, Denmark
Email: nikolaj.christian.torp@rsyd.dk

Background and aims: Alcohol intake influences cardiometabolic risk factors (CMRFs) such as hypertension and dyslipidemia, but the association between changes in the direct alcohol biomarker phosphatidylethanol (PEth) and CMRFs is unknown. We investigated the association between decreases in PEth and improvements in CMRFs among patients with steatotic liver disease (SLD).
Method: Single-center study of patients with SLD and a baseline and follow-up visit where PEth and CMRFs were available. Participants were subclassified into MASLD, MetALD and ALD based on hepatic steatosis (CAP ≥ 248 dB/m), CMRFs and self-reported current alcohol intake. Based on changes in PEth, participants were divided into a substantial decrease group (PEth reduction of ≥80 ng/mL from baseline to follow-up), a moderate decrease group (20–79 ng/mL reduction) and a no decrease group (<20 ng/mL reduction), who also served as the reference. Clinically meaningful improvements in blood pressure (systolic ≥5 mmHg reduction and diastolic ≥3 mmHg reduction) and the lipid profile (triglycerides ≥30% relative reduction, HDL ≥0.1 mmol/L increase and LDL ≥0.5 mmol/L reduction) were defined according to cardiovascular society recommendations. Regression models were adjusted for age, sex, smoking, as well as changes in waist circumference, HbA1c, anti-hypertensive and lipid-lowering drug use.
Results: We included 965 participants with a median time between visits of 25 months (IQR: 24–29). Distribution of MASLD/MetALD/ALD was 603/234/128 where the median baseline PEth in each subclass was 12/236/445 ng/mL. Across SLD subclasses, 16% had a substantial PEth decrease, 13% a moderate decrease and 71% no decrease. Both a substantial and moderate PEth decrease were associated with higher odds of clinically meaningful improvements in systolic blood pressure (OR = 1.73, 95% CI: 1.19–2.52, p = 0.004 and OR = 1.54, 95% CI: 1.03–2.30, p = 0.034), while a substantial, but not moderate, decrease in PEth was associated with triglycerides improvement (OR = 2.18, 95% CI: 1.37–3.48, p < 0.001). Both a substantial and a moderate decrease in PEth was associated with lower odds of HDL improvement (OR = 0.52, 95% CI: 0.35–0.79, p = 0.002 and OR = 0.54, 95% CI: 0.35–0.83, p = 0.005). There were no observed association between decreases in PEth and improvements in diastolic blood pressure nor LDL.
Conclusion: Reductions in PEth are associated with clinically meaningful improvements in blood pressure and lipid profile, why PEth may serve as an important tool to monitor patients with SLD.

THU-205
Prognostic impact of chronic kidney disease and proteinuria in metabolic dysfunction–associated steatotic liver disease

Shun-Ichi Wakabayashi[1], Takefumi Kimura[1], Nobuharu Tamaki[2], Naoki Tanaka[1], Masayuki Kurosaki[2]. *[1]Shinshu University School Of Medicine, Matsumoto, Japan; [2]Musashino Red Cross Hospital, Musashino, Japan*
Email: shun_1@me.com

Background and aims: Metabolic dysfunction–associated steatotic liver disease (MASLD) is a systemic condition associated with liver-related complications and extrahepatic organ dysfunction, including chronic kidney disease (CKD). Although CKD and proteinuria are frequently observed in MASLD, their prognostic significance for liver-related events (LRE), cardiovascular events (CVE), and all-cause mortality remains unclear. We aimed to investigate the associations of CKD and proteinuria with long-term clinical outcomes in patients with MASLD.
Method: This retrospective cohort study used the Japanese claims-based database. Patients with a fatty liver index ≥60 or with diagnosis of fatty liver disease were screened, and those fulfilling MASLD criteria with available serum creatinine and qualitative urine protein data were included. A total of 420,646 patients were analyzed. CKD was defined as an estimated glomerular filtration rate <60 mL/min/1.73 m^2, and proteinuria as ≥2+ (equivalent to 100 mg/dL) on urine dipstick testing. The primary endpoints were LRE (hepatic decompensation and hepatocellular carcinoma), CVE, and all-cause mortality.
Results: The cumulative incidence at 5 years was 0.06% for LRE, 1.01% for CVE, and 0.26% for all-cause mortality. At baseline, 8.0% of patients had CKD and 14.4% had proteinuria. Patients with CKD showed significantly higher 5-year cumulative incidences of LRE, CVE, and all-cause mortality than those without CKD (0.12% vs. 0.05%, 2.55% vs. 0.88%, and 0.58% vs. 0.23%, respectively; all log-rank p < 0.05). In multivariable analyses, CKD was independently associated with an increased risk of CVE (adjusted hazard ratio [aHR] 1.26; 95% CI, 1.16–1.37), but not with LRE (aHR 0.92; 95% CI, 0.63–1.35) or all-cause mortality (aHR 1.13; 95% CI, 0.95–1.35). In contrast, patients with proteinuria had higher 5-year cumulative incidences of LRE, CVE, and all-cause mortality than those without proteinuria (0.09% vs. 0.05%, 1.74% vs. 0.94%, and 0.41% vs. 0.23%, respectively; all log-rank p < 0.05). Proteinuria was independently associated with increased risks of LRE (aHR 1.72; 95% CI, 1.27–2.32), CVE (aHR 1.26; 95% CI, 1.16–1.37), and all-cause mortality (aHR 1.50; 95% CI, 1.30–1.74).
Conclusion: In MASLD, CKD was associated mainly with cardiovascular risk, whereas proteinuria was a robust predictor of liver-related events, cardiovascular events, and mortality. Assessment of proteinuria may improve risk stratification in patients with MASLD.

THU-206
Impact of fibrosis risk on health-related quality of life and activity in patients with metabolic dysfunction–associated steatohepatitis in Germany

Hayley Wallinger[1], Lena Amari[1], Riya Arora[2], Elisabeth de Laguiche[3], Riku Ota[3]. *[1]Adelphi Real World, Bollington, United Kingdom; [2]Novo Nordisk Service Centre, Bangalore, India; [3]Novo Nordisk, Søborg, Denmark*
Email: hayley.wallinger@omc.com

Background and aims: Metabolic dysfunction–associated steatohepatitis (MASH) is linked to progressive liver damage and diverse patient-reported burden. Given limited data on how fibrosis risk relates to health-related quality of life (HRQoL), we aimed to assess HRQoL and activity restrictions by fibrosis risk among patients with MASH (PwM) in Germany.
Method: We analyzed Germany data from the MASH Disease Specific Programme™, a cross-sectional physician- and patient survey conducted from January–June 2024. Physicians reported fibrosis risk for PwM, classified according to American Association for the Study of Liver Diseases (AASLD) 2023 guidance. Patients self-reported disease burden using the NASH-CHECK and Work Productivity and Activity Impairment (WPAI) questionnaires. NASH-CHECK scores range from 0 (least) to 10 (most impact). WPAI scores are expressed as percentages, with higher numbers indicating greater impairment. Indeterminate and high-risk fibrosis groups were each compared with the low-risk group after entropy balancing on age and sex. Reported age and sex are unweighted, descriptive only. Pairwise statistical tests compared outcomes versus the low-risk group.
Results: Overall, 65 physicians reported data for 650 patients, of whom 397 self-reported data (n = 204 low risk, n = 61 indeterminate risk, n = 33 high risk). Mean ± SD age was 54.2 ± 10.3, 57.6 ± 9.1, and 58.9 ± 10.5 years; female proportion was 40.7%, 34.4%, and 24.2%; and mean body mass index ± SD (kg/m^2) was 31.5 ± 4.0, 32.3 ± 3.9, and 31.5 ± 5.6 for low- indeterminate- and high-risk patients, respectively. Mean ± SD WPAI scores were higher in high- versus low-risk patients for overall work impairment (49.7 ± 23.9 vs. 21.3 ± 20.5) and daily activity impairment (55.1 ± 27.4 vs 36.1 ± 20.4); both p < 0.01.

High-risk patients reported greater impact than low-risk patients to NASH-CHECK activity limitations (4.0 ± 2.0 vs. 2.4 ± 1.6), emotional impact (4.5 ± 2.7 vs. 2.4 ± 1.3), social impact (4.5 ± 2.4 vs. 1.8 ± 1.2), cognitive symptoms (3.5 ± 2.3 vs. 1.6 ± 1.5), fatigue (5.0 ± 2.9 vs. 2.8 ± 2.3), itchy skin (4.3 ± 2.9 vs. 2.2 ± 2.0), and abdominal bloating (5.0 ± 2.9 vs. 2.8 ± 2.3) domains; all $p < 0.01$.

Conclusion: Among German PwM, higher fibrosis risk was associated with greater activity limitations as measured by NASH-CHECK and WPAI. These findings emphasize the importance of early fibrosis risk identification and targeted management to limit work impairment and improve HRQoL.

THU-211

Impact of small intestinal bacterial overgrowth on disease progression in metabolic dysfunction–associated steatotic liver disease

Ziteng Wang[1], Wentao Tan[2], Hongshan Wei[2], Hong Liu[1]. *[1]Beijing Shijitan hospital, Beijing, China; [2]Beijing Ditan hospital, Beijing, China*
Email: wangzi_t@163.com

Background and aims: Increasing evidence suggests that small intestinal bacterial overgrowth (SIBO) may play a contributory role in metabolic dysfunction–associated steatotic liver disease (MASLD). Alterations in intestinal microbial ecology, increased intestinal permeability, and dysregulated microbial metabolites have been proposed as key mechanisms linking SIBO to liver injury. This study sought to clarify the association between SIBO and MASLD, with an emphasis on gut microbial signatures and related metabolic characteristics.

Method: Consecutive individuals who underwent abdominal imaging and lactulose hydrogen–methane breath testing were retrospectively analyzed. Baseline characteristics were compared using independent-sample *t* tests. Associations between SIBO and MASLD were evaluated through stratified analyses and chi-square tests, while multivariate logistic regression was employed to identify independent predictors of MASLD. Fecal samples from patients with MASLD were further subjected to 16S rRNA gene sequencing to characterize gut microbiota profiles and infer metabolic functional differences according to SIBO status.

Results: Among 350 enrolled participants, 97 (27.7%) were diagnosed with MASLD, whereas 253 (72.3%) did not have MASLD. SIBO was detected in 300 individuals (85.7%). The prevalence of SIBO differed significantly between MASLD and non-MASLD groups. Multivariate analysis demonstrated that SIBO was independently associated with the presence of MASLD and correlated with greater disease severity, with methane-positive SIBO showing the strongest association. Microbial profiling revealed that MASLD was characterized by enrichment of Firmicutes, particularly taxa within Lactobacillales and Bacilli. In contrast, SIBO-positive patients exhibited a microbiota dominated by Proteobacteria, including increased abundance of the Burkholderiaceae family and genera such as *Dialister*, *Limnobacter*, and *Acidovorax*. Functional pathway analysis indicated that inter-group differences were mainly related to metabolic processes.

Conclusion: SIBO is closely linked to MASLD and its progression, with methane-positive SIBO displaying a more pronounced association with disease severity. MASLD and SIBO exhibit distinct gut microbial patterns, predominantly involving Firmicutes and Proteobacteria, respectively. Alterations in microbiota-related metabolic pathways may represent a key mechanistic link between SIBO and MASLD.

THU-212

Does size matter? Think again: smartphone-ready reasoning LLMs with RAG match frontier models for MASLD clinical decision support

Ernest Saenz[1], Juan Carlos Restrepo[2], Juan Turnes Vázquez[3], Maria Fernanda Saavedra Chacon[4], Gabriel Sebastián Díaz Ramírez[2], Camilo Andrés Torres Londoño[5], Yohana Poveda Salinas[6], Betty Morales Arrieta[7], María Cristina Torres Caro[8], Andres Gomez Aldana[9], Santiago Rodriguez-Mora[9], Jorge Ortiz[10], Diana Marcela Escobar Cardenas[5], Andreas Teufel[1], Ismael de Jesus Yepes Barreto[11]. *[1]Department of Medicine II, Division of Hepatology, Medical Faculty Mannheim, Heidelberg University, Mannheim, Germany; [2]Hospital Pablo Tobón Uribe, Medellín, Colombia; [3]University Hospital Complex Of Pontevedra, Pontevedra, Spain; [4]Clínica Ces, Medellín, Colombia; [5]Fundacion Valle Del Lili, Cali, Colombia; [6]Clínica Imbanaco, Cali, Colombia; [7]Hospital Universitario del Caribe, Cartagena de Indias, Colombia; [8]Fundacion Cardio Infantil Instituto De Cardiologia, Bogotá, Colombia; [9]Department of Internal Medicine, Division of Digestive Diseases, University of Cincinnati, Cincinnati, United States; [10]Clínica IMAT Oncomedica Auna, Monteria, Colombia; [11]Facultad de Medicina, Universidad de Cartagena, Cartagena, Colombia*
Email: ernest.phd@gmail.com

Background and aims: Metabolic dysfunction-associated steatotic liver disease (MASLD) requires evidence-based decision support, particularly in resource-limited settings serving Spanish-speaking populations (600+ million globally). Reasoning large language models (LLMs) combined with retrieval-augmented generation (RAG) may provide evidence-based recommendations, but optimal model size for clinical deployment remains unknown. We compared on-device reasoning LLMs (≤20 billion, edge-capable) versus frontier models in MASLD clinical assessments.

Method: Twelve reasoning LLMs spanning 8B to 671B parameters (plus SOTA models: Gemini-2.5-Pro, GPT-5, Claude-Sonnet-4) answered 120 hepatologist-designed multiple-choice questions (MCQ) across MASLD management. Models were grouped by size: Small (≤20B), Medium (21B–355B), Large (≥671B/proprietary). Temperature = 0 and thinking tokens = 50% model maximum). Then, top 3 models (from the MCQ test) integrated with RAG system (ChromaDB vector store; 7 clinical guidelines; text-embedding-3-small; MMR retrieval k = 15) answered 15 Spanish-language free-text clinical vignettes to assess cross-lingual performance. Twelve blinded hepatologists (mean experience 12 years) rated responses across 5 dimensions (Accuracy, Clarity, Clinical Satisfaction, Reasoning, Self-Awareness; 1–10 scale).

Results: In the MCQ test (4,320 responses), top performers were: Gemini-2.5-Pro 93.1% (95% CI 86.4%-96.0%), GLM-4.5–355B 92.8% (86.4%-96.0%), GPT-OSS-20B 88.3% (80.4%-92.3%). Size group means: Small 87.0%, Medium 90.3%, Large 92.4% ($\chi^2 = 23.01$, $p < 0.001$, Cramér's V = 0.073). No pairwise comparisons survived FDR correction. In the free-text test (Gemini = A, GPT-OSS = B, GLM = C), after Holm adjustment for within-dimension multiplicity, only one contrast achieved significance: GLM-4.5 exceeded Gemini on Accuracy ($p = 0.028$, mean difference 0.46 points, 95% CI 0.14–0.75), though the effect size was small (Vargha-Delaney A = 0.440) and this finding did not survive global FDR correction.

Conclusion: Small on-device reasoning LLMs (≤20B parameters) achieve frontier-level performance when integrated with RAG for MASLD clinical decision support. RAG evaluation showed no clinically meaningful differences among models after multiplicity control, with ceiling effects suggesting all three systems met expert standards. Deployment of open source edge-capable reasoning models with guideline retrieval could enable high-quality hepatology support in resource-limited settings without requiring proprietary or commercial models.

Background and aims: T2D is associated with a high prevalence of MASH, more rapid disease progression, and greater clinical burden, which together drive the economic burden of MASH. We aimed to estimate the economic burden of MASH among individuals with T2D across nine countries.

Method: An age-stratified Markov model was developed to project MASH burden in T2D over the next 2 decades in United States (US), Germany, Spain, France, Italy, United Kingdom (UK), Japan, Brazil, and Saudi Arabia (SA). Country-specific transition probabilities were derived from natural history data and calibrated to match each country's epidemiology. Transition probabilities were adjusted for T2D reflecting higher fibrosis progression rates and mortality risks. Therapeutic effects of MASH treatments (GLP-1 receptor agonists and resmetirom) were integrated into yearly transition matrices using country-specific assumptions for availability, coverage, adherence, and persistence. Time and adoption of GLP-1RA and resmetirom trajectories were informed by experts from each country. Drug prices were based on national benchmarks and projected forward using patent-erosion curves. Direct medical costs and indirect work productivity losses were updated annually using IMF inflation indices.

Results: From 2021 to 2040, total direct annual medical costs for MASH with T2D are estimated to increase from $14.39B to $68.73B in the US, $0.28B to $2.78B in Germany, $0.50B to $2.33B in Spain, $0.44B to $2.37B in France, $0.46B to $2.12B in Italy, $0.74B to $3.36B in UK, $1.10B to $6.83B in Brazil, $0.57B to $2.07B in SA, and $0.45B to $2.44B in Japan. If indirect costs of productivity loss are also included, total costs would further increase by 2–13 folds. Rising costs reflect growing MASH prevalence, progression to advanced disease, and uptake of MASH medications. The composition of direct medical spending shifts over time. In 2025, costs associated with liver-disease care accounted for >95% of direct medical costs in every country. However, unless the costs of anti-MASH drugs are reduced in the future, spending on MASH medications will substantially increase over time as a proportion of direct medical costs.

Conclusion: MASH in individuals with T2D is projected to impose an escalating economic burden over the next two decades, driven by increasing disease burden and growing uptake of MASH therapies. These findings highlight the need for effective, affordable treatment and prevention strategies to mitigate future economic burden.

THU-214

Integrated risk stratification for all-cause and cause-specific mortality in a large MASLD cohort in Taiwan

Ming-Lung Yu[1,2], Chung-Feng Huang[1,2], Pei-Chien Tsai[1,2], Ming-Lun Yeh[1,2]. *[1]National Sun Yat-Sen University, Gushan District, Taiwan; [2]Kaohsiung Medical Univ, Sanmin District, Taiwan*
Email: fish6069@gmail.com

Background and aims: Metabolic Dysfunction-associated Steatotic Liver Disease (MASLD) confers elevated long-term mortality risk. This study developed and validated an integrated risk stratification model incorporating cardiometabolic risk factors (CMRFs) and traditional predictors.

Method: Using the MJ cohort (1996–2022), we constructed Cox models and evaluated discrimination via time-dependent AUCs and calibration. An integer-based cumulative risk score was derived from the optimal model using weighted regression coefficients.

Results: Among 140,247 adults with MASLD (mean age 45.0 years; 61.2% male) followed for a median of 17 years, 15,584 deaths occurred (67.3/10,000 person-years). Sequential addition of covariates improved model performance, with the best model including CMRFs (underweight/obesity, diabetes, hypertension), age, sex, advanced fibrosis, and renal dysfunction. This model achieved a 10-year AUC of 0.84 and maintained consistently strong performance across 1–20 years. The resulting 0–17point risk score demonstrated a clear dose-response gradient. Individuals scoring ≥10 had over 80-fold higher mortality risk (HR 81.4; 95% CI 73.4–90.2) and a 20-year mortality of 74.4%, compared with 1.5% for scores ≤1. The score also showed excellent prediction for cause-specific mortality, particularly DM-related (AUC 0.92–0.97), liver-related (0.88–0.93), and ESRD mortality (0.90–0.93).

Conclusion: This integrated risk score provides a practical tool for early identification of high-risk MASLD patients and may guide targeted cardiometabolic, hepatic, and renal interventions to reduce long-term mortality.

GCKR rs1260326, dietary factors and incident liver-related events in patients with metabolic dysfunction-associated steatotic liver disease

Ziqi Zhang[1], Li Zhang[1], Lili Lu[1], Guang Ji[1]. [1]*Longhua Hospital, Shanghai University of Traditional Chinese Medicine, Shanghai, China*
Email: 22022628@shutcm.edu.cn

Background and aims: Gene-environment interactions have been increasingly recognized as important drivers of metabolic dysfunction-associated steatotic liver disease (MASLD) progression. However, how specific gene-diet interactions influence the transition from MASLD to adverse liver-related events (LREs) remains poorly understood. The glucokinase regulatory protein (*GCKR*) rs1260326 (C > T) variant has been identified as a genetic determinant of MASLD susceptibility. We aimed to evaluate the association between *GCKR* rs1260326 and the risk of LREs in MASLD and to identify dietary factors that may modify this association.
Method: This prospective cohort study included 126,129 adults with MASLD from the UK Biobank. The primary outcome was LREs, defined as a composite of cirrhosis, hepatic decompensation, hepatocellular carcinoma (HCC), liver transplantation, or liver-related mortality. Fine-Gray competing risk models were used to estimate subdistribution hazard ratios (sHRs). Circulating metabolomics and proteomics were applied to explore biological pathway alterations associated with the risk allele.
Results: During a median follow-up of 13.7 years, 1320 participants developed LREs. Compared to the CC genotype, the rs1260326 TT genotype was associated with an increased risk of LREs (sHR = 1.23, 95% CI 1.05–1.44), cirrhosis (sHR = 1.23, 95% CI 1.04–1.45) and HCC (sHR = 2.02, 95% CI 1.29–3.15). The association between rs1260326 TT genotype and LREs risk was more pronounced among individuals with higher carbohydrate intake, whereas it was attenuated among those with greater adherence to a Mediterranean diet or higher intakes of unsaturated fatty acids, vitamin E, and vegetables. For example, the TT genotype was associated with an increased risk of LREs among individuals with low adherence to the Mediterranean diet (sHR = 1.85, 95% CI 1.16–2.96), whereas no significant association was observed among those with high adherence (sHR = 0.64, 95% CI 0.30–1.35). Mechanistically, carriers of the risk allele exhibited alterations in lipid and branched-chain amino acid metabolism, accompanied by perturbations in mitochondrial function and oxidative stress, inflammatory signaling, and extracellular matrix-related pathways.
Conclusion: The *GCKR* rs1260326 C > T variant was associated with an increased risk of LREs in patients with MASLD, and this association was significantly modified by dietary factors. These findings support genetically informed personalized nutritional strategies, which may help reduce the risk of incident LRE in MASLD.

MASLD – Diagnostics and non-invasive assessment

Background and aims: Changes in liver stiffness measurement (LSM) by vibration-controlled transient elastography (VCTE) correlate with development of liver-related events (LREs) in patients with metabolic dysfunction-associated steatotic liver disease, but no data on biopsy-proven cirrhosis are available. As LSM has been assessed as a reasonably likely surrogate endpoint in trials on metabolic dysfunction-associated steatohepatitis (MASH) cirrhosis, we aimed to study if LSM change can reflect disease progression and regression in those with MASH cirrhosis.
Method: This cohort study included adult patients with biopsy-proven compensated MASH cirrhosis who had received at least two VCTE examinations between 6 months and 5 years apart at 16 centres across the US, Europe, and Asia, of which data were collected prospectively at 14 centres. The incidence of LREs in patients with and without LSM changes was determined, with non-liver-related death as a competing event.
Results: A total of 248 patients with MASH cirrhosis (baseline age 60.0 ± 10.0 years and 48.8% male) were recruited. 81.6% of the liver biopsies were performed within 1 year of the baseline VCTE. Baseline and second LSM measured after a median (IQR) interval of 1.4 (0.8–2.6) years were 19.1 (IQR 13.4–26.3) kPa and 16.8 (12.3–24.5) kPa, respectively. At a median (IQR) follow-up of 3.2 (1.3–5.0) years after the second LSM, 29 (11.7%) patients developed LREs, and the 5-year cumulative incidence was 18.7% (95% CI 12.6%–25.7%). The 5-year cumulative incidences were 21.2% (95% CI 10.4%–34.5%), 12.4% (5.4%–22.5%) and 27.2% (13.6%–42.8%) among those who had LSM absolute decrease by ≥5 kPa, change within 5 kPa and increase by ≥5 kPa. For relative change of LSM, the 5-year cumulative incidences of those with LSM relative decrease by ≥10%, ≥20% and ≥30% were 15.4% (95% CI 8.0%–25.0%), 16.3% (7.8%–27.4%) and 13.9% (5.0%–27.2%); compared to 23.7% (12.0%–37.8%), 28.0% (14.2%–43.6%) and 27.5% (13.6%–43.4%) in those with relative LSM increase by ≥10%, ≥20% and ≥30%, respectively. A relative increase of LSM ≥30% was associated with LREs (adjusted subdistribution hazard ratio [aSHR] 1.69, 95% CI 1.04–2.77, p = 0.035), while a relative decrease of LSM ≥30% was not associated with a reduced risk (aSHR 0.66, 95% CI 0.30–1.46, p = 0.307), after adjusting for baseline LSM.
Conclusion: A relative increase in LSM ≥30% from baseline was associated with disease progression, while a relative decrease of ≥30% did not reduce the risk of LREs, in patients with MASH cirrhosis.

Email: noureddinmd@pinnacleresearch.com

Background and aims: Several models for identifying MASH cirrhosis using non-invasive tests (NITs) have been proposed, although many scores, such as Agile-4, perform moderately in independent cohorts. Notably, the FDA and EMA do not currently support the use of NITs to define progression to cirrhosis, and a recent regulatory document emphasized that such tools must demonstrate high accuracy with both high sensitivity and specificity. We therefore developed a score using a large multicenter database to identify cirrhosis that meets these regulatory requirements.
Method: A database of patients with available biopsy results screened for enrollment in MASH clinical trials (n = 5963) was used to develop a model for predicting the presence of cirrhosis (n = 1289). Logistic regression was used in combination with up to 12 commonly collected non-invasive measures of MASH to create models for predicting cirrhosis. The best performing model was validated using 500 bootstrapped resamples.
Results: Of the 12287 linear regression models tested, 70 had both sensitivity and specificity ≥0.8. A score combining LSM, CAP, ELF, platelets, ALT, INR, and BMI had the highest performance, with an AUROC of 0.89 (95% CI: 0.87–0.90), with sensitivity of 0.82, specificity of 0.81, PPV of 0.59, and NPV of 0.93. Patients with higher LSM, ELF, and INR and those with lower platelet count, CAP, ALT, and BMI were at higher risk of having cirrhosis. The validation samples had an AUROC of 0.86, with a corrected calibration slope of 0.995, indicating negligible overfitting. The Cirrhosis-7 score performed better than other NIT-based scores for cirrhosis such as AGILE4 (AUROC 0.84), LSM alone (AUROC 0.79), and FIB4 (AUROC 0.76). It also uniquely demonstrates the highest combined sensitivity and specificity.
Conclusion: Out of over 12,000 models, the Cirrhosis-7 score incorporating LSM, CAP, ELF, and four clinical variables outperformed all others for detecting cirrhosis, with performance characteristics that have the potential to address regulatory requirements for defining progression to cirrhosis by achieving high accuracy with both high sensitivity and specificity.

TOP-065-YI

Incorporating an automated MASLD screening algorithm into a primary care precision diabetes care platform (iDiabetes) facilitates universal FIB4 screening, automated linkage to secondary care and identifies new cases of advanced fibrosis & cirrhosis

Damien Leith[1], Rachael Barrett[1], YeunYi Lin[1], Mya Win[1], Evelyn Anyebe[1], Paul Brennan[1], Ruairi Lynch[1], Ewan Pearson[1], John F Dillon[1]. [1]Ninewells Hospital & Medical School, Dundee, United Kingdom
Email: damienleith86@gmail.com

Background and aims: Despite the 2024 EASL recommendation of FIB4 screening for all people with type 2 diabetes [T2D], MASLD screening and hepatology referral for those at high risk of advanced fibrosis remains a challenge in primary care. We integrated a reflexive MASLD fibrosis screening algorithm, with automated linkage of high-risk individuals to secondary care, into *iDiabetesPlus*, a precision diabetes mellitus [DM] care platform being trialled in primary care in Scotland. Here, we present the key MASLD screening results from the first year of the *iDiabetesPlus* study.
Method: *iDiabetesPlus* was piloted from 28/10/24, then implemented as new standard DM care from 01/01/25 in 16 primary care practices in the Tayside region, Scotland. All patients with a DM diagnosis are automatically enrolled into *iDiabetesPlus* at their annual DM review. The *iDiabetesPlus* MASLD screening algorithm performs automated FIB4 screening for all patients. In those with ALT>30 additional reflex liver aetiological screening and NAFLD Fibrosis Score [NFS] calculation is performed, with reflexive Enhanced Liver Fibrosis [ELF] testing in those with indeterminate or high risk FIB4/NFS. Automated referral to secondary care is generated for those with ELF ≥9.8, FIB4 >2.67, NFS >0.675 or positive aetiology results. For all enrolled patients, *iDiabetesPlus* generates comprehensive DM and MASLD management recommendations for primary care practitioners and guidance on timing of interval FIB4 testing.
Results: From 28/10/24–31/10/25, 4533 people with DM were enrolled in *iDiabetesPlus* and eligible for a liver screen (41.8% female; mean age 65.8 years; 91.0% T2D, 7.0% T1D). 4499 (99.3%) of those enrolled received FIB4 screening. Of those with a FIB4 result, 2841 (63.1%) were <1.30, 1484 (33.0%) 1.30–2.67 and 174 (3.9%) >2.67.

973 (21.5%) enrolled patients received second-line ELF testing, with 521 (53.5%) ELF <9.8. 614 (13.55%) patients generated an automated secondary care referral. Of 435 Fibroscans performed to date, 226 (52.0%) had Liver Stiffness Measurements [LSM] <8 kPa, 108 (24.8%) LSM 8–11.9 kPa and 101 (23.2%) LSM ≥12 kPa.
Conclusion: The incorporation of MASLD screening into a precision diabetes care platform has achieved universal FIB4 testing in a real-world primary care DM population. Selected, second-line ELF testing reduces the number requiring secondary care referral by >50%. Importantly, our screening algorithm has identified new MASLD with advanced fibrosis or cirrhosis in 2.2% of 4,533 prospectively screened patients with DM.

TOP-066

Machine learning–based models with and without VCTE improve prescreening for at-risk MASH compared with FAST in the largest clinical trial validation cohort

Background and aims: The FAST score and the ALADDIN-MASH-VCTE model were developed to identify at-risk metabolic dysfunction–associated steatohepatitis (MASH), the target population for non-cirrhotic MASH clinical trials. In parallel, ALADDIN-MASH-Lab was designed to predict the same phenotype using routine laboratory data alone. Although FAST is widely used for prescreening, its sensitivity and trial enrollment efficiency are limited. We compared the diagnostic accuracy and screening performance for trial eligibility of FAST, ALADDIN-MASH-VCTE, and ALADDIN-MASH-Lab in a large cohort with biopsy-confirmed disease.
Method: We performed an external validation in 6,376 patients with paired liver biopsy and VCTE data, of whom 39.9% met regulatory trial criteria for at-risk MASH (MASH with ≥F2 fibrosis). Discrimination was assessed using AUC with DeLong comparison. To reflect clinical trial prescreening, thresholds were selected to maintain a biopsy screen-failure rate ≤33%, corresponding to a positive predictive value ≥0.67, while maximizing sensitivity. Under this fixed constraint, we compared true-positive yield and missed eligible cases across non-invasive tests.
Results: ALADDIN-MASH-VCTE demonstrated higher discrimination than FAST (AUC 0.725 [95% CI 0.712–0.738] vs 0.710 [0.697–0.723]; p = 0.00011), while the laboratory-only model, ALADDIN-MASH-Lab, was similar to FAST (AUC 0.714 vs 0.710; ΔAUC = +0.004; 95% CI −0.005 to +0.013). At a fixed biopsy screen-failure rate of 33%, FAST identified 12.3 true positives per 100 screened while missing 27.6 at-risk MASH cases. Under the same constraint, ALADDIN-MASH-VCTE identified 18.0 true positives and missed 21.9 cases, whereas ALADDIN-MASH-Lab achieved similar yield to FAST (14.2 true positives; 25.7 missed).
Conclusion: In a large external validation cohort, ALADDIN-MASH-VCTE (https://aihepatology.shinyapps.io/ALADDIN3) demonstrated superior performance compared with the current standard FAST for identification of at-risk MASH. At an equivalent acceptable biopsy screen-failure rate, ALADDIN-MASH-VCTE increased true-positive detection and reduced missed cases. Importantly, the laboratory-only model, ALADDIN-MASH-Lab, achieved discrimination and screening performance comparable to FAST despite not requiring VCTE. Derived in a multinational cohort and independently validated in the largest U.S. clinical trial screening database, these findings support the use of machine learning–based approaches to improve MASH trial recruitment, with and without access to VCTE.

Background and aims: Metabolic dysfunction-associated steatohepatitis (MASH), a progressive phenotype of metabolic dysfunction-associated steatotic liver disease (MASLD), is highly prevalent among individuals with type 2 diabetes (T2D) and markedly increases the risk of cirrhosis, hepatocellular carcinoma, and mortality. Patients with at-risk MASH (MASH + fibrosis stages F2–4) represent the primary target population for emerging pharmacotherapies. We aimed to established a non-invasive model for identifying at-risk MASH in T2D.
Method: In this prospective study, a derivation cohort undergoing liver biopsy from ten centers (n = 525) was used for model development. External validation was conducted in three independent multinational cohorts assessed by vibration-controlled transient elastography: the DiabetesLiver Integrated Management cohort (n = 3,711), Singapore cohort (n = 422), and NHANES cohort (n = 1,674). All participants were adults with T2D. At-risk MASH was defined histologically in the derivation cohort and by the FibroScan-aspartate aminotransferase [FAST] score in validation cohorts. Model performance was evaluated using the area under the receiver operating characteristic curve (AUROC), decision curve analysis and calibration analysis, and compared with the Fibrosis-4 index (FIB-4), non-alcoholic fatty liver disease fibrosis score (NFS), and AST/alanine aminotransferase (ALT) ratio (AAR).
Results: The derived model, termed the DiabetesMASH Index (DMI), incorporated age, waist circumference, ALT, and hemoglobin A1c. DMI demonstrated satisfactory discrimination in the derivation cohort (AUROC 0.79; 95% confidence interval [CI] 0.75–0.83) and consistently high performance across external validation cohorts (AUROC 0.91 [95% CI 0.89–0.94], 0.88 [0.80–0.96], and 0.90 [0.86–0.94], respectively), outperforming FIB-4, NFS, and AAR in all cohorts. Calibration analyses showed agreement between predicted and observed risks. In the derivation cohort, rule-out and rule-in thresholds were 0.184 (sensitivity 0.85; negative predictive value [NPV] 0.92) and 0.452 (specificity 0.90; PPV 0.57), respectively. The indeterminate zone accounted for 35.8% of patients in the derivation cohort and 19.9%, 24.8%, and 19.1% in validation cohorts.
Conclusion: DMI is a validated and affordable non-invasive tool for identifying at-risk MASH in patients with T2D, using routinely available variables.

A spatial metabolic atlas of liver lipid metabolism and fibrosis in metabolic dysfunction-associated steatotic liver disease

Patcharamon Seubnooch[1], Elaine Chng[2], Yayun Ren[2], Matteo Montani[3], Dina Tiniakos[4], Jean-François Dufour[5], Jaime Bosch[5], Nikolai Naoumov[6], Annalisa Berzigotti[5], Mojgan Masoodi[1]. *[1]Institute of Clinical Chemistry, Inselspital, Bern University Hospital, Bern, Switzerland; [2]Histoindex Pte. Email: mojgan.masoodi@insel.ch

Background and aims: Metabolic dysfunction-associated steatotic liver disease (MASLD) is a leading cause of chronic liver disease. Although fibrosis stage is a key determinant of clinical outcomes, the spatial metabolic alterations underlying fibrotic remodeling and disease progression are poorly characterised. Using a novel multimodal approach integrating high-spatial-resolution mass spectrometry-based metabolic mapping, second harmonic generation/two-photon excitation fluorescence (SHG/TPEF) microscopy, and computational modeling, we constructed a comprehensive spatial metabolic molecular atlas of the human liver.
Method: Liver biopsies from 36 MASLD patients (stage F0-F4) were analysed by desorption electrospray ionisation mass spectrometry imaging at 20 × 20 µm spatial resolution to define metabolic signatures associated with steatosis, lobular inflammation, ballooning and fibrosis. Histology-guided regions of interest were used to assess zone-specific lipid metabolism, steatosis and fibrosis regions. SHG/TPEF microscopy was applied on the liver samples to quantify collagen architecture, enabling spatial correlation of molecular profiles with zonation, intra-stage fibrotic heterogeneity, septa characteristics. Multiple-testing correction was applied using Benjamini-Hochberg False Discovery Rate (FDR), with FDR ≤ 5% considered significant.
Results: Distinct metabolic signatures comprising several hundred metabolites were identified across steatosis types (micro/macrovesicular), lobular inflammation and ballooning. In MASH, molecular species topography showed marked differences with zone-specific disruption of lipid metabolism. The strongest metabolic discrimination was between fibrotic and non-fibrotic regions, revealing pronounced metabolic heterogeneity within fibrotic tissue. Notably, septal regions exhibited distinct molecular profiles differentiating progressive from regressive septa, and previously unrecognised sex-specific differences.
Conclusion: We established a comprehensive high-resolution spatial lipid atlas in MASLD, demonstrating zone-specific alterations in lipid metabolism associated with fibrosis and disease progression in MASH. Distinct metabolic heterogeneity was observed within fibrotic tissue, including molecular differences between progressive and regressive septa and sex-specific metabolic patterns. Together, these findings provide new insights into fibrosis architecture and metabolic remodeling in MASH and may support the identification of zone-specific diagnostic markers.

Email: noureddinmd@pinnacleresearch.com

Background and aims: Accurate noninvasive identification of cirrhosis is essential for efficient enrollment of MASH-cirrhosis clinical trials. Vibration-controlled transient elastography (VCTE)–based scores such as Agile4 are commonly used for non-invasive identification of cirrhosis but is insensitive when applied in clinical trial screening. We developed two machine learning–based VCTE model (ALADDIN-Cirrhosis-VCTE) and routine laboratory only model (ALADDIN-Cirrhosis-Lab) and evaluated their performance against established Agile4 and VCTE.
Method: Models were derived in a multinational cohort of 2,962 patients undergoing VCTE, including 373 (12.6%) with biopsy-confirmed cirrhosis. External validation was performed in 6,376 patients undergoing screening for MASH-cirrhosis clinical trials with paired liver biopsy and VCTE data, of whom 20.8% met histologic cirrhosis criteria. Discrimination was assessed using AUC with DeLong comparison. Screening thresholds were selected to maintain a constant biopsy screen-failure rate of ≤33%, corresponding to a positive predictive value of at least 0.67. True-positive yield and missed cirrhosis cases were compared under this fixed screen-failure constraint.
Results: In external validation, ALADDIN-Cirrhosis-VCTE demonstrated higher discrimination than Agile4 (AUC 0.858 [95% CI 0.846–0.870] vs 0.842 [0.830–0.854]; DeLong $p = 1.5 \times 10^{-5}$). ALADDIN-Cirrhosis-Lab demonstrated higher discrimination than VCTE alone (AUC 0.808 [95% CI 0.795–0.821] vs 0.793 [0.779–0.807]). At equivalent acceptable screen-failure rates of 33%, Agile-4 identified 9.2 true positives per 100 screened while missing 11.6 cases. Under the same constraint, ALADDIN-Cirrhosis-VCTE identified 11.6 true cirrhosis cases per 100, and missed only 9.3. ALADDIN-Cirrhosis-Lab achieved superior yield to VCTE alone.
Conclusion: In a large external validation cohort drawn from clinical trial screening, a machine learning–based VCTE model (https://aihepatology.shinyapps.io/ALADDIN3) significantly improved identification of histology-defined cirrhosis compared with established VCTE-based scores. At a fixed acceptable biopsy screen-failure rate, ALADDIN-Cirrhosis-VCTE increased true-positive yield while reducing missed eligible cases. Importantly, the laboratory-only model, ALADDIN-Cirrhosis-Lab, is superior to VCTE alone and can be used when VCTE is unavailable. These findings support machine learning–based prescreening strategies to improve yield and reduce screen fails in MASH-cirrhosis clinical trial recruitment.

Can reliably measured transient elastography be trusted in obesity? Comparing the modifying effects of general and central adiposity in MASLD

Fredrik Åberg[1], Anni Heiskala[1], Panu K. Luukkonen[1,2,3,4], Rohit Loomba[5], Ville Männistö[6,7]. *[1]Helsinki University Hospital and University of Helsinki, Helsingfors, Finland; [2]Minerva Foundation Institute for Medical Research, Helsinki, Finland; [3]Department of Internal Medicine, University of Helsinki, Helsinki, Finland; [4]Molecular Medicine Finland (FIMM), Helsinki Institute of Life Sciences (HiLife), University of Helsinki, Helsinki, Finland; [5]MASLD Research Center, Division of Gastroenterology and Hepatology, University of California at San Diego, La Jolla, United States; [6]Department of Medicine, University of Eastern Finland, Kuopio, Finland; [7]Department of Medicine, Kuopio University Hospital, Kuopio, Finland*
Email: fredrik.aberg@helsinki.fi

Background and aims: Obesity increases transient elastography (TE) failure rates, but it is unclear how varying degrees of obesity and central adiposity affect its diagnostic performance among reliably measured TE examinations. We examined how adiposity influences TE diagnostic performance across different anthropometric measures, including only examinations meeting reliability criteria.
Method: From the NAFLD Adult Database 2, a prospective, non-interventional registry of the NASH CRN, we identified 949 adults enrolled 2009–2020 with MASLD and reliably measured TE. Data were provided by NIDDK CR, a program of the National Institute of Diabetes and Digestive and Kidney Diseases. Reliable TE was defined as ≥10 valid measurements with IQR/median ratio <30%. All participants had liver biopsy and available anthropometric data, including body mass index (BMI), waist circumference (WC), and waist-hip ratio (WHR). Of these, 578 (61%) were women, mean (SD) age 51 (12) yrs, BMI 34.3 (6.4) kg/m^2, WC 110 (14.8) cm, and WHR 0.95 (0.08). TE discrimination for significant (F2-F4) and advanced (F3-F4) fibrosis was assessed by AUCs across sex-specific BMI, WC, and WHR quartiles, with sensitivity and specificity estimated at 8 and 12 kPa.
Results: The discriminatory performance of TE for histological significant fibrosis declined across sex-specific quartiles of adiposity. AUCs by quartile (Q1-Q4) were: BMI 0.85, 0.83, 0.81, 0.75; WC 0.83, 0.82, 0.81, 0.75; and WHR 0.84, 0.82, 0.81, 0.77. For advanced fibrosis, the corresponding AUCs of TE decreased from 0.89 to 0.77 across BMI quartiles, 0.90 to 0.78 for WC, and 0.91 to 0.82 for WHR. Using the 8 kPa cutoff, TE specificity for detecting significant fibrosis declined from 84% to 52% across BMI quartiles, 84% to 49% for WC, and 77% to 60% for WHR, while sensitivity increased by 12–15%-points. With the 12 kPa cutoff, specificity of TE for detecting advanced fibrosis decreased from 93% to 74% (BMI), 93% to 76% (WC), and 89% to 82% (WHR), while sensitivity increased by 10%-points for BMI, 17 for WC, and was stable across WHR quartiles. AUCs for advanced fibrosis declined from BMI and WC Q3 to Q4 with both the M and XL probes.
Conclusion: Even when TE measurements fulfilled validity criteria, higher levels of general/central adiposity reduced the discriminatory performance of TE, mainly through declining specificity and a resulting increase in false positives. In individuals with obesity, complementary methods should be used to verify significant/advanced fibrosis.

Email: elmaimouni.cautar@gmail.com

Background and aims: Cardiometabolic risk factors (CMRF) drive progression in metabolic dysfunction-associated steatotic liver disease (MASLD) but data on their prevalence, control, and impact in advanced stages are limited. We aimed to assess (1) CMRF burden and control in MASLD-related advanced chronic liver disease (ACLD), and (2) the impact of changes in glycemic control and body weight on disease progression.
Method: Prospective, observational, multicenter study of patients with ACLD-MASLD defined by liver stiffness measurement (LSM) ≥ 10 kPa, F3–F4, or imaging signs of advanced disease. Clinical, laboratory and imaging data were collected at baseline and follow-up. LSM progression was defined as change from < 10 to ≥ 10 kPa or ≥ 30% increase; LSM improvement as transition from ≥ 10 to < 10 kPa or ≥ 30% reduction.
Results: A total of 635 patients were included (50.2% women; median age 66 years (interquartile range: 59–72). Median baseline LSM was 17.3 kPa (12–25.7) and controlled attenuation parameter 309 dB/m (269–351). Type 2 diabetes was present in 73% of patients (12.5% with poor glycemic control) and obesity in 64.7% (median body mass index 32 kg/m^2 [29–36]), while only 16.5% received GLP-1 receptor agonists. Overall, 82% had high or very high cardiovascular risk; LDL-cholesterol targets were not achieved in 55.9% and 56.5% were not receiving statins. Among 284 patients with ≥ 2 elastography assessments (spaced by ≥ 1 year), 14.8% showed LSM progression and 38.4% showed LSM improvement (median follow-up: 26 months [17–45]). Significant reductions in HbA1c (6.7% to 6.4%; p = 0.009) and weight (86 to 83 kg; p = 0.001) were observed. LSM progression was more frequent in patients with poor glycemic control (47.6% vs. 5.3%; p = 0.002), while LSM improvement was more common in those achieving good control (44.7% vs. 19%; p = 0.002). Increased or stable body weight was associated with LSM progression (28% and 17.6% vs. 8.3% in those with ≥ 5% weight loss; p = 0.03). Weight loss was directly associated with LSM improvement (58%, 43% and 33% of patients with ≥ 10%, 5–9.9% and < 5% weight loss; p = 0.028). Statin use was not associated with changes in LSM. LSM progression was associated with a higher risk of liver-related events (odds ratio 4.3; 95% confidence interval 95% 1.5–12.8; p = 0.013).
Conclusion: Poor control of CMRF is common in ACLD-MASLD. Improvements in glycemic control and weight loss are strongly associated with LSM improvement, supporting metabolic optimization to slow disease progression.

Normal ALT values in patients with MASLD: long-term outcomes and Fib-4 performance

Ali Abdul Hussein[1], Tanya Jayakar[1], Fernando Iorra[1], Maria Kalafateli[1], Michael Yee[1], Benjamin H. Mullish[1], Mark R Thursz[1], Pinelopi Manousou[1]. [1]*Imperial College London, London, United Kingdom*
Email: aliabdulhussein17@gmail.com

Background and aims: Current EASL guidelines recommend a two-tier fibrosis risk stratification strategy using Fibrosis-4 (FIB-4) followed by second-line testing. However, fibrosis assessment in clinical practice is often triggered by elevated alanine aminotransferase (ALT), potentially overlooking patients with normal ALT. We retrospectively evaluated clinical outcomes in MASLD patients with normal ALT and/or FIB-4, referred before implementation of two-tier pathways - a population that would likely be missed under current guidelines.
Method: We retrospectively examined patients with a diagnosis of MASLD, referred to a tertiary liver centre between 2012 and 2016. Diagnostic accuracy of FIB-4 (≥ 1.3) for advanced fibrosis was assessed using transient elastography (LSM ≥ 8 kPa) and liver biopsy (CRN fibrosis stage ≥ F3), stratified by ALT status. Longitudinal outcomes included liver-related events, cardiovascular events, and all-cause-mortality. Predictors of falsely reassuring FIB-4 results were assessed using univariate and multivariate regression models in patients with normal and abnormal ALT.
Results: Among 829 MASLD patients with MASLD identified, 244 (29.4%) had normal ALT at referral, of whom 61 (25%) had LSM ≥ 8 Kpa and 38 out of 76 (50%) had ≥ F3 on liver biopsy. FIB-4 demonstrated significantly poorer discrimination for LSM ≥ 8 kPa in patients with normal versus elevated ALT (AUC 0.590 vs 0.703; p = 0.038), and similarly modest discrimination for biopsy-confirmed fibrosis stage ≥ F3 across ALT strata, with no significant difference between groups (AUC 0.618 vs 0.634; p = 0.779). Despite this, among patients with normal ALT, elevated FIB-4 was strongly associated with incident liver-related events (hazard ratio [HR] 14.4; p = 0.011) and with a composite outcome of liver-related events, cardiovascular events, or death (adjusted HR 1.9; p = 0.031) (n = 39) over 5 years of follow-up, compared with those with FIB-4 < 1.3. Obesity, diabetes, hypertension, and hypercholesterolaemia were associated with FIB-4 misclassification using LSM as the reference standard.
Conclusion: In MASLD patients with normal ALT, FIB-4 shows limited diagnostic accuracy for advanced fibrosis but retains important prognostic value. Reliance on ALT-driven assessment may delay recognition of clinically significant disease, particularly in metabolically high-risk populations.

WED-042

Use of the ANTICIPATE NASH risk score to stratify patients with compensated MASH cirrhosis: data from a phase 3, double-blinded, randomized clinical trial assessing the safety and efficacy of pegozafermin (ENLIGHTEN-cirrhosis)

Juan G Abraldes[1], Arun J. Sanyal[2], Rohit Loomba[3], Quentin M. Anstee[4], Hank Mansbach[5], Cynthia L. Hartsfield[5], Jasmine Dowlat[5], Laura Contreras[5], Jennifer B Kang[5], Shibao Feng[5], Maya Margalit[5]. [1]*Liver Unit, Division of Gastroenterology, University of Alberta, Edmonton, Alberta, Canada; [2]Beth Israel Deaconess Medical Center, Harvard Medical School, Boston, MA, United States; [3]University of California San Diego, San Diego, CA, United States; [4]Newcastle University, Newcastle upon Tyne, United Kingdom; [5]89bio Inc, San Francisco, CA, United States*
Email: maya.margalit@89bio.com

Background and aims: Compensated MASH-cirrhosis is a continuum, ranging from early cirrhosis, discernible only histologically, to the brink of decompensation. Determining where patients are on this continuum is critical in designing MASH-cirrhosis clinical trials. ANTICIPATE NASH (AN), a non-invasive continuous risk score, was

designed to assess risks of CSPH and LREs in MASH. ENLIGHTEN-Cirrhosis (NCT06419374) is an ongoing Phase 3 trial designed to assess the efficacy and safety of pegozafermin in MASH-cirrhosis. The objective of this analysis was to explore the utility of AN to understand the distribution of patients along the compensated cirrhosis continuum.

Method: Presence of metabolic risk factors and biopsy-proven MASH are inclusion criteria in the ENLIGHTEN-cirrhosis study, and high-risk varices (large or with red-wale signs) are excluded. Baseline data from the first 337 subjects randomized to the ENLIGHTEN-Cirrhosis trial were analyzed by four baseline AN categories: AN <20% (1), AN ≥20% and <40% (2), AN ≥40% and <60% (3), and AN ≥60% (4).

Results: AN categories 1, 2, 3 and 4 included 131, 90, 65 and 51 subjects, respectively (39%, 27%, 19% and 15% of subjects randomized). Age, sex, presence of T2DM and BMI were generally balanced across AN subgroups. Mean baseline VCTE and platelets were: VCTE: 12.6, 18.8, 23.9 and 32.1 kPa; Platelets: 215, 168, 151 and 134 10^3/μL in groups 1, 2, 3 and 4, respectively. Higher AN categories were associated with higher mean ELF score, FIB-4, and GGT (For AN categories 1, 2, 3 and 4: ELF: 10.1, 10.6, 10.8 and 11.1, respectively; FIB4: 1.7, 2.2, 2.9 and 3.2, respectively; GGT: 61, 86, 101 and 123 U/L, respectively), and with an increased frequency of Laennec score 4c on liver biopsy and presence of small varices on EGD (Laennec score 4c in 9%, 16%, 26% and 47% of subjects, respectively; small varices in 23%, 21%, 32% and 39% of subjects, respectively, for AN categories 1, 2, 3 and 4). In contrast, across increasing AN categories, no clear association was observed with other biopsy features (e.g., total NAS score, individual NAS components) or MRI-PDFF.

Conclusion: Higher AN categories were associated with greater severity across multiple, complementary assessments of cirrhosis (NITs, biopsy findings, presence of varices) in this large cohort of well-characterized subjects with MASH-cirrhosis. These findings support the utility of AN for stratifying patients across the compensated MASH-cirrhosis spectrum.

WED-043

Combining vibration controlled transient elastography and enhanced liver fibrosis score lowers the false positive rate for identifying MASLD with significant fibrosis in patients with class 2 or higher obesity

Veeral Ajmera[1], Ricki Bettencourt[1], Bruno Vergès[2], Dominique Delaunay[3], Bertrand Cariou[4], Sybil Charrière[5], Seema Singh[1], Egbert Madamba[1], Lisa Richards[1], Rohit Loomba[1], Cyrielle Caussy[3]. *[1]University of California San Diego, La Jolla, United States; [2]Dijon University Hospital, Dijon, France; [3]Hospices Civils De Lyon, Lyon, France; [4]Nantes Université, Nantes, France; [5]Universite Claude Bernaard Lyon, Pierre-Benite, France*
Email: v1ajmera@ucsd.edu

Background and aims: Multiple international societies recommend a care pathway with sequential testing with FIB-4 and vibration-controlled transient elastography (VCTE) or enhanced liver fibrosis (ELF) score for populations at-risk for MASH. However, multiple studies demonstrate decreased diagnostic accuracy for VCTE in patients with high body mass index (BMI). We aimed to compare the diagnostic accuracy of VCTE and ELF among prospectively recruited patients at-risk for MASH with BMI ≥ 30 kg/m^2 using magnetic resonance elastography (MRE) or liver biopsy as the reference.

Method: This multicenter, international prospective study enrolled adults with type 2 diabetes (T2DM) recruited from primary care and endocrinology clinics. Participants underwent a standardized clinical research visit with ELF, VCTE and MRE assessment. Participants with alcohol intake exceeding AASLD guidance for MASLD were excluded. The outcomes were the diagnostic performance of ELF vs VCTE for significant fibrosis defined by a composite hierarchical criteria: 1. histological stage of fibrosis ≥F2 or 2. MRE ≥ 3.3 kPa or overt diagnosis of cirrhosis on imaging.

Results: The study population included 363 patients (42% men) with T2DM and obesity. The mean (±SD) age and BMI were 62.1 (±8.3) years and 34.5 (±3.8) kg/m^2, respectively. The prevalence of BMI ≥30–35 kg/m^2 and >35 kg/m^2 were 235 (64.7%) and 128 (35.3%), respectively. 110 (30.3%) had significant fibrosis on MRE (or biopsy). The AUROC c-statistic, sensitivity and specificity for a VCTE cut-point of 8 kPa were 0.80, 81%, and 79%, respectively. The AUROC c-statistic, sensitivity and specificity for an ELF cut-point of 9.2 were 0.60, 85%, and 35%, respectively. The diagnostic accuracy of VCTE decreased among patients with BMI >35 kg/m^2 but remained superior to ELF (c = 0.76 vs 0.62, P = 0.0126). In patients with BMI >35 kg/m^2 a combined cut point of VCTE ≥ 8 kPa and ELF ≥ 9.2 yielded an AUROC c-statistic, sensitivity and specificity of 0.79, 72%, and 87% respectively. The number of false positive cases was highest with ELF (45%), then VCTE (16%) and lowest with VCTE + ELF (9%) in patients with BMI >35 kg/m^2.

Conclusion: Despite a mild decrease in diagnostic accuracy, VCTE outperformed ELF for the diagnosis of at-risk MASH in patients with BMI >35 kg/m^2. Combining VCTE and ELF in this population lowers the false positive rate and therefore has significant implications for accurately identifying patients with at-risk MASH who warrant treatment.

WED-044

Anthropometric indices and body composition as predictors of liver fibrosis in young adults with metabolic dysfunction-associated steatotic liver disease: a systematic review and meta-analysis

Arash Akhavan Rezayat[1], Sarah Batool[2], Rochan Athreya Krishnamurthy[2], Talha Javed[2], Ayaz Iqbalbhai Shaikh[2], Arun Cherackakudy Joy[2], Muhammad Adil Irshad[2], Muhammad Moiz Ud-Din[2], Richard Aspinall[2], Avisnata Das[2]. *[1]Department of Gastroenterology & Hepatology, Portsmouth Hospitals University NHS Trust, Queen Alexandra Hospital,, Portsmouth, United Kingdom; [2]Deptartment of Gastroenterology & Hepatology, Portsmouth Hospitals University NHS Trust, Queen Alexandra Hospital, Portsmouth, United Kingdom*
Email: arash.rezayat@nhs.net

Background and aims: Metabolic dysfunction-associated steatotic liver disease (MASLD) increasingly affects young adults but there is no established method to predict which patients will develop liver fibrosis based on their body composition and physical measurements. We conducted a systematic review and meta-analysis to evaluate these parameters as risk factors for liver fibrosis in young adults with MASLD.

Method: We systematically searched PubMed, Embase, Web of Science, and Scopus for studies examining anthropometric and body composition risk factors for liver fibrosis in young adults (aged 18–40 years) with MASLD. Random-effects or fixed-effects meta-analyses were performed based on heterogeneity assessment (I^2). Odds ratios (OR) with 95% confidence intervals (CI) were calculated.

Results: The meta-analysis included nine studies which analyzed data from 15,370 patients. The study of central body fat distribution revealed waist-to-height ratio ≥0.5 as the most effective indicator which predicted liver fibrosis (sample size: 67; OR = 10.73, 95% CI: 8.79–13.1, single study). Waist-to-hip ratio revealed significant association (Sample size: 101; OR = 1.525, 95% CI: 1.002–2.322, single study), as did waist circumference (Sample size: 104; OR = 1.1, 95% CI: 1.02–1.17, single study). Pooled random-effect analysis of three studies confirmed general obesity as the main risk factor (11,919; OR = 7.63, 95% CI: 1.10–52.70, p < 0.001, I^2 of 97.50%), although with significant statistical heterogeneity. The six studies showed that being overweight created a steady link between the two conditions (14829 participants; OR = 1.30, 95% CI: 1.11–1.49, p < 0.001, I^2 = 89.31%). Muscle mass percentage correlated against liver fibrosis (Sample size: 88; OR 0.714, 95% CI: 0.606–0.812, single study).

Similarly, muscle mass-to-fat mass ratio showed a strong protective effect (88 participants; OR = 0.129, 95% CI: 0.048–0.351).
Conclusion: The waist-to-height ratio may provide better liver fibrosis prediction than traditional obesity measurements for young adults with MASLD. The preservation of muscle mass together with beneficial muscle-to-fat ratios were associated with protection against advanced fibrosis. Clinical evaluation should measure central body fat instead of relying solely on BMI for assessment and treatment plans should focus on decreasing abdominal fat while maintaining or improving muscle strength.

WED-045

Metabolic dysfunction, biochemical markers, and lifestyle factors in liver fibrosis development among young adults with metabolic dysfunction-associated steatotic liver disease: a systematic review and meta-analysis

Arash Akhavan Rezayat[1], Sarah Batool[1], Rochan Athreya Krishnamurthy[1], Talha Javed[1], Arun Cherackakudy Joy[1], Ayaz Iqbalbhai Shaikh[1], Muhammad Adil Irshad[1], Muhammad Moiz Ud-Din[1], Richard Aspinall[1], Avisnata Das[1]. [1]*Department of Gastroenterology & Hepatology, Portsmouth Hospitals University NHS Trust, Queen Alexandra Hospital, Portsmouth, United Kingdom*
Email: arash.rezayat@nhs.net

Background and aims: Understanding metabolic, biochemical, and lifestyle contributors to liver fibrosis in young adults with metabolic dysfunction-associated steatotic liver disease (MASLD) is essential for early intervention strategies. We performed a meta-analysis to evaluate these risk factors which will help doctors make better treatment decisions.
Method: We systematically searched major databases (Scopus, Web of science, PubMed, and Embase) for studies reporting associations between metabolic parameters, biochemical markers, lifestyle factors, and liver fibrosis in young adults (18–40 years) with MASLD. Pooled odds ratios (OR) with 95% confidence intervals (CI) were calculated using random or fixed-effects models based on heterogeneity (I^2) assessment.
Results: The meta-analysis included nine studies which analyzed data from 15,370 patients. Among metabolic risk factors, diabetes mellitus established the strongest association with liver fibrosis (Sample size: 11229; OR = 3.73, 95% CI: 1.69–8.23, p = 0.006, I^2 = 72.13%, 5 studies). This systematic review showed that hypertension (Sample size: 8353; OR = 1.13, 95% CI: 0.78–1.66 and a p = 0.593, I^2 = 0.00%) and hyperlipidemia (Sample size: 11953; OR = 1.00, 95% CI: 0.99–1.01, p = 0.602, I^2 = 0.00%, 3 studies) lacked strong associations with liver fibrosis in this age group. ALT levels above normal range demonstrated a small yet statistically significant link to the liver fibrosis in young adults (8256; OR = 1.14, 95% CI: 1.08–1.20, p = 0.101, I^2 = 56.45%). High CRP protein demonstrated no significant association (Sample size: OR = 0.95, 95% CI: 0.81–1.11, single study). Smoking also did not have any meaningful association with liver fibrosis in young adults (Sample size: 2721; OR = 1.97, 95% CI: 0.59–6.59, single study).
Conclusion: Young adults with MASLD have a different spectrum of risk factors for liver fibrosis to older people and some established cardiovascular risk factors (hypertension, hyperlipidemia) showed only minimal impact. Elevated ALT levels may provide modest predictive value. Further, prospective studies should be conducted to understand why smoking, hypertension, and dysplipidaemia are weaker associations with liver fibrosis in young adults with MASLD.

WED-050

Machine learning identifies hidden hepatic fibrosis in adults with normal FIB-4: a NHANES-based risk-stratification model

Issa Ali[1], Hala Mouhydeen[1], Zaid Ansari[1], Akram Ahmad[1], Bobby Zervos[1]. [1]*Cleveland Clinic-Florida, Weston, United States*
Email: alii3@ccf.org

Background and aims: Fibrosis, rather than steatosis, is the primary determinant of liver-related morbidity and mortality in metabolic dysfunction–associated steatotic liver disease (MASLD). Although FIB-4 is widely used as a first-line screening tool, its performance deteriorates in patients with metabolic risk factors, and many individuals with normal FIB-4 still harbor clinically significant fibrosis. In many clinical settings, FibroScan is not readily available, creating a major blind spot in fibrosis detection. Machine-learning (ML) models trained on routine clinical and laboratory data may enable risk stratification among patients with normal FIB-4 and no elastography results. We aimed to develop an ML model to identify significant fibrosis among adults with normal FIB-4 using nationally representative NHANES elastography data.
Method: We analyzed NHANES 2017–March 2020 participants with valid demographics, metabolic parameters, laboratory values, and liver elastography (VCTE). The cohort was restricted to adults with normal FIB-4 (<1.3 for age <65; <2.0 for age ≥65). Significant fibrosis was defined as liver stiffness ≥8.0 kPa. Predictors included body measurements (BMI and waist size), blood pressure, cholesterol and glucose markers, liver enzyme tests, platelet count, and fibrosis scores (FIB-4 and NAFLD Fibrosis Score), along with race and socioeconomic indicators. An XGBoost classifier was trained using stratified sampling and imbalance correction. Model performance was assessed using AUROC, AUPRC, and SHAP (Shapley values) for feature importance.
Results: Among 10,409 adults, 76.8% had normal FIB-4; within this subgroup, 8.3% had significant fibrosis by elastography. The ML model achieved an AUROC of 0.806 and an AUPRC of 0.353, outperforming traditional noninvasive scores such as FIB-4 and NFS, which typically yield AUROCs of 0.65–0.72 in metabolic populations. At a probability threshold of 0.5, sensitivity was 56%, specificity 88%, PPV 29%, and accuracy 92%. Key predictors included BMI, waist size, HDL cholesterol, systolic blood pressure, GGT, and HbA1c.
Conclusion: A machine-learning model using routine clinical data can identify more than half of significant fibrosis cases among patients with normal FIB-4, substantially outperforming current first-line tools. This approach provides an accessible method for risk stratification in settings without FibroScan, helping close the detection gap for subclinical fibrosis in MASLD and enabling earlier, targeted referral for elastography.

WED-051

Clinical characteristics of patients with low liver stiffness measurement (LSM) on VCTE and biopsy-proven at-risk MASH on biopsy

Naim Alkhouri[1], Elizabeth Brombosz[1], Grazina Binkauskiene[1], Winston Dunn[1], Marcelo Kugelmas[2], Aasim Sheikh[3], Alma Laura Ladrón de Guevara[4], John Poulos[5], Jörn M. Schattenberg[6], Mazen Noureddin[1]. [1]*Summit Clinical Research, San Antonio, United States;* [2]*South Denver Gastroenterology, Denver, United States;* [3]*GI Specialists of Georgi, Marietta, GA, United States;* [4]*Centro de Investigacion y Gastroenterologia, Mexico City, Mexico;* [5]*Coastal Research Institute, Fayetteville, NC, United States;* [6]*Saarland University, Saarbrücken, Germany*
Email: naim.alkhouri@gmail.com

Background and aims: Most guidelines and clinical trial inclusion criteria for MASH pharmacotherapies focus on patients with LSM ≥8 kPa to identify those with at-risk MASH (F2/F3 fibrosis + NAS ≥4 with ≥1 point in each category) likely to benefit from such therapies. However, there are patients with lower LSM who have at-risk MASH on biopsy. The aim of this study is to investigate whether there are additional variables that might predict at-risk MASH in patients with low LSM.
Method: A multicenter database of patients screened for enrollment in MASH clinical trials was analyzed, from which patients with at-risk MASH were identified. These patients were then grouped by and LSM < 8 kPa (generally excluded from trials for low LSM) and LSM ≥ 8 kPa

("traditional" LSM). Descriptive statistics were applied, and a two-sided *t*-test was used to compare the two groups.
Results: The database included 9,754 patients that received liver biopsy during screening for MASH clinical trials. 2195 patients had biopsy-proven at-risk MASH and out of these patients 224 (10%) had low LSM < 8 kPa. Patients in the low LSM group were younger (55 [47–62] years, median [IQR] vs 57 [49–64], p = 0.02) had lower BMI (34.4 [29.4–38.3] kg/m^2, median [IQR] vs 36.4 [32.1–41.4] for traditional LSM; p < 0.001), less diabetes (87, 40% vs 944, 49%; p < 0.006), and lower HbA1c (6.2 [5.7–7.0] vs 6.4 [5.8–7.3]%; p < 0.001). AST (33 [26–49] vs 40 [29–57] U/L; p < 0.001) and GGT (44 [30–66] vs 50 [34–80] U/L; p < 0.001) were higher in the low LSM group and the platelet count was significantly higher in the low LSM group (246 [205–293] vs 237 [199–283] per nL; p = 0.02). LDL cholesterol was higher (111 (80–143) vs 99 (73–131) mg/dL; p = 0.002) and TG were higher. Lipoprotein A was lower (8.0 [4.5–17.2] vs 13.6 [5.7–42.9]; p < 0.001) in the low LSM group. Non-invasive measures of MASH severity were lower in the low LSM group, including CAP (331 [301–368] vs 338 [310–367] dB/m; p = 0.009), ELF (9.5 [9.0–10.0] vs 9.9 [9.3–10.5]; p < 0.001), and FIB-4 (1.15 [0.79–1.55] vs 1.36 [0.97–1.88]; p < 0.001).
Conclusion: Patients with low LSM < 8 kPa and biopsy-proven at-risk MASH tend to be younger with lower BMI and HbA1C but higher LDL and TG. Furthermore, these patients have lower ELF and FIB4, both of which could be affected by age. A personalized cutoff for LSM based on clinical characteristics is potentially needed to identify these patients that are suitable for clinical trials.

WED-052

Metabolic dysfunction–associated fibrosis-5 outperforms fibrosis-4 index for detecting liver fibrosis in a population-based cohort

Email: drsaleh.a.alqahtani@gmail.com

Background and aims: Early identification of liver fibrosis is essential for optimizing care pathways in individuals with metabolic dysfunction-associated steatotic liver disease (MASLD). The metabolic dysfunction-associated fibrosis-5 (MAF-5) score is an age-independent, noninvasive fibrosis assessment tool incorporating waist circumference (WC), body mass index (BMI), diabetes status, aspartate aminotransferase (AST), and platelet count. We evaluated the diagnostic performance of MAF-5 and the fibrosis-4 Index (FIB-4) for detecting fibrosis, using liver stiffness measurement (LSM) by transient elastography (TE) as the reference standard.
Method: We analyzed data from adults enrolled in the Genomics and Environmental Noninvasive Evaluation for Saudi Intrahepatic Steatosis (GENESIS) cohort with complete data required to calculate MAF-5. Liver fibrosis was defined as LSM ≥ 8.0 kPa by TE. MASLD was defined as controlled attenuation parameter (CAP) ≥ 268 dB/m with at least one cardiometabolic risk factor. MAF-5 was categorized as low (<0), intermediate (0–1), and high (>1) fibrosis risk. Diagnostic performance metrics were calculated for MAF-5 > 1 and FIB-4 ≥ 1.3.
Results: Of the 2,688 participants enrolled, liver fibrosis was present in 54 participants (2.0%). Those with fibrosis were older (median 52 vs. 41 years, p < 0.001), more often male (70.4% vs. 48.5%, p = 0.001), had higher BMI (33.5 vs. 28.8 kg/m^2, p < 0.001), and had substantially higher MASLD prevalence (83.3% vs. 36.4%, p < 0.001). Median MAF-5 was significantly higher in the fibrosis group (2.1 vs. −1.5, p < 0.001). Fibrosis prevalence increased across MAF-5 categories: 11.1% in low-risk, 13.0% in intermediate-risk, and 75.9% in high-risk (p < 0.001). MAF-5 > 1 showed strong diagnostic performance with sensitivity 75.9%, specificity 84.4%, positive predictive value (PPV) 9.1%, and negative predictive value (NPV) 99.4%. In comparison, FIB-4 ≥ 1.3 had sensitivity 18.5%, specificity 93.4%, PPV 5.4%, and NPV 98.2%.
Conclusion: In this large population-based cohort, MAF-5 outperformed FIB-4 for detecting liver fibrosis defined by TE ≥ 8.0 kPa, demonstrating exceptionally high NPV and strong rule-out performance for liver fibrosis. Its age-independent structure and incorporation of metabolic parameters support the use of MAF-5 as an efficient first-line noninvasive screening tool for fibrosis risk stratification in MASLD care pathways, particularly in primary care and population-based settings.

WED-053

High burden of MASLD and fibrosis risk in type 1 diabetes: a FibroScan-based screening study

Abdullah Alguwaihes[1], Metib Alotaibi[2], Khaled Aburisheh[2], Mohamed El-Sharkawy[3], Hazim Bajri[2], Amani Alsadoon[4], Maram Alkhammash[4], Omar Alhazza[5], Khalid A Alswat. *[1]Division of Endocrinology, Department of Internal Medicine, College of Medicine, King Saud University, Riyadh, Saudi Arabia; [2]University Diabetes Center, King Saud University Medical City, King Saud University,, Riyadh, Saudi Arabia; [3]Diagnostic Radiology and Medical Imaging Department, College of Medicine, King Saud University, Riyadh, Saudi Arabia; [4]Liver Disease Research Center, College of Medicine, King Saud University, Riyadh, Saudi Arabia; [5]Family Medicine department, King Fahd military medical complex, Riyadh, Saudi Arabia*
Email: aalguwaihes@ksu.edu.sa

Background and aims: Metabolic dysfunction–associated steatotic liver disease (MASLD) is well described in type 2 diabetes, but its burden in type 1 diabetes mellitus (T1DM) remains under-recognized and liver assessment is not routinely incorporated into T1DM care. We aimed to define the prevalence and severity of FibroScan-defined steatosis and MASLD in individuals with T1DM, assess the presence of advanced fibrosis, and evaluate agreement between ultrasound and transient elastography.
Method: Cross-sectional screening of individuals aged ≥14 years with ≥1-year T1DM. Hepatic steatosis and fibrosis were assessed using FibroScan (controlled attenuation parameter [CAP], liver stiffness measurement [LSM]) and ultrasound. Steatosis was defined as CAP ≥248 dB/m; MASLD as steatosis plus ≥1 metabolic risk factor; and advanced fibrosis as LSM ≥8.2 kPa. Steatosis severity was CAP-graded. Associations between LSM and glycemic or clinical parameters (HbA1c, diabetes duration, time-in-range) were assessed, and ultrasound–FibroScan agreement evaluated.

Results: Among 150 individuals with T1DM, FibroScan-defined steatosis (CAP ≥248 dB/m) was present in 54 (36.0%), and 43 (28.7%) fulfilled criteria for MASLD. MASLD prevalence was higher among individuals treated with multiple daily injections (30.0%) compared with insulin pump therapy (18.8%), and increased with age, peaking in the 40–49-year group. CAP values averaged 233 ± 54 dB/m, with steatosis severity distributed as S1 in 16.7%, S2 in 4.0%, and S3 in 15.3%. Median liver stiffness was 4.4 kPa (IQR 1.7); 4 participants (2.7%) had LSM ≥8.2 kPa, indicating advanced fibrosis. Associations between LSM and glycemic or clinical parameters were weak (HbA1c r = – 0.11; diabetes duration r = 0.18; time-in-range r = 0.09). Ultrasound showed moderate agreement with FibroScan for steatosis detection (κ = 0.469), with sensitivity 57.1% and specificity 87.6%.
Conclusion: This study represents one of the largest FibroScan-based screening cohorts in T1DM reported to date, demonstrating that MASLD is common in individuals with T1DM, with a small but important proportion already meeting thresholds for advanced fibrosis. Reliance on glycemic markers and ultrasound underestimates liver disease burden. Incorporating non-invasive liver assessment into T1DM care pathways may enable earlier identification of at-risk individuals and more appropriate risk stratification.

Background and aims: The EASL guidelines include FIB-4 and elastography (ET) for identifying patients at high risk of advanced metabolic-associated steatotic liver disease (MASLD). This work aims to evaluate baseline characteristics and progression to cirrhosis among patients with significant fibrosis classified as low- vs. high-risk according to the EASL algorithm for MASLD.
Method: A total of 1544 MASLD patients from the HEPAMET registry with baseline FIB-4 and ET data were included. According to EASL criteria, the low-risk group was defined as FIB-4 <1.30 or FIB-4 >1.30 and ET <8 kPa, whereas the high-risk group was defined as FIB-4 >1.30 and ET >8 kPa. Significant fibrosis was defined as F2–F4. Patients with cirrhosis were excluded from the progression analysis (5 ± 2.6 years follow-up).
Results: Mean age was 55.3 ± 11.4 years, and 52.3% were men. MASH was present in 44.1% of patients, and fibrosis stages were: F0 26%, F1 25.3%, F2 15.5%, F3 19.9%, F4 11.8%. Overall, 70.6% (1090/1544) were classified as high-risk. Significant fibrosis was present in 61.7% (661/1071) of the high-risk group vs. 15% (67/448) of the low-risk group. Age (59.3 ± 9.6 vs. 53.9 ± 11.4; p = 0.0001), albumin (4.41 ± 0.4 vs. 4.53 ± 0.3; p = 0.034), platelets (196 ± 67 vs. 236 ± 64; p = 0.0001), INR (1.06 ± 0.2 vs. 1.01 ± 0.1; p = 0.015), type 2 diabetes (65.1% vs. 47.8%; p = 0.005), and hypertension (67.9% vs. 47.8%; p = 0.001) were significantly different between high- and low-risk patients with significant fibrosis. ET was also higher in the high-risk group (17.9 ± 11.1 vs. 6.3 ± 1.4 kPa; p = 0.0001). During follow-up, 26.7% (60/225) of high-risk patients with significant fibrosis progressed to cirrhosis vs. 10.7% (3/28) in the low-risk group (log-rank 4.323; p = 0.038), with high-risk status independently predicting progression [HR 3.47 (95% CI 1.08–11.14)] after adjustment for age, sex, and baseline fibrosis stage.
Conclusion: Although some patients with significant fibrosis are not identified by the EASL algorithm, their baseline characteristics suggest a more indolent course and a significantly lower risk of progression to cirrhosis.

WED-055-YI
AI-based fibrosis detection in MASLD: evaluating swallow deep neural networks, large language models and foundation models vs. FIB-4

Gabriele De Vito[1], Eleni-Myrto Trifylli[2], Filomena Ferrucci[1], Athanasios Angelakis[3]. *[1]Dept. of Computer Science, Univ. of Salerno, Salerno, Italy; [2]GI-Liver Unit, 2nd Department of Internal Medicine, National and Kapodistrian University of Athens, Laboratory of Reliability and Quality Control in Laboratory Hematology (HemQcR), Department of Biomedical Sciences, Section of Medical Laboratories, School of Health & Caring Sciences, University of West Attica (UniWA), Athens, Greece; [3]Amsterdam University Medical Center, Amsterdam, Netherlands*
Email: a.angelakis@amsterdamumc.nl

Background and aims: Metabolic dysfunction-associated steatotic liver disease (MASLD) is a major global health burden, with advanced

fibrosis driving liver-related morbidity. FIB-4 is widely used for non-invasive fibrosis assessment but shows variable performance across populations. This study compared artificial intelligence models, including shallow deep neural networks (s-DNNs), tabular foundation models (TabPFN), and large language models (LLMs), with FIB-4 for advanced fibrosis detection across multiple MASLD cohorts.

Method: A total of 784 biopsy-confirmed MASLD pts were included from three cohorts: China (n = 540; training/internal validation), Malaysia (n = 147; val1), and India (n = 97; val2). The models were trained and evaluated using six clinical features: age, AST, ALT, PLT, FIB-4, and a FIB-4 threshold (1.3). The LLM "gpt-4o-2024–08–06" was tested in zero-shot (ZS) and fine-tuned (FT) settings, using structured prompts with the same input variables. The s-DNN comprised three hidden layers (17, 5, 23 nodes), ReLU activation, Adam optimizer (α = 0.001), dropout, and 100 epochs. Performance was evaluated over five independent runs using specificity (Spec), sensitivity (Sens), AUROC, and F1. The prevalence of advanced fibrosis was 27.6% (China), 21.08% (val1), and 32.98% (val2).

Results: FIB-4 achieved AUROC: 0.75 (Spec: 0.79, Sens: 0.71, F1: 0.57) in val1 and 0.60 (Spec: 0.66, Sens: 0.53, F1: 0.48) in val2. TabPFN showed high Spec (≥0.86) but low Sens (≤0.40), with AUROC values of 0.65 (F1: 0.45) in val1 and 0.63 (F1: 0.48) in val2. The ZS-LLM "gpt-4o-2024–08–06" achieved AUROC: 0.73 (Spec: 0.65 ± 0.02, Sens: 0.81 ± 0.02, F1: 0.52 ± 0.02) in val1 but dropped to 0.57 (F1: 0.47) in val2. FT improved LLM performance in val1 (AUROC: 0.75, F1: 0.56) but was inconsistent in val2 (AUROC: 0.63, F1: 0.50). The s-DNN consistently outperformed all models, achieving AUROC: 0.76 (Spec: 0.76, Sens: 0.74, F1: 0.56) in val1 and 0.66 (Spec: 0.71, Sens: 0.56, F1: 0.52) in val2.

Conclusion: The s-DNN consistently outperformed FIB-4, LLMs, and TabPFN for advanced fibrosis detection across cohorts, demonstrating the most balanced diagnostic performance. Although LLMs showed moderate accuracy, their variable sensitivity limits clinical reliability, while TabPFN exhibited high specificity but poor sensitivity. These findings suggest that domain-specific AI models trained on structured clinical data provide superior and more generalizable fibrosis assessment.

WED-056

NAFLD liver fat score outperforms controlled attenuation parameter for diagnosing hepatic steatosis in type 2 diabetes: an explainable artificial intelligence study

Athanasios Angelakis[1], Byron Lykiardopoulos[2], Wile Balkhed[3], Martin Bergram[4], Fredrik Iredahl[4], Markus Holmberg[2], Carl Edin[5], Carl-Johan Carlhäll[5], Tino Ebbers[5], Pontus Henriksson[2], Christian Simonsson[2], Karin Rådholm[2], Gunnar Cedersund[6], Mikael Forsgren[7], Olof Dahlqvist Leinhard[8], Cecilia Jönsson[2], Peter Lundberg[5], Stergios Kechagias[2], Nils Dahlström[5], Patrik Nasr[9], Mattias Ekstedt[5]. *[1]Amsterdam University Medical Center, Amsterdam, Netherlands; [2]Department of Health, Medicine and Caring Sciences, Linköping University, Linköping, Sweden; [3]Wallenberg Center for Molecular Medicine (WCMM), Linköping University,, Linköping, Sweden; [4]Primary Health Care Center, Department of Health, Medicine and Caring Sciences, Linköping University, Wallenberg Center for Molecular Medicine (WCMM), Linköping University, Linköping, Sweden 5Center for Medical Image Science and Visualization (CMIV), Linköping University, Linköping, Sweden; [5]Department of Health, Medicine and Caring Sciences, Linköping University, Center for Medical Image Science and Visualization (CMIV), Linköping University, Linköping, Sweden; [6]Department of Biomedical Engineering, Linköping University, Linköping, Sweden; [7]Department of Health, Medicine and Caring Sciences, Linköping University, Center for Medical Image Science and Visualization (CMIV), Linköping University, AMRA Medical AB, Linköping, Sweden; [8]Wallenberg Center for Molecular Medicine (WCMM), Linköping University, AMRA Medical AB, Linköping, Sweden; [9]Department of Health, Medicine and Caring Sciences, Linköping University, Wallenberg Center for Molecular Medicine (WCMM), Linköping University, Center for Medical Image Science and Visualization (CMIV), Linköping University, Linköping, Sweden*
Email: a.angelakis@amsterdamumc.nl

Background and aims: Metabolic dysfunction-associated steatotic liver disease (MASLD) is highly prevalent in patients with type 2 diabetes mellitus (T2DM) and requires accurate non-invasive assessment. The controlled attenuation parameter (CAP) is widely used but requires specialized equipment and shows uncertain performance compared with other non-invasive tests (NITs) in metabolically complex populations. We aimed to evaluate and rank NITs for magnetic resonance imaging proton density fat fraction (MRI-PDFF)-defined steatosis in T2DM using explainable artificial intelligence (XAI), and to assess whether machine learning (ML) improves diagnostic performance.

Method: A total of 247 patients with T2DM were analyzed. Of these, 54% had steatosis, i.e. MRI-PDFF ≥5%. The dataset was randomly split into training (n = 197, 80%) and test (n = 50, 20%) sets. A CatBoost (CB) ML model was trained/tuned (hyperparameters: iterators, learning rate, depth) with 10-fold cross validation (10CV) on the training set, using as features: CAP, Hepatic Steatosis Index (HSI), NAFLD Liver Fat Score (LFS), Fatty Liver Index, Lipid Accumulation Product, Visceral Adiposity Index, Triglyceride-Glucose Index, and FAST. XAI techniques including SHAP (Shapley Additive Explanations), CB's direct predictability feature importance, importance on the loss error, and correlation analysis were applied to assess feature importance.

Results: The AUROC mean ± SD with [95% CI] using 10CV was: CAP (cut-off: 248 dB/m) 0.84 ± 0.09 [0.68–1.00], LFS (cut-off: −0.64) 0.82 ± 0.10 [0.68–0.97], and CB 0.88 ± 0.07 [0.77–1.00]. On the test set, AUROC was CAP 0.87, LFS 0.90, and CB 0.95, with specificity for CAP 0.70, LFS 0.70, and CB 0.78. Sensitivity for CAP, LFS, and CB was 0.93. Correlation analysis showed CAP had the highest association with PDFF, Pearson (P): 0.61, Kendall (K): 0.49, Spearman (S): 0.68, while LFS showed similar trends (S: 0.64, K: 0.45) but lacked linear correlation (P: 0.14). Applying a 5% PDFF cut-off, LFS showed non-linear correlation with steatotic patients (Point-Biserial: 0.18), while CAP was 0.60. XAI methods confirmed LFS as the most important predictor.

Conclusion: LFS outperformed CAP for diagnosing steatosis in patients with T2DM, demonstrating higher predictive accuracy and metabolic relevance. XAI confirmed its diagnostic importance. LFS may represent a practical alternative to CAP for MASLD screening in primary care. Further studies should validate these findings and explore ML integration and fibrosis assessment.

WED-057-YI

Comparing non-invasive risk scores for predicting adverse liver outcomes in MASLD

Email: quee5084@ox.ac.uk

Background and aims: Risk stratification in metabolic dysfunction–associated steatotic liver disease (MASLD) is essential for identifying individuals at increased risk of major adverse liver outcomes (MALO) such cirrhosis and hepatocellular carcinoma. Multiple risk scores have been proposed across different populations, but their comparative performance to predict incident MALO in patients with confirmed MASLD remain unclear. The aim of this analysis was to compare the performance of several models to predict incident MALO.
Method: This analysis evaluated risk scores in an individual participant data meta-analysis (IPD-MA), comprising well-characterised MASLD cohorts with longitudinal follow-up for liver-related outcomes. We computed: Cirrhosis Outcome Risk Estimator (CORE), Fibrosis-4 (FIB-4), Metabolic dysfunction-Associated Fibrosis 5 score (MAF-5), Liver Risk Score (LRS), and Anticipate-NASH. To assess discrimination at yearly intervals up to 10 years, the area under the curve (AUC) was the primary metric. Calibration of the models was assessed using observed-to-expected (O:E) ratios and subgroup analyses examined each model's performance across different populations considering data availability for each model within the IPD to maximise sample size.
Results: The complete-case cohort, where data were available for all predictors, included participants from 14 independent studies (n = 927). The median age was 49 years (IQR 20–59), and 53.0% (n = 491) were male. Type 2 diabetes was present in 41.8%, and the median BMI was 28 kg/m^2 (IQR 25– 32). The median duration of follow-up was 4.8 years, during which 2.1% of participants experienced MALO. At 10 years, AUC demonstrated variable discriminatory performance across models: CORE 0.713, FIB-4 0.823, MAF-5 0.733, LRS 0.610, and Anticipate-NASH 0.703. Results from evaluation of each model separately were broadly consistent with FIB-4 showing the strongest discrimination in both analyses. The AUC for CORE (n = 1970) was 0.738; FIB-4 (n = 2326) 0.821; MAF-5 (n = 1403) 0.758; LRS (n = 1586) 0.684; and Anticipate-NASH (n = 2315) 0.770. Calibration varied between models. CORE underpredicted the incidence of MALO (O:E 2.567), whereas overprediction was observed for LRS (O:E 0.007) and MAF-5 (O:E 0.02).
Conclusion: The risk scores show heterogeneity in discrimination and calibration and are not interchangeable across populations. This highlights the importance of population specific validation and recalibration in patients with MASLD in clinical practice.

WED-058-YI

Primary care MASLD fibrosis risk stratification: real-world comparison of FIB-4–VCTE and SAFE–VCTE pathways

Afreen Ashraf[1], Ryan Wexler[1], Pavan Vuddanda[2], Panagiotis Trilianos[3], Arpan Mohanty[2]. *[1]Boston University School of Medicine, Boston, United States; [2]Boston Medical Center, Boston, United States; [3]East Boston Neighborhood Health, East Boston, United States*
Email: afreen@bu.edu

Background and aims: Current guidelines recommend tiered fibrosis risk stratification for patients with metabolic dysfunction–associated steatotic liver disease (MASLD) in primary care using the Fibrosis-4 (FIB-4) index followed by vibration-controlled transient elastography (VCTE) for intermediate risk. However, evidence suggests FIB-4 may underperform in identifying intermediate fibrosis. The steatosis-associated fibrosis estimator (SAFE), which integrates age, BMI, diabetes, platelets, aminotransferases, and globulin, followed by VCTE, is alternatively proposed. We compared real-world performance of FIB-4-VCTE and SAFE-VCTE pathways in a large safety-net primary care cohort, assessing diagnostic accuracy against liver biopsy and magnetic resonance elastography (MRE).
Method: We analyzed 1,095 consecutive primary care patients at risk for MASLD (61% female; mean age 48 years; 89.5% Hispanic) who underwent VCTE and had complete data to calculate FIB-4 and SAFE. Referral indications included elevated liver enzymes, steatosis, diabetes/prediabetes, BMI >30 kg/m^2, or ≥2 cardiometabolic risk factors. Patients with significant alcohol use, known liver disease, repeat referrals, or incomplete data were excluded. A subgroup of 125 underwent biopsy or MRE; significant fibrosis was defined as ≥F2 or MRE ≥3.1 kPa. FIB-4 categories followed EASL age-specific thresholds for low, indeterminate, and high risk. SAFE fibrosis risk categories were defined as: low (<0), indeterminate (0–99), and high (≥100). Hepatology referral criteria were indeterminate risk with VCTE ≥8 kPa or high-risk classification. Outcomes included the proportion meeting criteria for hepatology referral, false-omission rate (low-risk classification despite significant fibrosis), false-positive rate (indeterminate or high-risk classification without significant fibrosis), and overall correct classification.
Results: Among 1,095 patients, FIB-4–VCTE led to 61 referrals (6%) versus 176 (16%) with SAFE–VCTE. In the biopsy/MRE subgroup, FIB-4–VCTE had a higher false-omission rate than SAFE–VCTE (25% vs 13%, p = 0.14). False-positive rates (52% vs 58%, p = 0.77) and correct classification (62% vs 70%, p = 0.18) were similar.
Conclusion: In a largely Hispanic U.S. safety-net primary care cohort, the SAFE–VCTE pathway increased hepatology referrals but reduced false-omission rate compared with FIB-4–VCTE, with similar overall diagnostic accuracy. Further studies are needed to optimally balance referral burden and fibrosis detection in primary care MASLD.

WED-059

Unlocking recruitment with LiverPRO in a phase III pilot study for metabolic dysfunction-associated steatohepatitis

Julie Astono[1], Katrine Lindvig[1], Maja Thiele[2], Aleksander Krag[2], Dimple Desai[3], Mazen Noureddin[4], Naim Alkhouri[4], Rashmee Patil[3]. *[1]Evido Health, Copenhagen, Denmark; [2]Department of Gastroenterology and Hepatology, Odense University Hospital, Institute of Clinical Research, University of Southern Denmark, Odense C, Denmark; [3]Pinnacle Clinical Research, San Antonio, United States; [4]Summit Clinical Research, San Antonio, United States*
Email: katrine@evido.health

Background and aims: Recruitment into phase III trials for metabolic dysfunction-associated steatohepatitis (MASH) is limited by low detection rates of clinically significant fibrosis (≥F2) and reliance on referral-based or manual prescreening. Scalable approaches are needed to identify at-risk individuals earlier and more systematically. This pilot evaluated the feasibility of LiverPRO, a data-driven fibrosis risk model applied to routinely collected laboratory data, as a pre-screening tool for clinical trial recruitment.

Method: We conducted a pragmatic US real-world pilot in which LiverPRO was applied to existing primary care laboratory datasets to identify individuals at risk of liver fibrosis. LiverPRO is designed to operate under heterogeneous data availability and does not require complete biomarker panels to estimate the probability of ≥F2 fibrosis. Individuals exceeding a predefined risk threshold (LiverPRO score ≥0.65) were flagged for further clinical evaluation. Downstream evaluation included opportunistic assessment with transient elastography (TE), and referral for liver biopsy according to site-specific protocols. Key outcomes included data processability, proportion of individuals flagged as at risk, and progression through downstream assessment steps.
Results: A total of 1,587 individuals were identified within the primary-care laboratory registry during the 2-month pilot period. LiverPRO was calculated in 1,371 individuals (86.4%). Of these, 171 individuals (12.5%) were flagged as being at increased risk of significant fibrosis (LiverPRO score ≥0.65). To date, 19 individuals have undergone transient elastography as part of downstream clinical evaluation. Among those assessed, 5 demonstrated liver stiffness values between 6 and 8 kPa, 3 between 8 and 12 kPa, and 1 >12 kPa. Following clinical review, 3 individuals were invited for further evaluation and potential trial recruitment. While no trial enrolments have occurred, the approach enabled identification of previously unrecognised at-risk individuals, several of whom met criteria for clinical management outside a trial.
Conclusion: This pilot demonstrates the feasibility of systematic pre-screening for liver fibrosis using routinely collected laboratory data. LiverPRO enabled scalable identification of individuals at increased fibrosis risk despite heterogeneous and incomplete datasets. As a pre-screening approach, this strategy may support identification of candidates for late-phase MASH trials.

WED-060-YI
Lower predictive performance of FIB-4 with lower eGFR categories: a cohort study of 63,587 persons
Hanne Åström[1], Axel Wester[1], Hannes Hagström[1,2], Juan-Jesus Carrero[3,4]. [1]*Karolinska Institutet, Department of Medicine, Huddinge, Stockholm, Sweden;* [2]*Karolinska University Hospital, Department of Upper GI, Division of Hepatology, Stockholm, Sweden;* [3]*Karolinska Institutet, Department of Medical Epidemiology and Biostatistics, Stockholm, Sweden;* [4]*Danderyd Hospital, Department of Clinical Science, Stockholm, Sweden*
Email: hanne.astrom@ki.se

Background and aims: Chronic kidney disease (CKD) is common in patients with metabolic dysfunction-associated steatotic liver disease (MASLD). It is unknown whether the guideline-recommended FIB-4 score predicts major adverse liver outcomes (MALO) in reduced eGFR. Here, we examined the association between eGFR, FIB-4, and MALO, and evaluated the discriminative ability of FIB-4 across eGFR groups in persons with or at high risk of MASLD.
Method: We included persons with or at high risk of MASLD in the Stockholm Creatinine Measurements (SCREAM) cohort, defined as diagnoses for MASLD, type 2 diabetes or obesity. The population was stratified by eGFR (≥90, 60–89, 30–59 and <30mL/min/1.73m^2) and age-adjusted FIB-4 (low, indeterminate, high). Cox regression estimated the association between FIB-4 and MALO within eGFR groups. Harrell's C-index was used to assess the discriminative ability of FIB-4 across eGFR groups.
Results: We included 63,587 persons with or at high risk of MASLD with a median follow-up of 4.9 years (IQR = 2.0–9.2). Across all eGFR groups, high FIB-4 was associated with higher rates of MALO compared to low FIB-4. The discriminative ability of FIB-4 was highest in persons with eGFR ≥90 (C-index = 0.77), and lowest in eGFR 30–59 (C-index = 0.64) and eGFR <30 (C-index = 0.69).
Conclusion: Higher FIB-4 scores were associated with an increased rate of MALO across all eGFR groups, but the discriminative ability of FIB-4 was strongest among those with eGFR ≥90. The reduced discrimination in lower eGFR suggests that other measures of liver fibrosis assessment may be needed in these persons.

WED-061
Routine testing of PNPLA3 and TM6SF2 genetic variants in MASLD: experience from outpatient hepatology clinics in southern Switzerland
Beatrice Barda[1,2], Chiara De Luca[1], Maurizia Bissig[1], Rossella Forlenza[1], Claudia Di Bartolomeo[1], Mario Uhr[3], Andreas Cerny[2]. [1]*Fondazione Epatocentro Ticino, Lugano, Switzerland;* [2]*Epatocentro Ticino, Lugano, Switzerland;* [3]*Medisyn, Bioggio, Switzerland*
Email: beatrice.barda@hin.ch

Background and aims: Metabolic dysfunction–associated steatotic liver disease (MASLD) is the most frequently diagnosed condition in hepatology outpatient clinics. Increasing attention has focused on genetic factors, and PNPLA3 I148M and TM6SF2 E167K variants have been associated with liver steatosis and a higher risk of metabolic dysfunction–related diseases. We report our experience with routine testing for these variants in patients referred for steatotic liver disease.
Method: We included patients followed between 2018 and 2024 at our outpatient hepatology center, organized as a hub-and-spoke model with six peripheral clinics across Ticino and a central hub in Lugano, Southern Switzerland. Patients were referred for liver steatosis on ultrasound, elevated liver enzymes, or increased ferritin levels. At baseline, all subjects underwent FibroScan®, abdominal ultrasound, and laboratory tests to exclude other causes of steatosis. PNPLA3 I148M and TM6SF2 E167K variant testing was performed after informed consent.
Results: Overall, 300 patients with MASLD were included. Most were male (62%), the mean age was 57 years, and 48% had a body mass index (BMI) >29 kg/m^2. Genetic testing showed no variants in 108 patients, heterozygosity for PNPLA3 in 104, heterozygosity for TM6SF2 in 14, homozygosity for PNPLA3 in 43, and homozygosity for TM6SF2 in 3 patients. Mixed genetic profiles were observed in 18 patients. Overall, about half of the cohort carried at least one variant. At baseline FibroScan®, 60% showed no fibrosis. Mild steatosis was present in 85% of patients, while 15% had severe steatosis. All patients received structured counseling, including clinical evaluation and nutritional support. Follow-up corresponded to the last visit, 2–4 years after baseline. Among patients with complete data, no significant association was found between liver improvement and specific genetic variants. Most patients remained stable, some improved liver stiffness, and only two worsened.
Conclusion: PNPLA3 and TM6SF2 variants were frequent in our MASLD population. Most patients showed stabilization or improvement of liver parameters, likely related to regular follow-up and lifestyle interventions. Awareness of genetic predisposition appeared to improve adherence to lifestyle changes. We have recently initiated a prospective MASLD cohort with annual follow-up, patient-reported outcomes, and systematic sample collection.

WED-062
Definite fibrotic metabolic-dysfunction associated steatohepatitis in referrals at center in Denmark
Mark Berner Hansen[1], Eva Efsen Dahl[1], Gro Linno Willemoe[2], Frank Vinholt Schiødt[1]. [1]*Digestive Disease Center K, Bispebjerg University Hospital, Copenhagen NV, Denmark;* [2]*Department of Pathology, Rigshospitalet, Copenhagen Ø, Denmark*
Email: mbh@dadlnet.dk

Background and aims: Management guidelines by EASL and other societies for metabolic dysfunction-associated steatotic liver disease (MASLD), recommend mainly targeting patients with fibrotic metabolic-dysfunction associated steatohepatitis (MASH) and metabolic risk factors for progression of disease. Accordingly, fibrotic MASH patients have increased risk for developing serious late stage complications and as such in need of urgent management at expert

care centers. Real-world experience (RWE) with respect to the proportion of referred patients diagnosed with definite fibrotic MASH is limited. Here we report our RWE at a Danish referral university hospital center.

Method: Adult patients with metabolic syndrome and/or elevated alanine aminotransferases (ALT >50) referred in a 5-year period (2018–2022) on suspicion of fibrotic MASH were retrospectively included. Medical history, anthropometric measurements, routine (blood tests, ultrasound) and specific examinations were applied. Liver biopsy was offered for definite diagnosis and to evaluate MASLD characteristics. Patient demographics and characteristics, absolute and proportion of patients with definite MASLD and fibrotic MASH are reported.

Results: A total of 137 adult patients was included. Ten percent of patients were evaluated without liver biopsy and diagnosed with chronic liver diseases other than MASLD. Liver-biopsied patients (n = 123) had a mean age of 49 years, half were males. Overweight or obesity was present in 94%, dyslipidemia in 74%, hypertension in 40% and type 2 diabetes mellitus in 34%. Of all 137 patients, 104 (76%) were diagnosed with definite MASLD and 80 (58%) with definite MASH. Seventy-four (54%) patients had definite fibrotic MASH, while 41 (30%) had significant (F2-F4) fibrotic MASH. Eight patients (6%) had cirrhotic (F4) MASH.

Conclusion: This real-world retrospective study indicates that about half of the referred patients, all evaluated according to recent EASL management guidelines with cardio-vascular risk profile, were diagnosed with definite fibrotic MASH. As such, we conclude that the new management guidelines are useful for identifying a relevant high proportion of fibrotic MASH patients among referrals in a real-world setting at a referral center in Denmark.

Background and aims: In metabolic dysfunction-associated steatotic liver disease (MASLD), disease activity is a key feature of steatohepatitis (MASH) diagnosis and drives fibrosis progression. MASLD activity can only be assessed by liver biopsy. We aimed to develop a non-invasive test to measure MASLD activity, named ActiMASH.

Method: The present study was nested in the multicenter prospective QUID-NASH trial (NCT03634098), including 407 patients with type 2 diabetes (derivation, n = 273; validation, n = 134), and liver biopsy available. RNAseq was performed on liver samples. Liver stiffness measurement (LSM) by vibration-controlled transient elastography was performed at inclusion and during follow-up. Proteomics was performed on circulating extracellular vesicles (EVs) from 23 patients (8 steatosis, 15 MASH), allowing identification of an EV biomarker then measured by filtration/ELISA on derivation and validation populations. To develop ActiMASH, a logistic regression was performed on the derivation population, and then validated.

Results: Proteomics showed that plasma EV protein composition was altered in MASH. We identified transferrin receptor (TFRC) carried by large EVs (TFRC-lEVs), as associated with MASH in both derivation and validation populations ($p < 0.001$ and $p = 0.02$), as well as with ballooning ($p = 0.002$ and $p = 0.02$). Liver transcriptomics showed that one of the three upregulated pathways in patients with high TFRC-lEVs was heme metabolism. In two different hepatocyte cancer cell lines, MASH-mimicking conditions increased TFRC-lEVs release, while decreasing intracellular TFRC. TFRC-lEV, sex, AST and triglycerides were independently associated with MASH in the derivation population. These variables were included into a score, named ActiMASH, having an AUROC for MASH of 0.81 in both populations. ActiMASH increased with NAS ($p < 0.0001$ in both populations). Aiming for 80% sensitivity for MASH, the 45 cut-off was set. As compared with current EASL guidelines' strategy, ActiMASH ≥ 45 as a screening tool followed by LSM ≥ 8 kPa for at-risk MASH diagnosis, improved sensitivity of the strategy from 0.36 to 0.68, with specificity decreasing only from 0.87 to 0.83. After a median follow-up of 4 years, 10 patients had an increase in LSM > 5 kPa: all had initial ActiMASH ≥ 45, while none of those <45 had LSM progression ($p = 0.007$).

Conclusion: We developed ActiMASH, a blood-based test including circulating EVs, able to estimate MASLD activity and predict fibrosis progression in patients with diabetes.

WED-069

Optimizing hepatocellular cancer surveillance in metabolic dysfunction–associated steatotic liver disease based on liver stiffness measurement

Email: luis.calzadillabertot@uwa.edu.au

Background and aims: Metabolic dysfunction–associated steatotic liver disease (MASLD) is an increasingly common cause of hepatocellular carcinoma (HCC) with 30–40% of HCC cases occurring in the absence of cirrhosis. Risk stratification tools to identify those at highest risk who would benefit from HCC surveillance are not clearly defined. We aimed to examine the accuracy of liver stiffness measurement (LSM) to predict incident HCC in patients with MASLD and identify the optimum thresholds to enter patients into HCC surveillance.
Method: We evaluated a multicentre retrospective cohort of MASLD subjects collated from tertiary centres in Australia (n = 4) and Spain (n = 10) as part of the Spanish HEPAmet registry cohort. Subjects had a baseline LSM by transient elastography and were followed for the outcome of incident HCC. Annual incidence rates of HCC were calculated and stratified by LSM categories. Baseline covariates, cumulative incidence and thresholds associated with incident HCC were investigated by competing risk regression.
Results: Of 3387 patients followed for a median of 4.8 years (IQR 2.5–6.2) and 16,226 person-years, 66 subjects (1.9%) developed HCC. Mean age was 58.7 years, 53% were male and the median LSM was 8.6 kPa (IQR 5.6–14.1). The five-year cumulative incidence of HCC was 0.3% among patients with a baseline LSM <10 kPa, 1.7% for LSM 10–14.9 kPa, 2.3% for LSM 15–19.9 kPa, and 7.9% in those with LSM >20 kPa (all $p < 0.001$). Compared to subjects with LSM <10 kPa, HCC risk increased by LSM category, (10–14.9 kPa, subHazard Ratio = 5.5), (15–19.9 kPa, sHR = 10.3) and (>20 kPa, sHR = 23.9). Competing risk regression identified LSM, age and diabetes as independent predictors of HCC. The annual HCC incidence exceeding 1.5% were met in subjects within the LSM category of >20 kPa (1.7%/yr, 95% CI 1.25–2.33) and among patients with diabetes and LSM between 15 and 19.9 kPa (2.06%/yr, 95% CI 1.40–2.90). The annual HCC incidence exceeding 1% was additionally met in the LSM category 15–19.9 kPa (1.26%/yr, 95% CI 0.38–1.65) and were consistently above this threshold when stratified by diabetes status and sex.
Conclusion: LSM can effectively stratifies HCC risk in MASLD. Thresholds ≥20 kPa meet surveillance criteria and ≥15 kPa –19.9 indicate elevated risk specially in the presence of diabetes and should be considered for cost- effective analysis. These findings support a practical, non-invasive approach to personalize HCC surveillance in MASLD, potentially improving early detection and resource allocation.

WED-070

MASH-iScan: a non-invasive method for diagnosing MASH using ultrasound and artificial intelligence

Jennifer Cathcart[1], Laurence Still[2], James S Bowness[3], Ruairi Lynch[4], John Dillon[1]. *[1]University of Dundee, Dundee, United Kingdom; [2]Independent Consultant, Cardiff, United Kingdom; [3]University College London, London, United Kingdom; [4]NHS Tayside, Dundee, United Kingdom*
Email: jeni123@live.com

Background and aims: Metabolic dysfunction-associated steatohepatitis (MASH), the co-existence of steatosis and inflammation, is a leading cause of progression to fibrosis and hepatocellular cancer (HCC). (1) Currently the gold standard for diagnosis of MASH is via liver biopsy which carries significant risks including mortality. (2) Therefore, a better non-invasive test to diagnosis MASH is needed. The aim of this project is to explore whether artificial intelligence (AI), when applied to ultrasound imaging and routine clinical data, can accurately diagnose MASH.
Method: We retrospectively obtained non-targeted liver biopsies slides from November 2013 to November 2023 in NHS Tayside. The biopsies were scored with non-alcoholic fatty liver disease activity score (NAS) criteria, then paired with ultrasound images within 6 months, blood tests within 3 months of biopsy and demographics. Trained medical annotators scored the ultrasound images against a defined checklist and ultrasound parameters were computed digitally using bounding boxes and region of interest (ROI) selected by the annotators to total 12 ultrasound parameters. We utilised machine learning to develop a mathematical model from our input data of digital ultrasound parameters and checklist, blood tests and demographics. Support Vector Machine (SVM) emerged as the most effective model.
Results: We obtained 102 ultrasound images with paired biopsies within 6 months. We used leave-one-out cross validation due to the small sample size. The best Area under the receiver operating curve (AUROC) was for NAS ≥3 with an AUROC 0.86 and secondly for NAS ≥4 with an AUROC of 0.83. The NAS ≥3 model has a high negative predictive value (NPV) (100.0), thus a negative test for this model would confidently rule-out MASH. The latter NAS ≥4 model would rule-in MASH (NAS ≥4) with good sensitivity (84.4) and specifically (81.4) and NPV (91.9) identifying a cohort of patients to treat.
Conclusion: Both models exceeded the accepted standard of 0.80 for a diagnostic test accuracy. There was an element of overtraining due

to a small sample size resulting in high test characteristics in some statistical measures, therefore the models need an external validation which is underway. The project demonstrates that ultrasound parameters can be utilised to diagnosis MASH and may offer a non-invasive cost-effective simple alternative to biopsy to diagnosis MASH.

WED-071

Clinical relevance of repeating FIB-4 in the screening strategy for identifying metabolic dysfunction–associated liver disease-related advanced fibrosis

Yasmina Chouik[1], Cécile Terrien[2], Devi Guemon[3], Emmanuel Disse[3], Bérénice Ségrestin[3], Massimo Levrero[1], Paul Hermabessière[4], Adèle Delamarre[4], Cyrielle Caussy[5]. *[1]Department of Hepatology, Croix Rousse Hospital, Hepatology Institute EVEREST, Hospices Civils de Lyon, INSERM U1350 PaThLiv, Université Claude Bernard Lyon 1, Lyon, France; [2]Centre d'Investigation de la Fibrose Hépatique, Hôpital Haut-Lévêque, Bordeaux University Hospital, Bordeaux, France; [3]Hospices Civils de Lyon, Département Endocrinologie, Diabète et Nutrition, Hôpital Lyon Sud, Pierre-Bénite, France; [4]Centre d'Investigation de la Fibrose Hépatique, Hôpital Haut-Lévêque, Bordeaux University Hospital, Bordeaux Institute of Oncology, INSERM U1312, University of Bordeaux, Bordeaux, France; [5]Hospices Civils de Lyon, Département Endocrinologie, Diabète et Nutrition, Hôpital Lyon Sud, Univ Lyon, CarMen Laboratory, INSERM, INRA, INSA Lyon, Université Claude Bernard Lyon 1, Pierre-Bénite, France*
Email: yasmina.chouik@inserm.fr

Background and aims: The EASL-EASD-EASO guidelines recently proposed a screening strategy for MASLD-related advanced fibrosis (AF). In patients with intermediate FIB-4 (1.30–2.67), two strategies are proposed: i) the immediate referral to hepatologist for a second-line test, or ii) repeating FIB-4 at 1 year after intensified management of comorbidities. In patients with initial low FIB-4 < 1.30, monitoring FIB-4 every 1–3 years is suggested. However, there are no strong evidence supporting these recommendations. Therefore, we assessed the clinical relevance of these recommendations.

Method: A retrospective cohort including MASLD patients with low or intermediate FIB-4 was conducted in 2 tertiary centers between 2018 and 2022. Inclusion criteria were the access to a liver stiffness measurement (LSM) concomitantly to the initial FIB-4, and repeated FIB-4 during follow-up.

Results: 625 patients were included. Median BMI was 34.0 kg/m^2 (30.8–39.0) and 70.7% of patients had T2D. Initial median FIB-4 was 1.31 (0.95–1.74) and 35.7% of patients had a high risk for AF. After 3 years of follow-up, median FIB-4 remained stable at 1.32 (1.01–1.92). Respectively, 21.3% and 22.4% of patients with initial low FIB-4 changed to the intermediate category at 1 and 3y. The negative predictive value for AF detection was not improved by repeating FIB-4 (76.8% at baseline, 71.6% at 1y and 75.3% at 3y).

Factors predicting change in FIB-4 category at 3y were age (OR: 1.16; CI95%: 1.0–1.1; p < 0.001), arterial hypertension (OR: 2.0; CI95%: 1.1–4.0; p = 0.019) and GLP1-RA introduction during the 3y period (OR: 0.2; CI95%: 0.0–0.7; p = 0.015). In patients with an initial intermediate FIB-4, 77.2% remain stable at 1y and 68.5% at 3y. Decrease from intermediate to low category occurred in 13.3% of patients at 1y and 16.8% at 3y. Factors associated with FIB-4 decrease at 1y were weight loss (OR: 1.1; CI95%: 1.0–1.1; p = 0.029) and introduction of a GLP1-RA during the year (OR: 4.4; CI95%: 1.2–16.6; p = 0.029).

Conclusion: The majority of MASLD patients did not change of FIB-4 category in a 3y time frame. Repeating FIB-4 over time does not seem effective in picking up false negative cases. In case of intermediate FIB-4, weight loss and GLP1-RA treatment are associated with FIB-4 normalization at 1y, but this effect is temporary and observed in few patients. These data suggest that a second-line NIT should be systemically performed in patients with intermediate FIB-4 in order to limit clinical inertia.

WED-072

ACT on MASH: a multi-country cross-sectional online survey of awareness, understanding, stigma, and perceptions of MASLD, MASH, and related cardiometabolic comorbidities among healthcare professionals

Cyrielle Caussy[1], Husam Albarmawi[2], Edwige-Ludiwyne Balzac[3], Julio Burman[4], Nathalie Eklöf[5], Takumi Kawaguchi[6], Nobuyoshi Kosaka[7], Jeff McIntyre[8], Lauren Nephew[9], Arash Pakseresht[10], Sahar Saeed[11], Jörn M. Schattenberg[12]. *[1]Hospices Civils de Lyon, Département Endocrinologie, Diabète et Nutrition, Hôpital Lyon Sud, Univ Lyon, CarMen Laboratory, INSERM, INRA, INSA Lyon, Université Claude Bernard Lyon 1, Pierre-Bénite, France; [2]Novo Nordisk, Mainz, Germany; [3]Novo Nordisk, France, Paris, France; [4]European Liver Patients' Association, Brussels, Belgium; [5]Novo Nordisk, Soberg, Denmark; [6]Division of Gastroenterology, Department of Medicine, Kurume University School of Medicine, Kurume, Japan; [7]Novo Nordisk, Japan, Tokyo, Japan; [8]Global Liver Institute, Washington, DC, United States; [9]Indiana University School of Medicine, Indianapolis, United States; [10]Novo Nordisk, Canada, Mississauga, Canada; [11]Queens University, Ontario, Canada; [12]Department of Medicine, Saarland University Medical Center, Homburg, Germany*
Email: cyrielle.caussy@chu-lyon.fr

Background and aims: Metabolic-dysfunction-associated steatotic liver disease (MASLD) is the most prevalent chronic liver disease worldwide; however, there has been limited research on healthcare professionals' (HCPs) awareness, knowledge, and perceptions of MASLD and metabolic dysfunction-associated steatohepatitis (MASH), and their associations with cardiometabolic comorbidities.

Method: In 2025, an online cross-sectional survey was conducted with HCPs from Canada, France, Germany, Japan, and the United States (US). HCPs were recruited via online panels and included gastroenterologists, hepatologists, endocrinologists, cardiologists, obesity specialists, primary care physicians, radiologists, and nurse practitioners/physician assistants (US only).

Results: 774 HCPs completed the survey from Canada (n = 65), the US (n = 301), France (n = 125), Germany (n = 120), and Japan (n = 163). HCPs reported a median of 20 years in clinical practice, and most worked in outpatient (49%) or hospital settings (42%). Most HCPs reported being "very" or "extremely" knowledgeable about MASLD (62%) and MASH (63%). Overall, 82% were aware of differences between MASLD and MASH; this varied notably by specialty (highest among hepatologists [98%] and lowest among cardiologists [72%]) and less by country (US, 80%; Canada, 88%; France, 77%; Germany, 81%; Japan, 90%). 48% of HCPs overall reported being "very" or "extremely" confident in identifying people at risk of MASH. 87% agreed that MASH and MASLD increase the risk of cardiovascular events, and 89% agreed that early diagnosis/management improves health outcomes. Overall, HCPs reported that nearly half of their patients with MASLD (45%) and MASH (42%) were diagnosed after an incidental finding. Radiologists reported incidental findings of MASLD and MASH in 21% and 14% of scans evaluated in a typical month, respectively. The proportion of HCPs who reported that screening patients with cardiometabolic conditions for MASH is "very" or "extremely" important varied by condition, ranging from 42% for chronic kidney disease to 86% for persistently elevated liver enzymes. 30% of HCPs reported that fear of stigmatizing patients with obesity was a barrier to screening.

Conclusion: Based on these results, we identified gaps in HCPs' confidence in identifying patients at risk of MASLD/MASH, a high frequency of incidental findings of these conditions, and disparities in the perceived importance of screening at-risk patients, highlighting areas for improving health professional education.

WED-073

Metabolic and cognitive effects of a 6-month dietary intervention in patients with MASLD: a prospective study

Francesca Saba[1], Gian Paolo Caviglia[1], Marta Guariglia[1], Francesca Pisano[1], Angelo Armandi[1], Chiara Rosso[1], Ilaria Goitre[2], Eleonora Dileo[1], Kamela Gjini[1], Simona Bo[2], Elisabetta Bugianesi[1]. [1]*Division of Gastroenterology and Hepatology, Department of Medical Sciences, University of Turin, Turin, Italy;* [2]*Division of Clinical Nutrition, Department of Medical Sciences, University of Turin, Turin, Italy*
Email: francesca.saba@unito.it

Background and aims: Metabolic dysfunction–associated steatotic liver disease (MASLD) is the hepatic manifestation of metabolic syndrome and has been increasingly linked to cognitive impairment. We evaluated whether a 6-month hypocaloric dietary intervention improves metabolic outcomes and cognitive performance, and explored the mediating role of circulating adipokines, hepatokines, and myokines.
Method: We conducted a prospective study including 136 adults with MASLD (median age 51 [42–61] years, 36% male, T2DM 14.7%, obesity 59.6%). Metabolic endpoints were defined as a body mass index (BMI) reduction ≥5%, and a controlled attenuation parameter (CAP) reduction ≥10%. Circulating cytokines were measured using a BioPlex (Luminex) platform. Cognitive function was assessed with the Repeatable Battery for the Assessment of Neuropsychological Status (RBANS); an RBANS total score ≤85 identified patients with mild cognitive impairment. All parameters were evaluated at baseline (T0) and after 6 months (6M).
Results: After 6 months, 31.6% of patients achieved a BMI reduction ≥5% (n = 43), and 39.0% achieved a CAP reduction ≥10% (n = 53). Weight loss was independently associated with CAP improvement (OR = 4.02, 95% CI 3.14–15.68; $p < 0.001$). Responders showed significant reductions in ALT, AST, and γ-GT (all $p < 0.001$), along with improvement in serum insulin ($p < 0.001$) and triglycerides ($p = 0.007$). Weight loss ≥5% was associated with remodeling of the hepato-adipose axis, characterized by reduced leptin and ANGPTL3 levels and increased adiponectin, as well as attenuation of systemic inflammation (reduced IL-1β, IL-6, and TNF-α). Among patients with baseline RBANS ≤85 (n = 52), the total RBANS score improved from 77 to 81 ($p < 0.001$), with significant gains in immediate memory (88 to 96, $p = 0.002$) and delayed memory (92 to 96, $p = 0.020$). In multivariate analysis including anthropometric, metabolic, hepatic, cognitive, and cytokine-related parameters, baseline RBANS score ($\beta = -0.19$, $p = 0.001$) and 6M–T0 changes in BMI ($\beta = 2.02$, $p = 0.009$), leptin ($\beta = -0.0014$, $p = 0.021$), and ANGPTL3 ($\beta = -0.45$, $p < 0.001$) independently predicted 6M–T0 changes in RBANS total score.
Conclusion: A weight loss ≥5% is associated with significant reductions in liver steatosis and improvements in hepato-metabolic and inflammatory profiles, accompanied by cognitive benefits in patients with mild cognitive impairment. These findings strengthen the rationale for structured lifestyle interventions as a cornerstone of MASLD management.

WED-074

C-reactive protein-triglyceride glucose index and fasting C-peptide to high-density lipoprotein cholesterol ratio as predictors for advanced fibrosis in patients with type 2 diabetes and metabolic dysfunction-associated steatotic liver disease

Georgiana-Diana Cazac-Panaite[1], Elena-Daniela Grigorescu[1,2], Adina-Bianca Foșălău[1,2], Alina Onofriescu[1,2], Cristina-Mihaela Lăcătușu[1,2], Bogdan-Mircea Mihai[1,2]. [1]*Unit of Diabetes, Nutrition, and Metabolic Diseases, Faculty of Medicine, Grigore T. Popa University of Medicine and Pharmacy, Iasi, Romania;* [2]*JUD. IASI, SAT REDIU, COM. REDIU, Romania*
Email: georgiana-diana_cazac@umfiasi.ro

Background and aims: Insulin resistance, low-grade inflammation, and metabolic disturbances drive the progression of metabolic dysfunction–associated steatotic liver disease (MASLD) to fibrosis in type 2 diabetes mellitus (T2DM). Early identification of high-risk patients remains challenging in routine practice. We explored the predictive value of the C-reactive protein–triglyceride-glucose index (CTI) and the fasting C-peptide-to-high-density lipoprotein cholesterol ratio (FCP/HDL) for advanced liver steatosis and fibrosis in patients with T2DM and MASLD.
Method: This analysis includes baseline data from a prospective doctoral study conducted at the Clinical Center of Diabetes, Nutrition, and Metabolic Diseases. Patients with T2DM and MASLD who were not optimally controlled were enrolled. After informed consent, anthropometric, biochemical assessments and transient elastography were performed. Metabolic and inflammatory indices, including CTI and FCP/HDL, were calculated using validated formulas.
Results: Seventy-two patients were enrolled (48.6% men), with a mean age of 59.09 ± 9.02 years, a median duration of T2DM of 2 years (IQR 6), and a median HbA1c of 6.95% (IQR 1.1). Mean body mass index was 33.93 ± 5.93 kg/m^2. Obesity was identified in 70.8% of participants. Mean controlled attenuation parameter (CAP) and liver stiffness measurement (LSM) values were 296.49 ± 61.07 dB/m and 7.05 ± 2.52 kPa. Moderate-to-severe steatosis and fibrosis were observed in 62.5% and 72.2% of patients, respectively. F2–F4 stages were identified in 18 subjects. The mean/median (± SD/IQR) values of studied markers were: cardiometabolic index (CMI) 1.04 ± 0.86, CTI 8.50 ± 0.68, FCP/HDL 3.29 (2.26), HbA1c/HDL 6.49 ± 1.67, and C-reactive protein 0.4 ± 0.33 mg/mL. Positive significant associations existed between LSM and CTI ($r = 0.335$, $p = 0.004$), FCP/HDL ($r = 0.270$, $p = 0.024$), and between CAP and CTI ($r = 0.417$, $p < 0.001$), and FCP/HDL ($r = 0.278$, $p = 0.020$). CTI (AUROC 0.677, CI: 0.544–0.809, $p = 0.048$) and FCP/HDL (AUROC 0.655, CI: 0.529–0.781, $p = 0.030$) were identified as predictors of moderate-to-severe steatosis. CTI (AUROC 0.656, CI: 0.510–0.803, $p = 0.048$) and FCP/HDL (AUROC 0.697, CI: 0.567–0.827, $p = 0.015$) were also identified as predictors of advanced hepatic fibrosis.
Conclusion: These findings suggest that composite metabolic and inflammatory indices may be useful, non-invasive tools for identifying patients with T2DM at risk of progression to advanced liver fibrosis in large-scale screening initiatives.

WED-075

Comparison of clinical care pathways for metabolic dysfunction-associated steatotic liver disease (MASLD) in type 2 diabetes (T2D) in the dawn of effective pharmacological therapy

Wah-Kheong Chan[1], Vincent Wai-Sun Wong[2,3], Lee Lee Lai[1], Nik Raihan Nik Mustapha[4], Pavitratha Puspanathan[5], Jimmy Che-To Lai[2,3], Terry Cheuk-Fung Yip[2,3], Grace Lai-Hung Wong[2,3], Sanjiv Mahadeva[1]. [1]*Gastroenterology and Hepatology Unit, Department of Medicine, Faculty of Medicine, Universiti Malaya, Kuala Lumpur, Malaysia;* [2]*Department of Medicine and Therapeutics, Medical Data Analytics Centre, The Chinese University of Hong Kong, Hong Kong, China;* [3]*State Key Laboratory of Digestive Disease, Institute of Digestive Disease, The Chinese University of Hong Kong, Hong Kong, China;* [4]*Department of Pathology, Hospital Sultanah Bahiyah, Alor Setar, Malaysia;* [5]*Department of Pathology, Hospital Pulau Pinang, Pulau Pinang, Malaysia*
Email: wahkheong2003@hotmail.com

Background and aims: This study aimed to evaluate different approaches in using non-invasive tests to identify patients with T2D (1) for pharmacological therapy for metabolic dysfunction-associated steatohepatitis (MASH) and (2) for having advanced fibrosis or cirrhosis.
Method: This study included patients with MASLD and T2D who underwent liver biopsy and liver stiffness measurement (LSM) by vibration-controlled transient elastography. Patients with histological MASH and F2-F3 fibrosis were considered as candidates for pharmacological therapy.
Results: The data of 537 patients were analysed (mean age 55.3 ± 10.5 years, 52.1% male). The use of LSM 10–15 kPa instead of 8–15 kPa

decreased the proportion of patients identified for pharmacological therapy from 40.4% to 25.0% with more patients correctly classified (70.0% vs. 61.7%), lower false positive rate (59.7% vs. 65.4%), and marginally higher false negative rate (18.9% vs. 17.0%). The 2-step approach (Fibrosis-4 index [FIB-4] based on age-specific cut-offs, followed by LSM if abnormal FIB-4) decreased the proportion of patients identified for pharmacological therapy to as low as 10.6% (when using LSM 10–15 kPa) with more patients correctly classified (up to 75.7%), lower false positive rate (down to 40.0%), and marginally higher false negative rate (highest 22.3%). The 2-step approach decreased the proportion of patients with LSM 15.1–20 kPa from 8.0% to 4.5% and increased correct identification of patients for pharmacological therapy from 41.9% to 57.9% for this group of patients, where pharmacological therapy would be considered. The use of LSM ≥10 kPa instead of ≥8 kPa decreased the proportion of patients identified as having advanced fibrosis or cirrhosis from 55.5% to 40.4% with more patients correctly classified (76.4% vs. 70.6%), lower false positive rate (34.0% vs. 43.6%), but higher false negative rate (16.8% vs. 11.7%). The 2-step approach decreased the proportion of patients identified as having advanced fibrosis or cirrhosis to as low as 19.0% (when using LSM ≥10 kPa) with more patients correctly classified (up to 81.3%), lower false positive rate (down to 17.5%), but higher false negative rate (highest 22.2%).

Conclusion: The results of this study support the use of the 2-step approach to identify patients with T2D for pharmacological therapy for MASLD and for having advanced fibrosis or cirrhosis, and provide important data when considering the LSM cut-offs to be used in the 2-step approach.

WED-076

Mapping somatic evolution in steatotic liver disease through integrated tissue and organoid genomics

Alessandro Cherubini[1], Stefania Mira[2], Vittoria Moretti[1], Hadi Eidgah Torgabehei[3], Elia Casirati[1], Laura Cerami[1], Giulia Periti[1], Francesco Malvestiti[2], Serena Pelusi[1], Daniele Dondossola[4], Daniele Prati[1], Luisa Ronzoni[1], Luca Valenti[5]. *[1]Precision Medicine Lab - Department of Transfusion Medicine, Fondazione IRCCS Ca' Granda Ospedale Maggiore Policlinico Milano, Milan, Italy; [2]Department of Pathophysiology and Transplantation, Università degli Studi di Milano, Milan, Italy; [3]Omic Sciences Lab, Scientific Direction, Fondazione IRCCS ca' Granda Ospedale Maggiore Policlinico Milano, Milan, Italy; [4]General and Liver Transplant Surgery Unit, Fondazione IRCCS Ca' Granda, Ospedale Maggiore Policlinico Milano, Department of Pathophysiology and Transplantation, Università degli Studi di Milano, Milan, Italy; [5]Precision Medicine Lab - Department of Transfusion Medicine, Fondazione IRCCS Ca' Granda Ospedale Maggiore Policlinico Milano, Department of Pathophysiology and Transplantation, Università degli Studi di Milano, Milan, Italy*
Email: alessandro.cherubini@policlinico.mi.it

Background and aims: Steatotic liver disease (SLD), including MASLD, is a global health burden that can progress to cirrhosis and hepatocellular carcinoma (HCC). Somatic mutations contribute to fibrosis and carcinogenesis, yet the interplay between somatic and germline factors remains unclear. We integrated somatic mutation analysis via targeted next-generation sequencing (NGS) with germline risk profiling in liver tissues and human liver organoids (HLOs) to elucidate SLD molecular trajectories.

Method: We analyzed liver and blood samples from 46 individuals: 25 SLD, 17 viral hepatitis (B/C), and 4 histologically normal controls. HLOs were successfully derived from 21 cases. A custom 75-gene panel (chromatin remodeling, cell cycle, lipid metabolism, hepatocarcinogenesis) was sequenced (Illumina NextSeq2000). Somatic variants were identified using Mutect2/Funcotator, filtering germline variants via matched blood. The MASLD polygenic risk score (PRS-5: PNPLA3–TM6SF2–GCKR–MBOAT7–HSD17B13) was genotyped for all subjects.

Results: We identified 195 somatic variants in non-tumoral tissues (60.8% of patients). Mutations in *FOXO1*, *RPS6KA3*, and *APOB* were frequent in SLD, while *SF3B1*, *LRP1B*, and *PTPN13* were enriched in viral hepatitis. One SLD patient exhibited a hypermutated phenotype (126 variants) linked to a germline *MLH1* mutation. HLOs harbored 92 somatic variants (85.7% of cases), showing distinct mutational signatures from matched tissues but similar overall burden. Mutations in chromatin remodeling genes (*ARID2*, *KMT2B/C/D*) were more frequent in HLOs, suggesting culture-induced selection. HCC samples showed recurrent *TERT*, *CTNNB1*, and *TP53* mutations. PRS-5 values were higher in SLD but without significant inter-group differences.

Conclusion: Our study reveals distinct somatic landscapes between SLD and viral hepatitis, identifying *FOXO1*, *RPS6KA3*, and *APOB* as key genes in metabolic injury. Despite shared germline backgrounds, HLOs exhibit unique mutational patterns reflecting in vitro clonal evolution. Integrating tissue and organoid sequencing provides novel insights into the synergy between inherited and acquired genetic alterations. This HLO biobank represents a valuable platform for precision medicine and mechanistic studies in SLD and HCC.

WED-077

External validation of a parsimonious machine learning model for detecting significant fibrosis in obese patients with metabolic dysfunction–associated steatotic liver disease (MASLD)

Ahmed Cordie[1,2,3], Ahmed Kamel[4], Rabab Omar[1], Essa Abdelaal[1], Mohamed Fahmy[5], Dina Helmy[6], Sherif Musa[1], Maria Stepanova[2], Gamal Esmat[1,4], Zobair M. Younossi[2,7]. *[1]Cairo University, Endemic Hepatogastroenterology and Infectious Diseases Department, Cairo, Egypt; [2]The Global NASH/MASH Council (GNC), Washington, DC, United States; [3]Cairo University Hospitals, HIV Clinic, Cairo, Egypt; [4]Cairo University, Clinical Pharmacy Department, Cairo, Egypt; [5]Cairo University, Department of General and Laparoscopic Surgery, Cairo, Egypt; [6]Cairo University, Department of Pathology, Cairo, Egypt; [7]Center for Outcomes Research in Liver Diseases, Washington, DC, USA, Washington, DC, United States*
Email: ahmed.cordie@cu.edu.eg

Background and aims: Although non-invasive tests (NITs) are widely used to risk-stratify patients with MASLD, their performance is suboptimal in individuals with obesity who are at high risk of advanced liver disease. Moreover, complex composite scores such as AGILE 3+ require multiple laboratory and clinical parameters, limiting their applicability in routine practice. We developed a parsimonious four-variable elastic net model and externally validated its performance in a large multinational cohort.

Method: The development cohort included 120 biopsy-proven MASH patients with BMI ≥35 kg/m^2 with available extensive clinical data. An elastic net model incorporating liver stiffness measurement (LSM), BMI, AST ratio, and age was developed using bootstrap resampling (1,000 iterations) with out-of-bag validation. Significant fibrosis (F≥2) was the primary outcome of the analysis. External validation was performed in 2,365 MASLD patients with BMI ≥35 kg/m^2 from the Global NASH/MASH Registry. Model performance at the development-derived threshold (0.29) was compared with established NITs including AGILE 3+, FAST, FIB-4, APRI, NFS, BARD, and LSM alone.

Results: In the development cohort, the elastic net model demonstrated good discrimination for significant fibrosis, achieving an AUC of 0.798 (95% CI 0.700–0.890) and outperforming other NITs, including FIB-4, FAST, and LSM alone. In the large external validation cohort (F≥2 prevalence 69%), the model retained robust performance with an AUC of 0.801 (95% CI 0.781–0.820). At the predefined probability threshold, sensitivity was 73.1% and specificity 73.8%, yielding a high positive predictive value (86.1%) and moderate negative predictive value (55.2%). Diagnostic performance was comparable to AGILE 3+ (AUC 0.822) despite the model requiring substantially fewer clinical and laboratory inputs. Importantly,

discrimination remained stable across subgroups defined by sex, diabetes status, age, and BMI, supporting the generalizability of the model in obese MASLD patients.
Conclusion: A parsimonious four-variable elastic net model showed robust external validation for detecting significant fibrosis in MASH patients with obesity, with performance comparable to more complex composite scores such as AGILE 3+. Its minimal data requirements enhance feasibility for routine clinical use and support its role in optimizing biopsy selection, particularly in resource-limited settings.

WED-078
Is the fatty liver index just measuring BMI? Evidence from NHANES and an HIV cohort
Ahmed Cordie[1], Ahmed Kamel[2], Rahma Mohamed[1], Gamal Esmat[3], Giada Sebastiani[4]. [1]*Cairo University Hospitals HIV Clinic, Endemic Medicine Department, Faculty of Medicine, Cairo University, Cairo, Egypt;* [2]*Clinical Pharmacy Department, Faculty of Pharmacy, Cairo University, Cairo, Egypt;* [3]*Endemic Medicine Department, Faculty of Medicine, Cairo University, Cairo, Egypt;* [4]*Department of Medicine, McGill University, Montreal, QC, Canada*
Email: ahmed.cordie@cu.edu.eg

Background and aims: The Fatty Liver Index (FLI) is widely used to screen for steatotic liver disease (SLD), yet both indices rely heavily on body mass index (BMI). Whether additional FLI components (waist circumference, triglycerides, gamma-glutamyl transferase [GGT]) provide incremental diagnostic value beyond BMI alone remains uncertain. In people living with HIV (PLWH), antiretroviral therapy (ART)-associated and metabolic alterations may further undermine the performance of anthropometric-based indices. We compared FLI performance in a general population cohort and in PLWH, testing whether FLI components add incremental value beyond BMI.
Method: We analysed 3,217 adults with controlled attenuation parameter (CAP) measurements from NHANES 2017–2018 (n = 2,556) and a cohort of PLWH from Egypt (n = 661). SLD was defined as CAP ≥248 dB/m. Diagnostic performance was assessed using the area under the receiver operating characteristic curve (AUC) for BMI alone and individual FLI components. Incremental discrimination beyond BMI was evaluated using DeLong tests, likelihood ratio tests, and net reclassification improvement (NRI). Subgroup analyses were performed across BMI categories (<25, 25–30, ≥30 kg/m^2).
Results: SLD prevalence was versus 28.0% in PLWH. Overall, FLI discrimination was acceptable in both populations (AUC 0.838, 95% CI 0.823–0.854 in NHANES; 0.780, 0.740–0.821 in PLWH), but BMI alone achieved comparable discrimination (0.800 and 0.778, respectively). In NHANES, FLI components provided modest but statistically significant incremental value beyond BMI (ΔAUC +0.039, p < 0.001; NRI 0.069, 95% CI 0.041–0.098). In contrast, no incremental value was observed in PLWH (ΔAUC +0.010, p = 0.320; NRI 0.054, 95% CI –0.002–0.104), and none of the individual FLI components improved discrimination beyond BMI (all p > 0.4). Across BMI strata, FLI performance declines substantially in normal-weight individuals, with AUCs of 0.752 in NHANES and 0.581 in PLWH. The standard FLI ≥60 threshold demonstrated very low sensitivity for lean SLD (NHANES 3.8%; PLWH 2.9%).
Conclusion: FLI provides limited incremental diagnostic value beyond BMI in the general population and no advantage in PLWH, suggesting that HIV- and ART-related metabolic alterations disrupt standard anthropometric–hepatic relationships. The standard FLI ≥60 threshold fails to identify over 95% of lean SLD cases regardless of population. In PLWH and lean individuals, direct hepatic assessment with transient elastography should be favoured over FLI-based screening.

WED-079
Evaluation of metabolic dysfunction-associated steatohepatitis in adults and children using ultrasound derived fat fraction and elastography with MRI proton density fat fraction and elastography as reference standard
Jean-Michel Correas[1], Anne-Marie Tissier[1], Yassin Labyed[2], Arati Gurung[2]. [1]*Necker University Hospital, Paris, France;* [2]*Siemens Healthineers, Issaquah, United States*
Email: jmc.correas@gmail.com

Background and aims: Metabolic dysfunction-associated steatotic liver disease (MASLD), the most common chronic liver disease worldwide, can progress to metabolic dysfunction-associated steatohepatitis (MASH), marked by hepatocellular inflammation and risk of fibrosis, cirrhosis, or hepatocellular carcinoma. Over half of individuals with MASLD and most with MASH are overweight or obese, with prevalence rising in children. The aim of the study was to evaluate the performance of ultrasound derived fat fraction (UDFF) and shear wave elastography (SWE) in routine clinical practice for assessment of MASH in adults and children using MRI proton density fat fraction (PDFF) and elastography (MRE) as the reference standards respectively.
Method: This was a prospective study approved by the Ethics Committee to enrol patients with suspected MASLD. Same-day MRI and ultrasound exams were performed. The diagnostic accuracy of UDFF for classifying PDFF-defined steatosis grades was assessed using the area under the receiver operating characteristic curve (AUC); PDFF thresholds were 6.4%, 17.4% and 22.1% for S1, S2 and S3 respectively for adults and 6.4%, 17.5% and 23.3% for children following the MASH Clinical Research Network guidance. The MRE threshold of 3.14 kPa was used for detecting significant fibrosis (F2).
Results: A total of 247 patients were enrolled. Nineteen patients had missing PDFF data; the final analysis for steatosis included 228 patients (90 adults, 138 children). The overall mean age was 16 years, with adults averaging 60 years and children 14 years. The mean BMI was higher in children (36 kg.m^{-2}) compared to adults (30 kg.m^{-2}, p < 0.001). The overall mean UDFF was 13% with a mean of 19% in adults and 7% in children (p < 0.001). The overall AUCs were 0.91 (0.85, 0.97), 0.94 (0.90, 0.98), and 0.89 (0.83, 0.95) for staging S1, S2 and S3 respectively; correlation coefficient between UDFF and PDFF was 0.81. Ninety-six patients had missing MRE data; the final analysis for fibrosis included 151 patients. The overall mean SWE was 3.60 kPa with a mean of 3.25 kPa in adults and 5.05 kPa in children (p < 0.001). The overall AUC was 0.90 (0.81, 0.98) for classifying F2 with a correlation coefficient of 0.76.
Conclusion: Both UDFF and SWE showed strong diagnostic accuracy for MRI-defined steatosis and fibrosis and can be seamlessly incorporated into routine liver ultrasound exams in adults and children, including those with severe obesity.

WED-083
Prevalence of elevated fibrosis-4 index in adults from primary care and associated clinical factors
Michele Montori[1], Martina Dalla Bella[1], Maria Ricci[1], Federica Carlino[1], Paolo Core[2], Paola Lodolini[2], Antonio Marracino[2], Massimiliano Luzi[2], Marco Angelo Danilo Giulioni[2], Guido Sanpaolo[2], Martina Zucchi[2], Annalisa Pini[2], Rachele De liberato[2], Manuela Zucchi[2], Alessia Di Giovannangelo[2], Andrea Lucarelli[2], Emanuele Fiorini[2], Gianluca Svegliati Baroni[1]. [1]*Azienda Ospedaliero-Universitaria delle Marche, Ancona, Italy;* [2]*ASUR (ASL) Marche, Ancona, Italy*
Email: michele.montori@ospedaliriuniti.marche.it

Background and aims: Non-invasive fibrosis scores such as the fibrosis-4 index (FIB-4) enable large-scale identification of individuals at risk for advanced liver disease using routinely available laboratory data. However, population-level estimates from unselected primary care settings remain limited, and clinical factors associated with abnormal FIB-4 values across commonly used

thresholds are incompletely characterized. This study aimed to estimate the prevalence of elevated FIB-4 in a general adult primary care population and to examine associated metabolic and clinical factors.

Method: Electronic general practitioners records were screened for adults with available laboratory data. Among 18,993 individuals, 12,124 adults aged 18–80 years without known chronic liver disease were included. Three cohorts were analysed: the overall population, adults aged 40–70 years, and a metabolically high-risk group defined by obesity, diabetes, or elevated transaminases. FIB-4 positivity was assessed using standard and age-adjusted thresholds. Associations with elevated FIB-4 were evaluated using multivariable logistic regression.

Results: In the overall population, 40.0% had FIB-4 >1.3 and 5.8% ≥2.67. Prevalence of FIB-4 ≥2.67 increased to 10.5% in the high-risk group and was lower among adults aged 40–70 years (2.2%) (all $p < 0.001$). Individuals with FIB-4 ≥2.67 showed a higher prevalence of diabetes (23.2% vs 12.1%) and elevated transaminases (20.8% vs 8.0%) compared with those with FIB-4 ≤1.3. Male sex was associated with a higher burden of metabolic risk factors, including obesity (6.3% vs 5.3%, $p < 0.01$) and diabetes (13.8% vs 10.5%, $p < 0.001$). In adjusted analyses, male sex and hypertension showed the strongest independent associations with FIB-4 ≥2.67 (adjusted odds ratio 1.86 and 2.35, respectively; both $p < 0.001$).

Conclusion: FIB-4 values compatible with advanced fibrosis are common in primary care, affecting nearly 6% of unselected adults and exceeding 10% in metabolically at-risk individuals. Male sex and hypertension were consistently associated with elevated FIB-4 values. These findings support opportunistic FIB-4 calculation from routine laboratory tests as a first-step triage strategy and highlight the need for structured pathways linking primary care to second-line fibrosis assessment.

WED-084

GRIPonMASH preliminary results: comparison of FIB-4 and MAF-5 as first-line tests to rule out advanced fibrosis in primary care

Schattenberg[17,18], Céline Fournier-Poizat[19], Jo Massoels[19], Oscar Franco[1], Diederick Grobbee[1,2], Manuel Castro Cabezas[2,4,5]. *[1]Julius Center for Health Sciences and Primary Care, UMC Utrecht, Utrecht, Netherlands; [2]Julius Clinical Research B.V., Zeist, Netherlands; [3]Amsterdam University Medical Centre, Amsterdam, Netherlands; [4]Franciscus Gasthuis & Vlietland, Rotterdam, Netherlands; [5]Erasmus MC Medical Center, Rotterdam, Netherlands; [6]Harokopio University of Athens, Athens, Greece; [7]Universidade de Lisboa, Lisbon, Portugal; [8]General University Hospital, Charles University, Prague, Czech Republic; [9]University Hospital Antwerp, Antwerp, Belgium; [10]Institute of Clinical Physiology, National Research Council, Pisa, Italy; [11]Fondazione Policlinico Universitario Agostino Gemelli IRCCS, Rome, Italy; [12]Università Cattolica del Sacro Cuore, Rome, Italy; [13]CUB Hôpital Erasme, Université Libre de Bruxelles, Brussels, Belgium; [14]Medical Education Research and Innovation Center s.r.l., Bucharest, Romania; [15]Sorbonne University, Paris, France; [16]Virgen del Rocio University Hospital, Seville, Spain; [17]Saarland University Medical Center, Homburg, Germany; [18]Saarland University, Homburg, Germany; [19]Echosens SA, Paris, France*
Email: v.d.dejong-5@umcutrecht.nl

Background and aims: International guidelines recommend 2-step pathways to screen for advanced fibrosis in populations at-risk, typically using the Fibrosis-4 index (FIB-4) followed by liver stiffness measurement (LSM) by VCTE. However, FIB-4's accuracy to (pre) screen in general populations remains debated. The Metabolic Dysfunction–Associated Fibrosis 5 (MAF-5) score was developed specifically for those populations. We aim to compare FIB-4 and MAF-5 as first-line tests to rule out advanced fibrosis, with LSM by VCTE as reference.

Method: GRIPonMASH is a prospective study, screening 10,000 high-risk individuals (T2DM, metabolic syndrome, obesity or arterial hypertension) without any prior other liver disease across 10 European countries. Rule-out cutoff for FIB-4 was <1.3 (or <2.0 if >65 years of age) and for MAF-5 <0. Participants <35 years of age were excluded, as FIB-4 is known to perform poorly in this group. Advanced fibrosis was ruled out if LSM <8.0 kPa. In this preliminary analysis descriptive statistics (median [IQR] or percentage) are reported. Negative predictive value (NPV) and sensitivity (SENS) of FIB-4/MAF-5 rule-out cutoff with LSM by VCTE as reference method were calculated. Results were also stratified by sex and primary diagnosis for inclusion (PDI).

Results: The preliminary cohort included 1050 participants recruited at primary care centers (75%) or through advertisement (25%). Median age was 60 [IQR: 13] years, BMI 31.0 [7.5] kg/m^2 and 53% was female. PDI was: 39% obesity, 36% arterial hypertension, 18% T2DM and 7% metabolic syndrome. Median LSM was 4.9 [2.0] kPa and 93% scored <8.0 kPa. Median FIB-4 was 1.2 [0.7] and MAF-5 0.8 [3.0]. Based on FIB-4, 25% of screened individuals would be referred to the 2nd test. NPV was 0.94 and sensitivity 0.38. Based on MAF-5, 65% would need the 2nd test, but this went up to 94% for PDI T2DM. NPV was 0.98 and SENS 0.92. Sex did not affect reported NPV/SENS. SENS of FIB-4 varied by PDI (0.21 to 0.67), for MAF-5 it remained stable, except for hypertension (drop to 0.78).

Conclusion: MAF-5 shows excellent NPV/SENS, at the cost of referring 65% to the 2nd test. NPV of FIB-4 is acceptably high with only 25% requiring a 2nd test, but SENS is substantially inferior (more false negatives). Presence of cardiometabolic diseases (PDI) influences SENS. Large-scale data is needed to optimize screening strategies.

GRIPonMASH is supported by Innovative Health Initiative Joint Undertaking, its members and its contributing partners under grant agreement No 101132946.

WED-085

Deep learning integration of nuclear magnetic resonance metabolomics and NASH-FibroTest biomarkers improves blood-based prediction of liver fat measured by magnetic resonance imaging

Olivier Deckmyn[1], Valentina Peta[1], Thierry Poynard[1,2]. *[1]BioPredictive, Paris, France; [2]Sorbonne University, Pitié Salpêtrière, ICAN, Paris, France*
Email: olivier.deckmyn@biopredictive.com

Background and aims: Magnetic resonance imaging proton density fat fraction (MRI-PDFF) is the reference for quantifying hepatic steatosis but is not suitable for large scale screening or longitudinal follow up. Nuclear magnetic resonance (NMR) metabolomics captures lipid signatures associated with hepatic fat accumulation, while Nash-FibroTest (NFT) biomarkers reflect liver injuries and metabolic dysfunction. We aimed to assess whether deep learning models combining NMR and available NFT biomarkers improve discrimination of PDFF-defined steatosis stages.

Method: Participants from the UK Biobank with available PDFF, NMR, and a subset of NFT markers (SteatoTest-2-proxy: ALT and AST transaminases, gamma-glutamyltranspeptidase, apolipoproteinA1, triglycerides, cholesterol, glycated hemoglobin, age, sex with R^2 = 0.91[%95 CI 0.88–0.92] vs original SteatoTest-2, n = 307) were included. High dimensional NMR data were reduced using unsupervised and supervised feature selection approaches. Multilayer perceptron models were trained using independent training, validation, and test sets. Model performance was evaluated using the area under the receiver operating characteristic curve (AUC) with 95 percent confidence intervals for clinically (%95CI) relevant liver fat thresholds.

Results: A total of 8,091 participants were analyzed. The combined 20 best NMR (dominated by HDL lipid composition and fatty acid profiles, including cholesteryl esters, phospholipids, PUFA/SFA ratios, and selected amino acids) and SteatoTest-2-proxy model demonstrated good discrimination across multiple PDFF-defined thresholds. AUC values were 0.766 (%95CI 0.733–0.800) for S0 vs S1A–S3, 0.766 (0.726–0.806) for S0–S1A vs S1B–S3, and 0.780 (0.668–0.872) for S0–S1B vs S2–S3. Severe steatosis discrimination (S0–S2 vs S3) was 0.884 (0.779–0.957), with limited reliability due to few S3 cases (n = 10). Performance was consistent across sex specific analyses.
Conclusion: Deep learning integration of NMR and available NFT biomarkers enables robust blood-based discrimination of PDFF-defined steatosis stages. This multimodal approach supports scalable and noninvasive assessment of steatosis severity in large populations with steatotic liver disease and warrants further validation in cohorts enriched for advanced steatosis.

WED-086
Low vitamin D levels are independently associated with increased fibrosis risk in metabolic dysfunction-associated steatotic liver disease

Youness Dendane[1], Mouhssine Benderrou[1], Ouiam Elmqaddem[1], Hajar Koulali[1], Abdelkrim Zazour[1], Zahi Ismaili[1], Ghizlane Kharrasse[1]. *[1]Department of Hepato-Gastroenterology, Mohammed VI University Hospital, Oujda, Morocco, Digestive Diseases Research Laboratory (LARMAD), Faculty of Medicine and Pharmacy, Mohammed First University, Oujda, Morocco, Oujda, Morocco*
Email: dendane.youness@gmail.com

Background and aims: Metabolic dysfunction-associated steatotic liver disease is a leading cause of chronic liver disease worldwide. Liver fibrosis is the main determinant of prognosis, yet simple markers for routine risk stratification remain limited. Vitamin D, at the intersection of metabolic and immune pathways, may reflect fibrotic severity. We aimed to evaluate the association between low vitamin D levels and increased fibrosis risk in metabolic dysfunction-associated steatotic liver disease.
Method: We conducted a retrospective single-centre study including 56 patients with metabolic dysfunction-associated steatotic liver disease followed between January 2020 and December 2024 with available serum vitamin D measurements. Data collected included age, sex, body mass index, diabetes, metabolic syndrome, liver tests, C-reactive protein, and albumin. Increased fibrosis risk was defined as FIB-4 ≥ 1.3. Vitamin D insufficiency was defined as < 30 ng/mL and severe deficiency as < 10 ng/mL. Associations were assessed using univariate and multivariable analyses adjusted for age, sex, body mass index, and metabolic parameters.
Results: Median age was 52 years, 56 percent were men, and median body mass index was 30 kg/m^2. Increased fibrosis risk (FIB-4 ≥ 1.3) was observed in 34 percent of patients. Vitamin D insufficiency was present in 62 percent, including 18 percent with severe deficiency. Median vitamin D levels were lower in patients with increased fibrosis risk than in those without (18 ng/mL [interquartile range 12–25] vs 25 ng/mL [interquartile range 19–32]; p = 0.03). Vitamin D insufficiency was more frequent in the fibrosis-risk group (71 percent vs 54 percent; p = 0.04). In multivariable analysis, vitamin D < 30 ng/mL remained independently associated with increased fibrosis risk (adjusted odds ratio 2.1; 95 percent confidence interval 1.0–4.5; p = 0.046).
Conclusion: Low vitamin D levels are common in metabolic dysfunction-associated steatotic liver disease and are independently associated with increased fibrosis risk. Vitamin D assessment may represent a simple and widely available complementary tool for fibrosis risk stratification. These findings should be confirmed in larger prospective cohorts.

WED-087
AI-derived macrophage density reveals hot and cold fibrosis endotypes with distinct biomarker profiles in metabolic dysfunction–associated steatohepatitis

Zoltan Derdak[1], Ying-Wooi Wan[1], Vandana Gupta[1], Lara Murray[2], Shima Nofallah[2], Guillaume Chhor[2], Kutbuddin Akbary[3], Dean Tai[3], Regina Lemus[1], Andressa de Zawadzki[4], Diana Julie Leeming[4], Morten Karsdal[4], Amon Asgharpour[5], Juan Pablo Arab[5], Haakan Wennbo[1], Arun J. Sanyal[5], Paresh Thakker[1]. *[1]Takeda Development Center Americas, Inc., Cambridge, MA, United States; [2]PathAI, Boston, MA, United States; [3]HistoIndex Pte Ltd, Singapore, Singapore; [4]Nordic Bioscience A/S, Herlev, Denmark; [5]Virginia Commonwealth University, Richmond, VA, United States*
Email: zoltan.derdak@takeda.com

Background and aims: In metabolic dysfunction-associated steatohepatitis (MASH), the biological activity driving fibrogenesis is heterogenous and not adequately represented by CRN fibrosis stage alone. We evaluated a hot vs cold fibrosis framework, defined by AI-measured macrophage density and linked to non-invasive tests (NITs), to identify biologically distinct endotypes and assess candidate NITs for patient selection in early clinical trials.
Method: Liver micro-architecture was quantified in 150 biopsy-confirmed MASH patients from the Stravitz-Sanyal Institute using LiverExplore* (PathAI, Boston, MA, *For Research Use Only. Not for use in diagnostic procedures) and by SHG/TPEF (Histoindex, Singapore) to assess the qFibrosis score. CRN Fibrosis was centrally staged. Hot fibrosis was defined as significant fibrosis by CRN staging (F ≥ 2) with macrophage density ≥ 250 cells/mm^2 by LiverExplore, and cold fibrosis as CRN F ≥ 2 with density < 250 cells/mm^2. Clinical variables and NITs were compared, including PRO-C3 (Roche Elecsys PRO-C3), CTX III, CTX III/PRO-C3 ratio, enhanced liver fibrosis (ELF) score, thrombospondin 2 (TSP2), and liver stiffness by vibration-controlled transient elastography (VCTE).
Results: The median qFibrosis score was 1.86 (IQR 1.27–3.07). Hot fibrosis accounted for 65% of cases and showed higher AST, ELF, PRO-C3, and TSP2 compared to cold fibrosis cases, while liver stiffness was similar. CTX III and CTX III/PRO-C3 ratios tended to be higher in cold fibrosis. NAS, steatosis, and ballooning did not differ, but hot fibrosis showed greater lobular inflammation. Within standard Phase 2b/3 MASH criteria (F ≥ 2; NAS ≥ 4 with ≥1 in each domain), tightening the lobular inflammation threshold from ≥ 1 to ≥ 2 substantially reduced the proportion of cold fibrosis cases, from ~ 50% to ~ 25%. High PRO-C3 (≥ 40 ng/mL) further enriched for hot fibrosis (88%; ~ 10% cold). Low PRO-C3 in cold fibrosis reflects low fibrogenic activity and limited capacity for further PRO-C3 decline.
Conclusion: Hot and cold fibrosis represent biologically distinct MASH endotypes. Elevated PRO-C3 enriches for active fibrogenesis, while cold fibrosis reflects a stable, low-fibrogenic state unlikely to respond to anti-fibrogenic therapies. Endotype- and biomarker-based enrichment may improve alignment between mechanism and therapeutic response in MASH trials.

WED-088
A simple PNPLA3–HSD17B13 genetic risk score predicts major adverse liver-related outcomes in high-risk MASLD

Luis Antonio Diaz[1], Kaleb Tesfai[1], Jonathan Dounel[1], Nikhil Kalita[1], Egbert Madamba[1], Seema Singh[1], Lisa Richards[1], Rohit Loomba[1], Veeral Ajmera[1]. *[1]University of California San Diego, La Jolla, United States*
Email: v1ajmera@health.ucsd.edu

Background and aims: MASLD with significant fibrosis is associated with major adverse liver-related outcomes (MALOs). However, there are limited data on the effect of genetic risk on MALOs across different baseline risk stages. Therefore, we aimed to evaluate the impact of genetic risk on MALOs according to baseline fibrosis risk determined by noninvasive tests (NITs).

Method: We prospectively enrolled adults with MASLD. All participants underwent a standardized research visit including magnetic resonance elastography (MRE), vibration-controlled transient elastography (VCTE), and genotyping for *PNPLA3* (rs738409) and *HSD17B13* (rs72613567). A genetic risk score (GRS) was made by summing the effect alleles of *PNPLA3* minus the protective *HSD17B13* variant and was dichotomized based on the median value into a high and low category. We defined three risk groups, including: "low risk": MRE < 3.0 kPa or VCTE < 8.0 kPa, "indeterminate risk": MRE 3.0–4.66 kPa or VCTE 8.0–11.9 kPa, and "high risk": MRE ≥ 4.67 kPa or VCTE ≥ 12.0 kPa. MALO was defined as hepatic decompensation or progression to cirrhosis. We performed Cox Regression models adjusted by age, sex, ethnicity, type 2 diabetes (T2D), body mass index (BMI), hypertension, dyslipidemia, and GRS.
Results: We included 1,125 participants (60.6% women; median [IQR] age was 59 [48–67] years; and 35.9% Hispanics). The median BMI was 30.2 [26.4–34.4] kg/m^2, and the prevalence of T2D was 53.9%. NITs identified 74.5% as low risk, 15.7% as indeterminate risk, and 9.8% as high risk for fibrosis. A total of 50.5% had a high GRS. Participants with a high GRS had a higher incidence of MALOs (19.0 vs. 6.2 events per 1,000 PY, p < 0.0001). In adjusted models, age (HR 1.05; 95% CI: 1.03–1.08, p < 0.0001), Hispanic ethnicity (HR 1.92; 95% CI: 1.13–3.26, p = 0.016), hypertension (HR 1.80; 95% CI: 1.01–3.18, p = 0.045), and high GRS (HR 2.49; 95% CI: 1.36–4.57, p = 0.003) were significant predictors of MALO. Within the low-risk category, high GRS was not associated with MALO (HR 0.78; 95% CI: 0.16–3.82, p = 0.756). However, among participants in the indeterminate or high fibrosis risk group, high GRS was associated with a higher risk of MALOs (HR 2.24; 95% CI: 1.14–4.40, p = 0.019).
Conclusion: After NIT-based risk stratification, a simple GRS was a significant predictor of MALOs in those with indeterminate or high fibrosis risk groups. Our findings support the use of genetic testing to further refine risk stratification, particularly in individuals with significant fibrosis identified by NITs.

WED-089
Optimizing prescreening for VCTE-LSM ≥8 kPa to support treatment eligibility in metabolic dysfunction–associated steatohepatitis

Email: aleksander.krag@rsyd.dk

Background and aims: Access to vibration-controlled transient elastography (VCTE) remains limited, yet current guidance for resmetirom and semaglutide in metabolic dysfunction–associated steatohepatitis (MASH) relies on liver stiffness measurement (LSM) ≥ 8 kPa to identify significant fibrosis. Efficient pre-screening using non-invasive tests (NITs) is therefore essential to prioritize patients for LSM. We evaluated the diagnostic performance and clinical utility of a laboratory-based machine-learning NIT to identify individuals with LSM ≥ 8 kPa in a large population-based cohort.
Method: Invitations to the Danish cohort were sent to randomly selected private electronic mailboxes and organized in two recruitment tracks: 1) unselected: invited regardless of risk factors, 2) at-risk: invited to participate if they had metabolic or alcohol risk factors. Participants were eligible for inclusion if they were aged 30–75 years, had no known chronic liver disease, cancer, or other diseases with an expected survival of less than one year. Participants underwent same-day assessment including VCTE, blood sampling, and anthropometry measurements among others. The diagnostic performance of the ALADDIN-F2-Lab model, CORE score, FIB-4, LiverRisk score (LRS), and SAFE to identify LSM ≥ 8 kPa was compared by area under the receiver operating characteristic curve (AUC), sensitivity at fixed 20% referral, and referrals to reach 80% sensitivity in the total Danish cohort.
Results: The total Danish cohort (n = 6,407) had a median age of 57, 48% male, 9% with type 2 diabetes, 42.5% obese, and 6.2% with LSM>8 kPa. The AUCs (95% CI) for predicting significant fibrosis were for ALADDIN 0.815 (0.793–0.838), LRS 0.812 (0.787–0.837), CORE 0.793 (0.767–0.819), SAFE 0.789 (0.763–0.814), and FIB-4 0.633 (0.600–0.666). When limiting referral rates to 20%, the sensitivities were for: 64.6%, LRS: 62.6%, SAFE: 60.3%, CORE: 59.5%, and FIB-4: 39.7%. Reaching 80% sensitivity required referral rates of 37% (ALADDIN), 38% (LRS), 42% (CORE), 43% (SAFE), and 74% (FIB-4).
Conclusion: In a population-based cohort, routine laboratory-based machine-learning NITs accurately identified individuals with LSM ≥8 kPa, outperforming FIB-4 while reducing unnecessary referrals. Given the limited availability of VCTE and the central role of LSM ≥8 kPa in determining eligibility for MASH therapies, effective pre-screening is critical. Implementing routine laboratory-based machine-learning NITs may improve access to treatment and streamline referral pathways.

WED-090
Imaging of liver fibrogenesis in MASH by PDGFR-beta position emission tomography

Olof Eriksson[1,2], Johan Vessby[3], Fredrik Rorsman[3], Talakad G. Lohith[4], Cyrille Sur[4], Zoltan Derdak[4], Yoann Petibon[4], Thuy Tran[5], Lennart Nedar[5], Per Hagmar[2], Martin Schain[6], Bogdan Mitran[2], Ayman Abouzayed[2], Edvin Johansson[6], Olle Korsgren[1], Lars Johansson[6], Haakan Wennbo[4]. *[1]Uppsala Universitet, Antaros Tracer AB, Uppsala, Sweden; [2]Antaros Tracer AB, Göteborg, Sweden; [3]Akademiska Sjukhuset, Uppsala, Sweden; [4]Takeda Development Center Americas, Cambridge, United States; [5]Karolinska Inst, Solna, Sweden; [6]Antaros Medical AB, Mölndal, Sweden*
Email: olof.eriksson@ilk.uu.se

Background and aims: Existing imaging methods based on elastography assess fibrosis but not active fibrogenesis in liver. Platelet Derived Growth Factor Receptor beta (PDGFRb) is upregulated in activated hepatic stellate cells and therefore could be a marker of fibrogenesis. [^{68}Ga]Ga-ATH001 is a Positron Emission Tomography (PET) tracer targeting PDGFRb for longitudinal, non-invasive quantification of active fibrosis in liver. Here, we present the performance and reproducibility of [^{68}Ga]Ga-ATH001 in a First-in-Human study in subjects with Metabolic dysfunction-associated Steatohepatitis (MASH).

Method: Study cohorts recruited were healthy subjects without history of liver disease (n = 6) and subjects diagnosed with MASH (n = 6, plasma Pro-C3 ≥12.6 ng/mL indicating active fibrosis). Subjects were administered 2.0–2.5 MBq/kg [^{68}Ga]Ga-ATH001 (corresponding to <1 µg/kg peptide mass) and examined by PET/ Magnetic Resonance Imaging (MRI) for up to 3 hours. Liver assessments also included Magnetic Resonance Elastography (MRE), Proton Density Fat Fraction (PDFF) and Transient Elastography (TE, FibroScan). A subset of subjects (n = 2 healthy and n = 3 MASH subjects) were re-scanned by [^{68}Ga]Ga-ATH001 PET/MRI within 2 weeks to assess test-retest reproducibility. Uptake in liver and other major tissues was reported as Standardized Uptake Values (SUVs). Liver SUV was corrected for fat fraction.
Results: No adverse events related to administration of [^{68}Ga]Ga-ATH001 was observed. Fat fraction was higher in the MASH cohort than healthy controls (19.1 ± 6.9% (mean ± SD) vs 4.1 ± 5.5% in healthy controls, $p < 0.01$). Liver stiffness as assessed by MRE was also higher in the MASH cohort than healthy controls (2.7 ± 0.5 kPa vs 2.1 ± 0.3 kPa, $p < 0.05$). TE values were 8.6 ± 1.7 kPa in the MASH cohort. [^{68}Ga]Ga-ATH001 exhibited fast biodistribution and rapid clearance from circulation and most tissues. PET uptake in liver 2 h post-injection was almost twice as high in subjects with MASH compared to healthy (SUV_{mean} = 5.7 ± 1.0 vs 3.2 ± 0.6, $p < 0.001$). High uptake was also observed in PDGFRβ avid spleen while excretion was almost completely mediated by kidney. [^{68}Ga]Ga-ATH001 uptake in liver demonstrated a percent coefficient of variation (%CV) of 3.3%.
Conclusion: [^{68}Ga]Ga-ATH001 is a novel PDGFRβ-targeting PET tracer for non-invasive assessment of active liver fibrosis. [^{68}Ga]Ga-ATH001 demonstrates strong liver uptake in MASH patients with active fibrosis, combined with excellent test-retest reproducibility.

WED-091
A new definition of burning-out MASLD using albumin and amino acid imbalance
Hideki Fujii[1], Sawako Uchida-Kobayashi[1]. [1]*Graduate School of Medicine, Osaka Metropolitan University, Osaka, Japan*
Email: sawako@omu.ac.jp

Background and aims: Li et al. recently described the phenomenon of progressive fibrosis accompanied by hepatic fat loss in MASLD as "burning-out," characterized by a downward trend in the controlled attenuation parameter (CAP) and an upward trend in liver stiffness measurement (LSM) via vibration-controlled transient elastography (VCTE) (PMID: 40113099). We hypothesized that this transition is associated with an amino acid imbalance, even in the presence of normal serum albumin (Alb) levels. This study aimed to characterize "burning-out MASLD" based on serum branched-chain amino acid to tyrosine ratio (BTR) and albumin, and to assess its clinical and non-invasive features.
Method: In this cross-sectional study, we analyzed 214 MASLD patients who underwent VCTE. Amino acid imbalance was assessed using BTR. Patients were stratified into three groups:
- Control group: BTR ≥ median and Alb ≥ 4.0 g/dL
- Burning-out group: BTR < median and Alb ≥ 4.0 g/dL
- Burned-out group: BTR < median and Alb < 4.0 g/dL

Patients not fitting these categories were excluded from further analysis. We compared clinical parameters, particularly LSM and CAP, among the three groups. Group differences were evaluated using one-way ANOVA followed by Dunnett's post hoc test with the burning-out group as the reference.
Results: Among 214 patients (median age 61 [IQR 53–70.3] years; 44% male; median BMI 26.8 [23.8–30.1] kg/m^2), the median Alb was 4.3 g/dL and BTR 6.4. Type 2 diabetes and hypertension were present in 36% and 47%, respectively. Seventeen patients were excluded based on the stratification criteria. Among the remaining patients, 92 were assigned to the control group, 72 to the burning-out group, and 33 to the burned-out group. Mean LSM, CAP, and FAST score in the control group were 6.9 kPa, 289 dB/m, and 0.29, respectively. Compared with the burning-out group, the burned-out group exhibited significantly higher LSM (20.7 vs. 7.8 kPa, $p < 0.001$), lower CAP (253 vs. 280 dB/m, $p = 0.047$), and higher FAST score (0.73 vs. 0.38, $p < 0.001$).
Conclusion: Our findings suggest that "burning-out MASLD" may represent a distinct transitional phenotype characterized by preserved hepatic fat content despite the onset of metabolic dysfunction. BTR may serve as a non-invasive biomarker to identify patients in this intermediate stage, enabling earlier intervention before progression to advanced fibrosis.

WED-092-YI
Implementation of enhanced liver fibrosis testing in type 2 diabetes to improve detection of at-risk metabolic dysfunction-associated steatohepatitis to optimize hepatology referrals: a duke health analysis
Maison Furley[1], Tom Kaminski[2], Zach Wolf[2], Artem Boltyenkov[3], Amreen Dinani[1]. [1]*Duke University Hospital, Durham, United States;* [2]*Clinetic, Durham, United States;* [3]*Siemens Healthcare Diagnostics, Mishawaka, United States*
Email: maison.furley@duke.edu

Background and aims: Type 2 diabetes (T2D) is accepted as a high-risk population to develop metabolic dysfunction-associated steatotic liver disease (MASLD), metabolic dysfunction-associated steatohepatitis (MASH), and advanced fibrosis. Screening for at-risk MASH in T2D remains low despite consensus guidance recommending a two-step approach starting with Fibrosis-4 (FIB-4) followed by a second-line test for indeterminate results. Enhanced Liver Fibrosis (ELF) test is a blood-based test that can be employed as a second-line test, but its real-world performance in endocrinology settings is not well described. The aim of this study was to evaluate the use of ELF test in endocrinology clinics at the Duke University Health System (DUHS) and assess the impact on fibrosis risk detection and hepatology referrals.
Method: This retrospective observational study (09/2024 to 11/2025) examined the use of the ELF test by endocrinology during routine care of patients with T2D. ELF testing was piloted in select endocrine clinics. All tests were tracked, and results were categorized using a threshold ≥ 9.8, indicative of significant fibrosis risk. Hepatology referrals and completed hepatology visits were recorded. Using these data alongside historical data for the broader adult T2D Duke University Health System (DUHS) population, we projected the impact of implementing this care pathway across the entire DUHS.
Results: On an annualized basis, DUHS endocrinologists saw 1,113 T2D patients with a FIB-4 > 2.67 and 2,965 T2D patients with a FIB-4 ≥ 1.3 and < 2.67 of which 25.3% and 13.0% had a subsequent hepatology visit, respectively. Over the study period, 64 patients with T2D underwent ELF testing. Thirty patients (46.9%) had ELF > 9.8; all were referred, and 70.0% completed the visit. Implementation of a two-step risk assessment protocol could increase hepatology visits by 1,085 (162.9%) per year. For patients with indeterminate FIB-4 results, ELF test was projected to reduce unnecessary referrals by 205 (53.1%) among individuals expected to have low ELF scores and increase appropriate hepatology visits by 792 (438.9%), among those with elevated ELF scores.
Conclusion: System-wide adoption of a two-step fibrosis assessment pathway (FIB-4 followed by ELF) has the potential to significantly increase early detection of *at*-risk MASH while reducing unnecessary specialist utilization. Given the large projected increase in hepatology visits, the topic of how to optimize implementation warrants further research and discussion.

WED-093-YI

Cardiometabolic risk factor burden predicts longitudinal liver stiffness trajectories in metabolic dysfunction-associated steatotic liver disease-related compensated advanced chronic liver disease

Zouhir Gadi[1,2], Lotte Schoenmakers[1,2], Wilhelmus J Kwanten[1,2], Luisa Vonghia[1,2], Sven Francque[1,2]. *[1]Department of Gastroenterology and Hepatology, Antwerp University Hospital, Edegem, Belgium; [2]Laboratory of Experimental Medicine and Pediatrics, Faculty of Medicine and Health Care Sciences, University of Antwerp, Edegem, Belgium*
Email: Zouhir.Gadi@student.uantwerpen.be

Background and aims: Cardiometabolic risk factors (CMRFs) linked to metabolic dysfunction–associated steatotic liver disease (MASLD) include overweight/obesity, impaired glucose metabolism, hypertension, hypertriglyceridaemia, and low high-density lipoprotein cholesterol. In MASLD-related compensated advanced chronic liver disease (cACLD), the cumulative impact of CMRF burden on longitudinal liver stiffness, a key non-invasive monitoring marker, remains poorly defined.
Method: We included 93 adults with biopsy-proven MASLD and cACLD (F3–F4 fibrosis) who had at least two Vibration-Controlled Transient Elastography (VCTE) liver stiffness measurements (LSMs) approximately one year apart, with paired biochemical assessment. Baseline LSM was defined at cACLD diagnosis and follow-up LSM as the most recent measurement, only first and last LSMs were analysed. Exclusion criteria included other chronic liver diseases, metabolic alcohol-related liver disease, bariatric surgery, baseline decompensation, or liver transplantation. CMRFs (range 1–5) were recorded at baseline. LSM trajectories were categorised as improved (≥20% decrease), stable (−20% to +20%), or worsened (≥20% increase). Clinical outcomes included incident hepatic decompensation events, defined as ascites, variceal bleeding, hepatic encephalopathy, or development of oesophageal varices, and all-cause mortality.
Results: The cohort comprised 55 men (59%) and 38 women (41%), 62 patients (67%) had F3 and 31 (33%) F4 fibrosis. CMRF burden was 1 in 2 patients (2.2%), 2 in 13 (14.0%), 3 in 32 (34.4%), 4 in 27 (29.0%), and 5 in 19 (20.4%), 84% had ≥3 CMRFs. Median interval between LSMs was 72 weeks (IQR 46.5). Baseline LSM increased with CMRF burden (15.44–17.85 kPa in 1–3 CMRFs vs. 21.08–21.98 kPa in 4–5). AST, ALT, and GGT levels similarly worsened with higher CMRF load. Mean LSM change ranged from −38.9% in 1 CMRF to +19.5% in 3 CMRFs, with minimal change in 5 CMRFs. Overall, 39% improved, 34% remained stable, and 27% worsened, with progression most frequent in the 3- and 5-CMRF groups. Over a median 4.3-year follow-up, ascites and non-bleeding oesophageal varices occurred in 5.4% each. All-cause mortality was 7.5%, exclusively in patients with ≥3 CMRFs, accompanied by marked LSM progression.
Conclusion: In MASLD-related cACLD, CMRF burden stratifies liver stiffness trajectories. Lower metabolic burden is linked to LSM improvement, while three or more CMRFs increase progression risk, supporting systematic cardiometabolic assessment and targeted care.

WED-094

Contrast-enhanced ultrasound in metabolic dysfunction-associated steatotic liver disease: towards a non-invasive marker of histological disease activity

Zouhir Gadi[1,2], Wilhelmus J Kwanten[1,2], Ann Driessen[3], Thomas Vanwolleghem[1], Sven Francque[1,2], Luisa Vonghia[1,2]. *[1]Department of Gastroenterology and Hepatology, Antwerp University Hospital, Edegem, Belgium; [2]Laboratory of Experimental Medicine and Pediatrics, Faculty of Medicine and Health Care Sciences, University of Antwerp, Edegem, Belgium; [3]Department of Pathology, Antwerp University Hospital, Edegem, Belgium*
Email: Zouhir.Gadi@student.uantwerpen.be

Background and aims: Microvascular dysfunction plays a key role in metabolic dysfunction-associated steatotic liver disease (MASLD). Time-intensity curve (TIC) analysis from contrast-enhanced ultrasound (CEUS) quantifies hepatic (micro)vascular perfusion and may provide a non-invasive marker of disease severity. This study evaluated whether TIC parameters reflect MASLD severity and diagnostic accuracy.
Method: Patients undergoing liver biopsy for MASLD were prospectively included after informed consent and underwent CEUS with TIC analysis of eleven perfusion parameters on the same day, in the fasting state. Histology assessed steatosis, ballooning, inflammation, activity, fibrosis stage (F), presence of metabolic dysfunction-associated steatohepatitis (MASH) and at-risk MASH, defined as MASH with fibrosis stages F2-F3. Conventional ultrasound (US) Doppler, liver stiffness measurement (LSM), controlled attenuation parameter (CAP) and spleen stiffness measurement (SSM) were performed, and hepatic venous pressure gradient (HVPG) data were available in a subset.
Results: Sixty-eight patients with adequate biopsy and CEUS data were included (61 MASLD, 7 controls); 30 MASLD patients had MASH. Fibrosis stages were F0 (n = 15), F1 (n = 14), F2 (n = 17), F3 (n = 8), and F4 (n = 14), defining controls (n = 7), low-risk MASLD F0–1 (n = 18), at-risk MASH F2–3 (n = 19), and MASLD cirrhosis F4 (n = 14). TIC parameters correlated with histology. Steatosis grade correlated negatively with MGrad (rho = –0.438), Grad (rho = –0.255), AUC (rho = –0.473), and WOAUC (rho = –0.436), with similar associations for US steatosis and CAP. Ballooning correlated positively with WIAUC (rho = 0.262), while inflammation and activity correlated negatively with WOAUC (rho = – 0.334 and – 0.302). Fibrosis correlated positively with WIAUC (rho = 0.404), TTOP (rho = 0.326), and TWR (rho = 0.320), and negatively with Grad (rho = –0.278). LSM correlated negatively with perfusion intensity (rho = –0.300) and positively with WIAUC (rho = 0.287); no associations were observed with SSM, Doppler, or HVPG (rho = 0.348). WIAUC was higher in MASH than non-MASH MASLD (median 733.0 vs. 675.8 AU). Across disease stages, WIAUC increased with delayed TTOP and increased TWR. Diagnostic performance was fair for MASH (AUC 0.655) and comparable for significant fibrosis using WIAUC, TTOP, and TWR (AUC 0.728–0.737).
Conclusion: TIC-derived parameters correlated with MASLD severity and progressive microvascular impairment in advancing MASH, supporting CEUS as a non-invasive adjunct.

WED-095

FIB-4 in clinical laboratory data: reporting and feasibility evaluation in Germany

Thomas Jensen[1], Andres Garcia[1], Elena Kisseleff[1], Anna Stuermlinger[1], Anna Rubinski[2], Livia Woeller[2], Stephan Koelsch[1], Philipp Hessenberger[2]. *[1]Boehringer Ingelheim Pharma GmbH & Co. KG, Ingelheim, Germany; [2]Health Data Technologies GmbH, Neckarsulm, Germany*
Email: thomas.jensen@boehringer-ingelheim.com

Background and aims: MASLD affects an estimated 30% of adults globally and between 10% and 30% of these individuals will progress to MASH[1,2]. Both conditions remain underdiagnosed and expert consensus underscores the necessity to increase diagnostic rates[3]. Clinical guidelines recommend the FIB-4 score as initial step for screening and diagnosis. This project had two objectives: 1. quantify current utilisation of FIB-4 scores; 2. assess availability of laboratory parameters necessary for FIB-4 score calculation (age, ALT, AST, platelet count).
Method: We performed a retrospective observational study using data from a Bavarian laboratory network. Time frame of observation was January 2022 to December 2024. Inclusion criteria comprised adult patients belonging to predefined MASLD/MASH risk groups in line with current EASL guidelines. Cardiometabolic risk factors were defined according to EASL–EASD–EASO guidelines. To quantify utilisation of FIB-4 (objective 1), all laboratory records containing a reported FIB-4 score were identified and counted. We then assessed

whether parameters required for Fib-4 calculation were available (objective 2). Analysis was performed exclusively on pseudonymised datasets, all outputs were anonymised prior to reporting.
Results: Of the 1.4 million patients in the database, 521,084 met all predefined eligibility criteria. Calculation of FIB-4 scores was rarely performed, with frequencies from 0.11% to 0.75% across risk cohorts. For example, only 0.15% of patients with diabetes had a FIB-4 score reported. However, a substantial proportion of reports had necessary laboratory parameters, enabling FIB-4 score calculation. Availability of laboratory parameters required for FIB-4 score calculation was 61.4% in the diabetes cohort, 70.7% in the prediabetes cohort, 66.5% in the dyslipidaemia cohort, and exceeded 98% in various combined-risk cohorts, such as prediabetes plus abnormal ALT/AST and diabetes plus dyslipidaemia.
Conclusion: Although FIB-4 score is recommended as primary screening tool for MASH in all major guidelines, this investigation demonstrates that the proportion of at-risk patients for whom FIB-4 score calculation is performed remains extremely low. Given the high availability of laboratory parameters, clinical laboratories are positioned to automate FIB-4 calculation. Furthermore, implementation of educational initiatives for healthcare professionals is essential to promote the use of FIB-4 in order to enhance identification of at-risk individuals.

Parallel combination of FIB-4 and enhanced liver fibrosis test improves prognostication in metabolic dysfunction-associated steatohepatitis
Matthew Gee[1,2], Rachel Fonstad[2], Jordan J. Feld[1,3], Keyur Patel[1,3], Arun J. Sanyal[4]. *[1]Institute of Medical Science, Temerty Faculty of Medicine, University of Toronto, Toronto, Canada; [2]Siemens Healthineers, Tarrytown, United States; [3]Division of Gastroenterology, Department of Medicine, Toronto Centre for Liver Disease, Toronto General Hospital, University Health Network, Toronto, Canada; [4]Stravitz-Sanyal Institute for Liver Disease and Metabolic Health, Division of Gastroenterology, Hepatology and Nutrition, Virginia Commonwealth University School of Medicine, Richmond, United States*
Email: matthew.gee@siemens-healthineers.com

Background and aims: Metabolic dysfunction-associated steatohepatitis (MASH) is a leading cause of cirrhosis and liver-related mortality. Clinical practice guidance from EASL and other societies recommend sequential measurement by non-invasive tests (NITs) to identify patients most at risk of progressing to liver-related events (LREs). These risk-assessment pathways typically begin with FIB-4 and are followed by either vibration-controlled transient elastography (VCTE) or Enhanced Liver Fibrosis (ELF). We aimed to determine whether parallel measurement of FIB-4 and ELF improves risk stratification in patients with MASH and advanced fibrosis.
Method: Data were pooled from 5 large placebo-controlled trials in patients with MASH and advanced fibrosis (NCT01672866, NCT01672879, NCT02462967, NCT03053050, NCT03053063), excluding patients without ELF or FIB-4 at baseline. Patients were organized in a 3 × 4 heatmap based on previously determined cutoffs for FIB-4 (1.30, 3.48) and ELF (9.00, 11.30, 12.80). Liver-related events (LREs) were a composite endpoint of clinical manifestations of decompensation, (qualification for) transplant, and liver-related death, based on the first event per patient. LRE risk (%), LREs per 1000 years of patient follow-up (LRE/1000 PY), and Cox proportional hazard ratio (HR) were calculated with 95% confidence intervals. Time-dependent area under the receiver operating characteristic curve (AUC(t)) and net reclassification improvement (NRI) analyses were also performed.
Results: 113 of 2276 study participants had LREs during the follow-up period (median: 15.9 months). There was a progressive increase in LRE risk with increasing ELF score in each FIB-4 risk category, and vice versa. The combined FIB-4 + ELF heatmap identified 5 strata that were differentiated in terms of LRE risk (0.4%, 2%, 9%, 16%, 40%). Similar trends were seen for LRE/1000PY and Cox HR. NRI for the FIB-4 + ELF model vs FIB-4 alone was 0.44 (95% CI: 0.34, 0.54). 92 more of the 2163 (4%) non-LRE patients were correctly assigned as low risk and 65/113 (58%) patients with LREs were reclassified upwards. The AUC (t) for the combined model was significantly different ($p < 0.05$) than FIB-4 alone at timepoints after 3 months.
Conclusion: The parallel measurement of FIB-4 and ELF improves prognostic performance over that of the individual tests and offers a pragmatic option to facilitate prognostic clinical decision making in patients with MASLD/MASH, especially in settings where imaging elastography is not readily available.

WED-100-YI
A novel machine learning-based algorithm improves risk stratification of patients with MASLD compared to FIB-4
Kamela Gjini[1,2], Mirko Zoncapè[3,4], Antonio Liguori[5], Katrine Lindvig[6], Maja Thiele[7], Emmanuel Tsochatzis[2]. *[1]Division of Gastroenterology and Hepatology, Department of Medical Sciences, University of Turin, Turin, Italy; [2]Sheila Sherlock Liver Unit, Royal Free Hospital, London, UK, UCL Institute for Liver and Digestive Health, University College, London, United Kingdom; [3]Liver Unit, University of Verona and Azienda Ospedaliera Universitaria Integrata of Verona, Verona, Italy; [4]Clinica Medica 3, Azienda Ospedale Università di Padova, Padova, Italy; [5]Medical and Surgical Sciences Department, Fondazione Policlinico Universitario A. Email: kamelagjini@gmail.com

Background and aims: Metabolic dysfunction-associated steatotic liver disease (MASLD) is the leading cause of chronic liver disease worldwide. Early identification of advanced fibrosis (≥F3) is essential, as fibrosis stage is the strongest predictor of liver-related outcomes and mortality. Current guidelines recommend FIB-4 as the first-line test in primary care; however, its limitations highlight the need for more reliable tools. LiverPRO, a machine learning-based software using routine laboratory variables, has been proposed as an alternative. We aimed to compare the performance of LiverPRO F3 and FIB-4 for first-line risk stratification of advanced fibrosis in patients with MASLD.
Method: We conducted a retrospective cross-sectional study of 1818 consecutive MASLD patients referred to the hepatology clinic of the Royal Free Hospital, London (2016–2024). Two parallel referral pathways were constructed on the same cohort, using either FIB-4 or LiverPRO F3 as the first-line test for advanced fibrosis. Patients were stratified into low- intermediate- and high-risk categories using predefined thresholds (FIB-4: <1.3 low risk, >2.67 high risk; LiverPRO F3: <5% low risk, >15% high risk). Diagnostic performance of both pathways was assessed against a composite reference standard for advanced fibrosis, defined as either: histological stage ≥F3; liver stiffness >12 kPa; or liver stiffness >8 kPa + ELF score > 9.8. Net reclassification improvement (NRI) was used to assess the added value of LiverPRO vs. FIB-4. In addition, the performance of LiverPRO was validated against vibration-controlled transient elastography and liver biopsy.
Results: Among 1703 patients with valid reference standards, 389 (23%) had advanced fibrosis. Using FIB-4, 695 patients (41%) were classified as indeterminate, and 108/871 patients (13%) in the low-risk group had advanced fibrosis. LiverPRO F3 model identified 206 (12%) patients with advanced fibrosis at the high-risk threshold versus 78 (5%) with FIB-4 ($p < 0.0001$), reduced the number of missed cases in the low-risk group to 50/663 (8%) vs. 108/871 (13%) with FIB-4 ($p = 0.001$), and decreased the number of patients in the indeterminate-risk category to 606 (36%) vs. 695 (41%) ($p = 0.002$). Overall, LiverPRO F3 achieved a NRI of 0.21 compared with FIB-4.

Conclusion: In this large real-world MASLD cohort, LiverPRO F3 significantly improved first-line risk stratification of advanced fibrosis compared with FIB-4, reducing false negatives and identifying more patients with advanced fibrosis.

Email: igraupe@clinic.cat

Background and aims: Metabolic dysfunction–associated steatotic liver disease(MASLD) is the leading cause of liver disease worldwide, and its prevalence is expected to increase with the growing burden of cardiometabolic risk factors (CMRFs). However, population-based epidemiological data using controlled attenuation parameter(CAP), a validated noninvasive measure of hepatic steatosis, remain limited. Our aims were to assess the prevalence of MASLD in the general population using CAP for steatosis diagnosis, to determine the prevalence of confirmed chronic liver disease (CLD) among individuals with MASLD, and to evaluate the contribution of individual cardiometabolic criteria to CLD.
Method: Individuals aged ≥40 years enrolled in the population-based LiverScreen cohort with clinical and laboratory assessment and VCTE with LSM and CAP. Participants with LSM ≥8 kPa and/or alanine aminotransferase ≥1.5 × the upper limit of normal were referred for hepatology consultation. MASLD was defined as CAP ≥275 dB/m in the presence of ≥1 CMRF. Primary outcomes were the overall prevalence of MASLD and the prevalence of confirmed CLD among individuals with MASLD (defined by histologically fibrosis≥F1 and/or LSM≥10 kPa and/or ultrasound signs of advanced liver disease).
Results: Among 30,199 participants, 8,401 (28%) met MASLD criteria (mean age 59 years; 48% women; median CAP 307 [IQR 46]dB/m). The prevalence of CMRFs were overweight/obesity (96%), hypertension (82%), prediabetes/diabetes (53%), hypertriglyceridemia (53%), and low HDL cholesterol (42%); 31% had ≥2 CMRFs. LSM and CAP increased progressively with the number of CMRFs (LSM: 4.4, 4.7, 5.0, 5.2, 5.6 kPa; CAP: 296, 300, 307, 312, 320 dB/m for 1–5 CMRFs, respectively). LSM ≥8 kPa was observed in 8.0% of individuals with MASLD versus 2.6% without MASLD; LSM ≥10 kPa and ≥15 kPa were present in 4.3% and 1.2%, respectively. Among MASLD participants referred for hepatology consultation, CLD was confirmed in 263(39%), with 71% histologically confirmed. CLD prevalence increased from 21% in those with one CMRF to 55% in those with five. Type 2 diabetes was the only CMRF independently associated with confirmed CLD (OR 2.6, 95%CI 1.7–4.1).
Conclusion: MASLD affects nearly one-third of the European general population aged ≥40 years and is associated with a substantial burden of confirmed CLD. The severity of hepatic steatosis and liver fibrosis increases with the number of cardiometabolic risk factors, with type 2 diabetes conferring the highest risk of CLD.

Email: anna.alisi@opbg.net

Background and aims: Children and adults with metabolically dysfunction-associated steatotic liver disease (MASLD) are at

increased risk of adverse liver-related health outcomes, and its severe form of steatohepatitis (MASH) promises to be the leading cause of transplants in the future. Liver biopsy remains the diagnostic standard for MASH, making the search for reliable non-invasive biomarkers urgent. An influx of proinflammatory cells, necrotic hepatocyte death, and fibrosis characterise MASH at the tissue level, and liquid biopsy, particularly through the analysis of cell death and epigenetic signs in circulation, could offer a panel of non-invasive biomarkers. This study aimed to identify a panel of biochemical and epigenetic markers that may reflect the MASH phenotype.

Method: A total of 150 children and 126 adults with biopsy-proven MASLD were included in the study. Plasma samples collected from patients were used to investigate epigenetic markers, including the amount and fragment size of cell-free (cf)DNA, and levels of cf-mitochondrial DNA (cf-mtDNA), nucleosomes, total histone H3, and specific trimethylated or acetylated forms of histone H3. Epigenetic data were then combined with clinical and inflammatory data and used to train artificial intelligence (AI) models.

Results: Anthropometrical and clinical data were first pre-processed to extrapolate the most significant variables ($p < 0.05$, one-way Anova P) that distinguished MASH from non-MASH. In particular, body mass index (BMI), alanine aminotransferase, gamma-glutamyl transferase, triglycerides (TGs), high-density lipoprotein, Apolipoprotein A1, insulin, and HOMA-IR emerged in children; while only BMI and TGs emerged in adults. We combined these variables with inflammatory and epigenetic data and trained different machine learning algorithms. The support vector machine model was the most accurate for children (approximately 85%), while the K-Nearest Neighbours algorithm was the most accurate for adults (approximately 80%). Shapley Additive exPlanations revealed that TGs, cf-DNA concentration, and total circulating histone H3 levels were common variables that may explain the MASH phenotype in both children and adults.

Conclusion: These preliminary findings highlighted that integrating epigenetic features with clinical parameters enabled accurate MASH discrimination using AI modelling. Further studies on testing and validation datasets are warranted.

WED-103

Validation of a multimodal ultrasound and artificial intelligence approach for identifying advanced fibrosis in metabolic dysfunction-associated steatotic liver disease

Ipshita Gupta[1], Arati Gurung[2], Sujoy Kar[3], Sudhakar Kattoju[4], Jospin Dhivya[3]. [1]*Siemens Healthineers, Singapore, Singapore;* [2]*Siemens Healthineers, Issaquah, United States;* [3]*Apollo Hospitals, Hyderabad, India;* [4]*Apollo Hospitals, Chennai, India*
Email: drsujoy_k@apollohospitals.com

Background and aims: Metabolic dysfunction-associated steatotic liver disease (MASLD) affects nearly one quarter of adults worldwide, yet fibrosis detection remains invasive, underutilized, and delayed. We aimed to prospectively validate an artificial intelligence based liver fibrosis (AILF) model integrating ultrasound derived fat fraction (UDFF) and elastography parameters to improve non-invasive risk stratification for advanced fibrosis.

Method: The IRB-approved prospective multi-centre study enrolled adults with clinically suspected MASLD or abnormal liver function tests. The AILF model (extreme gradient boosting) integrated clinical variables including lab markers, medication, and the duration of liver disease to predict liver fibrosis risk using automated point shear-wave elastography measurements (Auto pSWE) as the reference standard. The cut off values used for Low, Moderate, High and Very High risk were <7;7–9.5;9.5–14;>14 kPa based on *EASL Clinical Practice Guidelines.* Diagnostic performance, agreement, and class-specific threshold optimization were assessed. A subset analysis was conducted to determine correlation between the quantitative ultrasound parameters, namely UDFF and Auto pSWE, and a comprehensive panel of lab biomarkers.

Results: Among 698 enrolled participants, 443 complete profiles (920 clinical encounters-outpatient visits) were analysed with an mean age of 53.55 years (Range: 41.5–65.5) and gender ratio of 69:31 (male:female). The model identified high-risk fibrosis (F3 & F4) in approximately 8%(35/443) and intermediate risk(F2) in 15% (66/443) of the participants. Threshold optimization targeting intermediate-risk classes improved macro-precision (0.88 [0.82–0.95]) and F1 scores (0.81[0.75–0.88]) while preserving discrimination (AUC 0.87 [0.81–0.94]) and agreement beyond chance (Cohen kappa 0.86). Duration of disease and medications had the highest feature importance. Among all biomarkers, elevated gamma-glutamyl transferase (GGT) showed strong correlation (Pearsons $R = 0.65$, $p < 0.05$) with liver stiffness, including in individuals with normal aminotransferases.

Conclusion: A multimodal ultrasound and artificial intelligence approach enables accurate, scalable, and non-invasive risk stratification of fibrosis in MASLD. Early identification of patients at risk for MASH and advanced fibrosis may reduce unnecessary biopsies, support longitudinal monitoring, and facilitate safer clinical deployment through threshold-optimized decision support.

WED-104

Changes in non-invasive tests PRO-C3, ADAPT, LiverRisk and FIB-4 can be used to predict changes in liver stiffness in patients with MASLD

Hannes Hegmar[1], Rickard Strandberg[1,2], Ying Shang[1], Morten Karsdal[3], Johan Vessby[4], Åsa Danielsson Borssén[5], Nils Nyhlin[6], Stergios Kechagias[7], Per Stal[1], Diana Julie Leeming[3], Mattias Ekstedt[7], Hannes Hagström[1]. [1]*Karolinska Institutet, Department of Medicine, Huddinge, Huddinge, Sweden;* [2]*Red Door Analytics, Stockholm, Sweden;* [3]*Nordic Bioscience, Herlev, Denmark;* [4]*Department of Medical Sciences, Gastroenterology Research Group, Uppsala University, Uppsala, Sweden;* [5]*Umeå University Hospital, Umeå, Sweden;* [6]*Department of Gastroenterology, Faculty of Medicine and Health, Örebro University, Örebro, Sweden;* [7]*Department of Gastroenterology and Hepatology, Department of Health, Medicine and Caring Sciences, Linköping University, Linköping, Sweden*
Email: hhegmar@gmail.com

Background and aims: Liver stiffness measurements (LSM) by vibration-controlled transient elastography (VCTE) are suggested to be used for disease monitoring, treatment initiation and treatment evaluation in patients with metabolic dysfunction-associated steatotic liver disease (MASLD). However, availability of VCTE may be limited. We evaluated relative changes in the blood-based non-invasive tests (NITs) PRO-C3, PRO-C6, ADAPT, LiverRiskScore (LRS), and FIB-4, and how they corresponded to a relative change of 30% in LSM by VCTE over time.

Method: A Swedish cohort of 287 patients with MASLD was followed for five years. Repeated measurements of LSM by VCTE, PRO-C3, PRO-C6, ADAPT, LRS, and FIB-4 were obtained at baseline and year one, three and five, respectively. A Bayesian linear mixed effects model was used to evaluate the relative change of the NITs needed to predict a 30% relative change in LSM by VCTE. Correlations between changes in NITs and LSM was calculated. Multiple imputation was used for missing data.

Results: There was a decrease in median LSM from 7.0 kPa to 6.2 kPa over five years. Median FIB-4 increased from 1.14 to 1.38 and ADAPT from 5.42 to 5.72. All NITs were in alignment at group level that LSM decreased over time. The reduction in NIT corresponding to a 30% decrease in LSM was found to depend strongly on the baseline value of the NIT. For a baseline FIB-4 value of 1.3, the corresponding reduction was between 80% to 90%, while for a baseline FIB-4 value of 3 and above, the corresponding reduction was 20–30%. ADAPT and LRS showed less dependence on the baseline values, where a reduction of 30% and 40%, respectively, corresponded to a 30% reduction in LSM. ADAPT had the highest correlation with LSM change with an R^2 0.31 (95% Credible interval [CI] = 0.30–0.32) where

PRO-C3, LRS, and FIB-4 had an R^2 of 0.20 (95% CI = 0.18–0.22), 0.21 (95% CI = 0.18–0.22), and 0.21 (95% CI = 0.19–0.22), respectively.
Conclusion: Changes in the NITs PRO-C3, ADAPT, LRS and FIB-4 were associated with changes in LSM by VCTE. Of the tested NITs, changes in ADAPT had the strongest correlation with changes in LSM, suggesting that it might be better in predicting change in LSM. However, the association was modest, and further studies are warranted to better identify blood-based markers that may be used in settings where VCTE is not available.

WED-105
Optimization of non-invasive screening algorithms for referral to liver elastography in the general population
Marta Hernández Conde[1], David Marti-Aguado[2], Hugo José Disla[1], Elba Llop Herrera[1], Jesús Rivera Esteban[1], Paloma Lluch-García[2], Francisco Bernabeu[1], Marta López-Gómez[1], Javier Abad Guerra[1], Ana Royuela[1], Desamparados Escudero-García[2], José Luis Calleja Panero[1]. *[1]Hospital Universitario Puerta De Hierro Majadahonda, Majadahonda, Spain; [2]Hospital Clínico Universitario, Valencia, Spain*
Email: marta.hernandez.conde@gmail.com

Background and aims: Current clinical guidelines recommend a sequential approach using non-invasive tests to identify liver fibrosis in MASLD. In line with EASL care pathways, this stepwise strategy aims to optimize case-finding in primary care while limiting unnecessary referrals for second-line testing. However, the real-world efficiency of different screening algorithms remains insufficiently defined. We evaluated multiple combinations of FIB-4, ELF, and FLI to identify the most accurate and operationally efficient strategy for referral to hospital-based transiente elastography(TE; FibroScan).
Method: Multicenter cross-sectional cohort study conducted in Madrid and Valencia. FIB-4 was calculated in all individuals aged 18–64 years undergoing routine blood testing including HbA1c in primary care. Patients with FIB-4 >1.3 underwent paired assessment with ELF, FLI, and TE, with significant fibrosis (SF; liver stiffness ≥8 kPa). Nine sequential screening algorithms applicable in primary care were evaluated, estimating sensitivity, specificity, predictive values, and referral rate (coverage), as a surrogate of health-system impact.
Results: A total of 2,609 individuals were included: 77% had FIB-4 <1.3, 22% FIB-4 1.3–2.67, and 2% FIB-4 ≥2.67. Among the 634 subjects with FIB-4 >1.3, 26.9% had type 2 diabetes and 15.6% had SF. Algorithms based solely on FIB-4 followed by TE showed acceptable diagnostic accuracy but resulted in excessive referrals (coverage 74%), conflicting with EASL recommendations to limit unnecessary second-line testing. Sequential strategies integrating metabolic and serological risk stratification achieved a more favorable balance between diagnostic accuracy and system efficiency. The FLI→ELF→TE pathway demonstrated sensitivity 0.72, negative predictive value 0.94, and a referral rate of 34.7%. The clinically recommended FIB-4→ELF→TE strategy maintained good sensitivity (0.76) but required a higher referral rate (46.6%). Although FLI→FIB-4→TE achieved maximal sensitivity (100%), it showed negligible discrimination (specificity 0.009) and doubled TE demand compared with more efficient pathways (coverage 62.3%).
Conclusion: The FLI→ELF→TE sequence provides the best diagnostic efficiency, maximizing detection of SF while maintaining a clinically acceptable number of TE examinations. Its implementation could optimize the use of TE resources, prioritize patients at higher risk of fibrosis, and improve the efficiency of diagnostic pathways in primary care.

WED-106
External validation of a standardized FLI without anthropometric data for the screening of significant liver fibrosis
Marta Hernández Conde[1], Hugo José Disla[1], Jesús Rivera Esteban[1], Paula Iruzubieta[2], Elba Llop Herrera[1], David Marti-Aguado[3], Maria Teresa Arias Loste[2], Christie Perelló[1], María Del Barrio[3], Paloma Lluch-García[3], Desamparados Escudero-García[3], Javier Crespo[2,4], José Luis Calleja Panero[1]. *[1]Hospital Universitario Puerta De Hierro Majadahonda, Majadahonda, Spain; [2]Hospital Valdecilla, Santander, Spain; [3]Hospital Clínico Universitario, Valencia, Spain; [4]Gastroenterology and Hepatology Department, Clinical and Translational Research in Digestive Diseases, Valdecilla Research Institute (IDIVAL), Marques de Valdecilla University Hospital, Santander, Spain*
Email: marta.hernandez.conde@gmail.com

Background and aims: The Fatty Liver Index (FLI) is a simple, inexpensive non-invasive test with potential utility for liver fibrosis screening; however, it requires body mass index (BMI) and waist circumference (WC), which are often unavailable in large-scale or opportunistic settings. We evaluated whether a "standardized" FLI (FLI-std), replacing BMI and WC with sex-specific mean values, preserves diagnostic performance non-inferior to the original FLI (FLI-o) for detecting significant fibrosis (SF; ≥F2), using transient elastography (TE) as reference.
Method: Two independent cohorts were analyzed: a derivation cohort (n = 634) and the external ETHON validation cohort (n = 6,180). Patients with FLI ≥ 60 were referred for TE assessment. Non-inferiority (NI) of FLI-std versus FLI-o was evaluated for sensitivity (margin $\delta = -5$ percentage points) and area under the ROC curve (AUC; $\Delta \geq -0.02$).
Results: The cohorts showed markedly different clinical profiles. The derivation cohort included older patients with higher metabolic risk, whereas ETHON represented a younger, more general population with lower SF prevalence (15.6% vs 3.9%; $p < 0.001$). In the derivation cohort, FLI-std showed sensitivity 0.94, specificity 0.40, and negative predictive value (NPV) 0.98, with a screening coverage of 65.4%. In the external validation cohort, the AUC of FLI-std (0.70; 95% CI 0.67–0.74) was comparable to FLI-o (0.71; 95% CI 0.67–0.75), with $\Delta AUC = -0.007$ ($p = 0.62$), fulfilling the NI criterion. FLI-std achieved higher sensitivity than FLI-o (0.71 vs 0.64), with a paired difference of +3.3 percentage points (95% CI −4.8 to +11.5), exceeding the NI margin. NPV remained high (~0.98), with improved detection of SF (40% vs 33%), at the expense of a modest reduction in specificity (0.61 vs 0.69).
Conclusion: Differences in cohort characteristics explain the lower absolute sensitivity observed in external validation without implying a true loss of discriminative capacity. A standardized FLI without BMI or WC preserves non-inferior diagnostic performance for SF detection in external validation. This simplified model enables scalable, pragmatic fibrosis screening pathways when anthropometric data are unavailable, without clinically relevant loss of accuracy.

WED-107
Biogenic amines as possible biomarkers of liver fibrosis severity in metabolic dysfunction-associated steatotic liver disease
Zdenka Hertelyova[1,2], Sylvia Drazilova[1], Dominika Toporcerova[1], Zuzana Gulasova[1], Daniela Szaboova[1], Peter Jarčuška[1]. *[1]Lekárska fakulta Univerzity Pavla Jozefa Šafárika v Košiciach, Košice, Slovakia; [2]Pavol Josef Safarik University, 2nd Internal Clinic, Kosice, Slovakia*
Email: zdenocka@gmail.com

Background and aims: Identification of patients with significant fibrosis is essential for accurate risk stratification in metabolic dysfunction–associated steatotic liver disease (MASLD). Non-invasive tools such as vibration-controlled transient elastography (VCTE) and the fibrosis-4 index (FIB-4) are widely used for fibrosis assessment; however, novel biomarkers are still needed. Biogenic amines are involved in metabolic and inflammatory pathways and may

contribute to MASLD progression. This study aimed to investigate the association between circulating biogenic amines and liver fibrosis severity; and to evaluate their diagnostic potential as non-invasive biomarkers of liver fibrosis in MASLD.

Method: A total of 68 adults (31 women, mean age 65.35 ± 9.26 years) with confirmed MASLD were prospectively enrolled. Liver fibrosis was assessed using VCTE and patients were stratified as follows: F0 – F1 (<7.0 kPa), F2 (≥7.0 – <8.8 kPa), F3 (≥ 8.8 – <12.0 kPa), and F4 (≥12.0 kPa). Serum samples were analysed by liquid chromatography–tandem mass spectrometry using the MxP® Quant 500 kit. Appropriate parametric and non-parametric statistical tests were applied. The diagnostic performance of selected biogenic amines and FIB-4 for significant fibrosis (≥ F2) and cirrhosis (F4) was assessed using receiver operating characteristic (ROC) curve analysis.

Results: Patients with significant fibrosis (F2 – F4) exhibited significantly higher circulating levels of several biogenic amines compared with those with no or mild fibrosis (F0 – F1), most notably beta-alanine 5.43 ± 0.89 vs 7.94 ± 0.80 µmol/l, $p < 0.001$; spermine 0.228 ± 0.032 vs 0.342 ± 0.071 µmol/l, $p < 0.001$; and putrescine 0.158 ± 0.040 to 0.309 ± 0.129 µmol/l, $p < 0.001$; whereas dopamine did not differ between both groups. ROC analysis demonstrated excellent diagnostic accuracy for significant fibrosis vs no or mild fibrosis in MASLD patients: AUC 0.99 for beta-alanine; AUC 0.95 for spermine; and AUC 0.85 for putrescine. ROC analysis also showed outsanding diagnostic accuracy for liver cirrhosis (F4) vs no cirrhosis in MASLD: 0.99 for beta alanine; 0.99 for spermine; and 0.98 for putrescine.

Conclusion: Beta-alanine, spermine, and putrescine are strongly associated with fibrosis severity in MASLD and demonstrate excellent diagnostic accuracy for significant fibrosis and cirrhosis. These findings suggest their potential role as novel non-invasive biomarkers for liver fibrosis assessment in MASLD patients.

WED-108

Diagnostic accuracy of non-invasive serum biomarkers for liver fibrosis in hepatocellular carcinoma patients with and without concurrent metabolic dysfunction–associated steatotic liver disease

Chun-Ting Ho[1,2], Chia-Jung Ho[1], Tsai Shin-Yu[1], Yi-Chen Lin[3], Yi-Hsiang Huang[4], Ming-Chih Hou[5], Jaw-Ching Wu[6], Chien-Wei Su[7]. *[1]Taipei Veterans General Hospital, Department of Medicine, Taipei, Taiwan; [2]National Yang Ming Chiao Tung University Yangming Campus, Ph.D. Program of Interdisciplinary Medicine, Taipei, Taiwan; [3]Linkou Chang Gung Memorial Hospital, Department of Medicine, Taoyuan City, Taiwan; [4]Taipei Veterans General Hospital, Department of Medical Research, Taipei, Taiwan; [5]Taipei Veterans General Hospital, Division of Gastroenterology and Hepatology, Department of Medicine, Taipei, Taiwan; [6]National Yang Ming Chiao Tung University Yangming Campus, Institute of Clinical Medicine, Taipei, Taiwan; [7]Taipei Veterans General Hospital, Division of General Medicine, Department of Medicine, Taipei, Taiwan*
Email: cwsu2@vghtpe.gov.tw

Background and aims: Non-invasive serum biomarkers (NISB) such as fibrosis-4 (FIB-4) and aspartate aminotransferase-to-platelet ratio index (APRI) are widely used to estimate liver fibrosis. However, their diagnostic accuracy may be altered in different subgroups of patients, such as hepatocellular carcinoma (HCC) and metabolic dysfunction–associated steatotic liver disease (MASLD). We aimed to evaluate the correlation between various NISBs and histological fibrosis severity and compare their accuracy in predicting cirrhosis in HCC patients with and without concurrent MASLD.

Method: 984 HCC patients who underwent curative resection at Taipei Veterans General Hospital with available pathological specimens and complete clinical data were included. Patients were divided into MASLD (n = 469) and non-MASLD (n = 515) groups accordingly. Spearman correlation was utilized to assess associations between ISHAK fibrosis scores and five NISBs: FIB-4, APRI, non-alcoholic fatty liver disease fibrosis score (NFS), BMI–AST/ALT ratio–diabetes mellitus (BARD) score, and AST/ALT ratio (AAR). Diagnostic accuracy for cirrhosis (ISHAK ≥5) was evaluated using receiver operating characteristic (ROC) analysis and compared across NISBs. Optimal single cutoffs were determined by maximizing Youden's index; rule-out and rule-in thresholds were determined corresponding to sensitivity >90% and specificity >80%, respectively.

Results: Among the cohort, 345 patients had histologically confirmed cirrhosis. FIB-4 and APRI demonstrated the strongest correlation with ISHAK fibrosis stage and showed comparative diagnostic accuracy for cirrhosis among all subgroups. For FIB-4, the optimal single cutoff was lower in the MASLD subgroup (2.439) than in the overall cohort and the non-MASLD subgroup (3.035 and 3.040, respectively). Using dual cutoffs, rule-out thresholds were consistent across all subgroups (1.328–1.423) and aligned well with current guidelines, while rule-in thresholds were substantially lower in patients with MASLD (2.659) compared with the overall cohort and non-MASLD subgroup (3.127 and 3.409, respectively).

Conclusion: NISBs such as FIB-4 and APRI demonstrated modest correlation with histological cirrhosis and comparable diagnostic accuracy across different etiologies. While the rule-out threshold around 1.3 for FIB-4 aligns with current guidelines, the one-point and rule-in diagnostic cutoff for HCC patients with concurrent MASLD were significantly lower, thus highlighting the necessity for subgroup-specific diagnostic thresholds.

WED-109

Unsupervised biomarker clustering reveals clinically relevant phenotypes in metabolic dysfunction–associated steatotic liver disease

Frederik Højbjerg Svejsø[1,2], Diana Julie Leeming[1], Puria Nabilou[3], Elias Rashu[3], Mira Thing[3], Mikkel Werge[3], Anders Junker[3], Line Egerod Lund[1,4], Morten Karsdal[1], Alejandro Mayorca Guiliani[1], Lise Lotte Gluud[3,5]. *[1]Nordic Bioscience A/S, Herlev, Denmark; [2]Biotech Research and Innovation Centre, University of Copenhagen, Copenhagen, Denmark; [3]Gastro Unit, Medical Division, Hvidovre Hospital, University of Copenhagen, Hvidovre, Denmark; [4]Department of Biomedical Sciences, University of Copenhagen, Copenhagen, Denmark; [5]Department of Clinical Medicine, University of Copenhagen, Copenhagen, Denmark*
Email: frsv@nordicbio.com

Background and aims: The Copenhagen Cohort of MASLD (CoCoMASLD) is an observational study aimed at identifying biomarkers and potential therapeutic targets in patients with metabolic dysfunction–associated steatotic liver disease (MASLD). Given the clinical and biological heterogeneity of MASLD, data-driven approaches may help identify distinct patient subgroups with differing hepatic and systemic risk profiles, including risk of cardiovascular disease. The aim of this study was to apply unsupervised clustering methods to a well-characterized MASLD cohort to identify patient endotypes.

Method: Baseline clinical and extracellular matrix (ECM)-based biomarker data were compiled for 863 MASLD patients and log-transformed. Patients with ≥25% missing values were excluded, leaving 638 patients. Remaining missing values were imputed, and all variables were Winsorized to reduce the influence of outliers and scaled for analysis. Principal component analysis (PCA) was performed, followed by k-means clustering, specifying three clusters based on biological relevance. Clusters were compared using baseline liver biopsy data available for 268 patients, and Fibroscan data for 619 patients. Differences in clinical and histological parameters, including liver stiffness, were assessed using the Wilcoxon rank-sum test.

Results: Clustering of baseline clinical and ECM biomarkers identified three patient groups. Cluster 1 (C1, n = 241) was characterized by elevated inflammatory and degradation markers (nordicC3M™, nordicC6M™) and high white blood cell counts. Cluster 2 (C2, n = 172) exhibited a fibrogenic profile with elevated nordicPRO-C3™ and

nordicPRO-C6™, while Cluster 3 (C3, n = 225) showed generally low biomarker levels but increased nordicC4G™, suggesting enhanced T-cell activity. Histological analyses showed higher steatosis grade in C1 compared with C2 ($p = 0.02$) and C3 ($p = 0.00047$). In contrast, C2 patients had markedly higher fibrosis scores than C1 ($p = 5.7 \times 10^{-9}$) and C3 ($p = 3.8 \times 10^{-9}$), accompanied by increased liver stiffness compared with C1 ($p = 5.4 \times 10^{-4}$) and C3 ($p < 2.22 \times 10^{-16}$).
Conclusion: Unsupervised clustering in MASLD patients identified three distinct phenotypic groups identified by systemic and routine markers. These findings demonstrate clinically meaningful heterogeneity in MASLD and highlight the value of biomarker-driven phenotyping for risk stratification.

WED-110-YI
External validation of the LiverPRO algorithm for liver fibrosis risk assessment in U.S. representative adults
He Huang[1], Laurens A. van Kleef[1], Katrine Lindvig[2], Harry L.A. Janssen[1], Maja Thiele[2], Willem Pieter Brouwer[1].
[1]Department of Gastroenterology and Hepatology, Erasmus Medical Center, University Medical Center Rotterdam, Rotterdam, Netherlands; [2]Centre for Liver Research, Department of Gastroenterology and Hepatology, Odense University Hospital, Odense, Denmark
Email: h.huang@erasmusmc.nl

Background and aims: LiverPRO is a new algorithm to predict liver fibrosis, with distinct formulas for F2, F3, and F4 stages. Unlike traditional scores, LiverPRO does not require all input variables; it automatically selects the best-performing model based on available data. The full model includes age, albumin, AST, bilirubin, sodium, cholesterol, GGT, ALP, platelets, and INR. We performed an external validation of LiverPRO in a nationally representative population.
Method: We used data from U.S. adults participating in NHANES (2017–2023), with LSM and LiverPRO components except for INR. Participants with heart failure or alcohol intake >50/60 g/day (female/male) were excluded. Diagnostic performance was assessed for LSM ≥8 and ≥12 kPa (commonly interpreted as compatible with significant and advanced fibrosis) using AUCs and detection rates at the proposed LiverPRO thresholds. Performance was evaluated in the overall population and relevant subgroups.
Results: The study included 10,852 adults (48.6% male, mean age 50 yr) of whom 60% had at least one indicator for screening, 10.5% had LSM ≥8 kPa and 3.6% had LSM ≥12 kPa. Using the LiverPRO F2 algorithm, 4.6% were classified high, 26.1% intermediate, and 69.3% low risk, with LSM ≥8 kPa prevalences of 37.5%, 16.1%, and 6.6%, respectively. At the 0.25 threshold, sensitivity and specificity for LSM ≥8 kPa were 57% and 72% and for LSM ≥12 kPa 69% and 71%. Among those meeting screening criteria, sensitivity and specificity remained largely unchanged (LSM ≥8 kPa: 59% and 63%; LSM ≥12 kPa: 69% and 61%). The F3 and F4 LiverPRO algorithms with their specific cut-offs did not improve performance for both LSM thresholds. The LiverPRO F2 algorithm achieved the highest AUC for LSM ≥8 kPa (0.71 vs 0.67/0.66 for F3/F4 model) and ≥ 12 kPa (0.76 vs 0.72/0.71). LiverPRO outperformed FIB-4 (AUC 0.61 and 0.67 for LSM ≥8 and 12 kPa). For LSM ≥8 kPa, AUCs were higher in females (0.73) than males (0.68), stable across age groups (18–35: 0.66; 35–65: 0.70; 65–80: 0.70), higher with at-risk alcohol consumption (0.74), and lower when meeting EASL–EASD–EASO screening criteria (0.66).
Conclusion: The LiverPRO algorithm was externally validated in a representative U.S. general population, where the F2 algorithm demonstrated the best performance for detecting LSM ≥8 and ≥12 kPa, producing a clear risk gradient across strata. Performance was highest among adults with at-risk alcohol consumption, indicating potential in a group where non-invasive tests often perform less consistently.

WED-111
Self-assessed health and healthcare utilisation identify individuals with increased liver stiffness in the general population
He Huang[1], Willem Pieter Brouwer[1], Harry L.A. Janssen[1], Laurens A. van Kleef[1]. *[1]Department of Gastroenterology and Hepatology, Erasmus Medical Center, University Medical Center Rotterdam, Rotterdam, Netherlands*
Email: h.huang@erasmusmc.nl

Background and aims: Liver stiffness measurement (LSM) is a non-invasive marker of liver fibrosis and is associated with increased risk of liver-related events and mortality. Given the relatively low incidence of these complications in the general population, population-wide screening for increased LSM remains controversial. Opportunistic screening within healthcare settings, alongside self-reported health, may represent a pragmatic alternative. We assessed the prevalence of increased LSM across healthcare utilisation patterns to assess its value as an entry point for opportunistic screening.
Method: We analysed adults aged 18–80 years with LSM data without heart failure from NHANES 2017–2023. Self-assessed health and healthcare utilisation were based on interviews. LSM was obtained using vibration-controlled transient elastography. Using the provided sample weights, we report on the prevalence of increased LSM across self-assessed health and healthcare utilisation measures, using LSM thresholds of ≥8, 10 and 12 kPa.
Results: Among 12,942 adults aged 18–80 years (mean age 50 years, 48% male), the weighted prevalence of LSM ≥8 kPa was 9.8%, LSM ≥10 kPa 5.5% and LSM ≥12 kPa 3.5%. The prevalence of LSM ≥8 kPa showed a strong gradient across self-assessed health strata, ranging from 5.3% among individuals reporting excellent health to 6.6% (very good), 12% (good), 16% (fair), and 22% (poor health). Notably, among participants reporting excellent health with LSM ≥8 kPa, 81% had LSM <12 kPa, whereas among those reporting poor health with LSM ≥8 kPa, 52% had LSM ≥12 kPa. In contrast, the weighted prevalence of LSM ≥8 kPa was similar for individuals with and without a routine place for healthcare (9.9% vs 9.6%), and among those who did and did not report contact with a mental health professional in the past year (10% vs 9.8%). In participants with available data on the times received health care over the past year (n = 7,551), the weighted prevalence of LSM ≥8 kPa was similar for 0–3 visits (7.3–7.9%) but higher for 4–9 visits (12%) and ≥10 visits (11%). This gradient was more pronounced at higher LSM thresholds.
Conclusion: A strong risk gradient was observed across self-assessed health categories for the prevalence of increased LSM, providing stronger discrimination than measures of health care utilisation. While healthcare contact remains essential for opportunistic screening strategies, reliance on utilisation alone may be insufficient to accurately identify individuals at risk of liver-related events.

WED-115
Prediabetes identifies a high-risk subgroup for advanced liver fibrosis in non-diabetic MASLD: a non-invasive risk stratification study
Trung Huynh[1], Hoai Phuong Huynh[2], Hoang Long Doan[2], Trinh Nguyen Tran Tuyet[3]. *[1]Department of Gastroenterology and Hepatology, Center for Gastrointestinal Endoscopy and Laparoscopic Surgery, Ho Chi Minh City, Viet Nam; [2]Department of Gastroenterology and Hepatology, Ho Chi Minh, Viet Nam; [3]Department of Internal Medicine, University of Medicine and Pharmacy at Ho Chi Minh City, Ho Chi Minh City, Vietnam, Ho Chi Minh City, Viet Nam*
Email: trunghv@tahospital.vn

Background and aims: Risk stratification for liver fibrosis in metabolic dysfunction-associated steatotic liver disease (MASLD) is commonly initiated after the development of overt diabetes. Prediabetes is highly prevalent but is not routinely considered an indication for fibrosis assessment. We aimed to evaluate the prevalence of significant and advanced liver fibrosis among non-

diabetic MASLD patients with prediabetes and to assess the utility of non-invasive tools for fibrosis risk stratification in this population.
Method: This cross-sectional study included consecutive non-diabetic MASLD patients evaluated at a tertiary referral center between 2024 and 2025. Prediabetes was defined according to standard glycaemic criteria. Liver fibrosis was assessed using the FIB-4 index and Acoustic Radiation Force Impulse (ARFI) elastography. The prevalence of significant (F≥2) and advanced fibrosis (F≥3) was determined. Factors associated with advanced fibrosis were analysed, and the diagnostic performance of FIB-4 was evaluated using receiver operating characteristic analysis.
Results: A total of 107 non-diabetic MASLD patients were included (mean age 47.3 ± 12.6 years; 56.1% male). Significant fibrosis (F≥2) was present in 15.0% of patients, while advanced fibrosis (F≥3) was identified in 11.3%. Among patients with prediabetes, 41.7% had advanced fibrosis despite the absence of overt diabetes. Age and AST level were independently associated with advanced fibrosis. FIB-4 demonstrated good diagnostic performance for advanced fibrosis, with an AUROC of 0.949.
Conclusion: Prediabetes is associated with a substantial burden of advanced liver fibrosis in non-diabetic MASLD patients. Assessment strategies based solely on diabetes status may delay identification of clinically relevant fibrosis. Non-invasive tools such as FIB-4 and ARFI elastography may support earlier fibrosis risk stratification in patients with prediabetes.

WED-116
Superiority of the FAST score compared to traditional non-invasive indices in detecting liver fibrosis in asymptomatic patients with type 2 diabetes mellitus

Mustafa Sahin[1], Fatma Tuğçe Şah Ünal[1], Zeynep Melekoğlu Ellik[2], Volkan Yılmaz[2], Digdem Kuru Oz[3], Hale Gokcan[2], Atilla Elhan[4], Rıfat Emral[1], Ramazan Idilman[2]. *[1]Ankara University Faculty of Medicine, Endocrinology Department, Ankara, Türkiye; [2]Ankara University Faculty of Medicine, Hepatology Department, Ankara, Türkiye; [3]Ankara University Faculty of Medicine, Radiology, Ankara, Türkiye; [4]Ankara University Faculty of Medicine, Statistics Department, Ankara, Türkiye*
Email: drsahinmustafa@yahoo.com

Background and aims: Metabolic dysfunction-associated steatotic liver disease (MASLD) has emerged as the most prevalent chronic liver disease worldwide. MASLD is a progressive condition and is strongly associated with various metabolic disorders. Although current guidelines recommend fibrosis screening for patients with Type 2 diabetes mellitus (T2DM), the efficacy of commonly used serum-based non-invasive fibrosis indices in this population remains suboptimal. This study aimed to determine the prevalence of hepatic steatosis and significant liver fibrosis in asymptomatic patients with T2DM and to systematically compare the diagnostic accuracy of the elastography-based FAST score with that of serum-based fibrosis scores.
Method: This prospective, cross-sectional single center study included 257 adults with T2DM. Demographic characteristics, diabetes duration, glycemic control, and antidiabetic treatment modalities were recorded for each participant. All patients underwent transient elastography to assess liver stiffness measurement (LSM) and controlled attenuation parameter (CAP). Significant fibrosis (≥F2) was defined as LSM ≥8.0 kPa, while hepatic steatosis was defined as CAP >238 dB/m, with severe steatosis characterized by CAP >290 dB/m. Non-invasive fibrosis indices, including the FAST score, FIB-4, NAFLD Fibrosis Score (NFS), APRI, and the AST/ALT ratio, were calculated contemporaneously. Diagnostic performance of these indices was evaluated using receiver operating characteristic curve analysis and odds ratios.
Results: The mean age of the cohort was 58.2 ± 8.8 years, with 61% of participants being female. The mean duration of T2DM was 11.4 ± 7.2 years, and the mean HbA1c level was 8.2% ± 1.8. Hepatic steatosis was highly prevalent as 94% of patients exhibited hepatic steatosis, while 56% exhibited severe steatosis. Significant liver fibrosis was detected in 26% of patients. The FAST score demonstrated the highest diagnostic accuracy for detecting significant fibrosis, with an area under the curve (AUC) of 0.906 (95% CI 0.86–0.94; OR 46.18), achieving high sensitivity (93.9%) and acceptable specificity (74.9%).
Conclusion: More than half of asymptomatic patients with T2DM exhibit MASLD, while one in four patients with clinically significant liver fibrosis. The elastography-based FAST score demonstrates markedly superior diagnostic accuracy and should be prioritized for the non-invasive identification of metabolic dysfunction-associated steatohepatitis in patients with T2DM.

WED-117
Optimizing drug development in populations with compensated MASH cirrhosis by integration of the disease severity index from the HepQuant DuO test in trial design

Joanne Imperial[1], Michael McRae[2], Greg Everson[1]. *[1]HepQuant, LLC, Denver, Colorado, United States; [2]Custom DX Solutions LLC, Houston, Texas, United States*
Email: michael.mcrae@hepquant.com

Background and aims: The significant heterogeneity in liver function within compensated MASH cirrhosis complicates trial design. The Disease Severity Index (DSI), a non-invasive, functional biomarker derived from the oral cholate challenge test (HepQuant DuO), is proposed as a reasonably likely surrogate endpoint (RLSE) for clinical outcomes. This analysis explores the relationship between baseline DSI, changes in DSI, and estimated risk of clinical outcome using a hypothetical trial framework.
Method: We modeled a 5-year, randomized (3:1 drug:placebo) trial of 720 patients with compensated MASH cirrhosis. Baseline DSI data was pooled from recent clinical trials of 193 cACLD patients with compensated MASH cirrhosis (mean DSI 21.5 ± 6.5). Clinical outcome probabilities were derived using Cox proportional hazards regression (RISK ACE models, Kittelson 2024). We estimated event rates across a range of baseline DSI values and evaluated the impact of change in DSI after 1 year of treatment on the risk for clinical outcome. Statistical significance thresholds were calculated using Chi-squared and paired t-tests. Enrichment strategies incorporating high-risk subjects (DSI ≥ 24) were assessed.
Results: For baseline DSI of 22, the estimated clinical outcome rates were 4.6%, 11.3%, and 24.1% at 1, 2, and 5 years, respectively. A 2-unit reduction in DSI decreased the 5-year risk to 14.0%, and no change in DSI reduced risk to 21.0%. Conversely, a 2-unit increase in DSI increased the 5-year risk to 30.6%. Responder analysis achieved significance when the change in DSI (delta DSI) was −2.0 in the treatment arm versus no change in the placebo arm ($p = 0.03$). For smaller differences between arms, enrichment with high-risk subjects (DSI ≥ 24) markedly reduced the required sample size for statistical significance ($p < 0.05$): +112 subjects for delta DSI −1.5; +320 for delta DSI −0.5; +536 for delta DSI −0.5. A mean DSI reduction of 1.0 between baseline and end of treatment in the treatment arm, assuming no change in placebo arm, achieved statistical significance by paired t-test ($p = 0.048$).
Conclusion: Baseline DSI and change in DSI are dynamic and sensitive indicators of liver disease progression and response to treatment in compensated MASH cirrhosis. Incorporating DSI as an RLSE can optimize trial design, reduce sample size, enable adaptive strategies, and provide early functional endpoints linked to clinical outcomes.

WED-118

Prognostic significance of a 5 kPa absolute change in liver stiffness measurements (LSM) to predict liver-related events in patients with compensated advanced metabolic dysfunction-associated steatotic liver disease (MASLD)

Email: 1155223326@link.cuhk.edu.hk

Background and aims: Previous studies demonstrated the prognostic value of relative changes in LSM by vibration-controlled transient elastography (VCTE). Although absolute LSM change is simpler to interpret, its clinical significance remains unclear. This study assessed whether a 5 kPa absolute change in LSM could predict liver-related events (LREs) in patients with MASLD and a baseline LSM between 10 and 20 kPa.

Method: This cohort study included patients with MASLD who underwent VCTE examinations at 16 centres across the US, Europe, and Asia between 2004 and 2023. Eligible patients had baseline LSM of 10–20 kPa and one or more reliable LSMs at least 12 months apart. Change in LSM was defined as the difference between baseline and follow-up measurements, categorized as follows: regression (a reduction of ≥5 kPa), stable (a change of −5 kPa to +5 kPa), and progression (an increase of ≥5 kPa). The primary outcome was occurrence of LREs, a composite of hepatic decompensation and hepatocellular carcinoma. The prediction was compared with a relative LSM change of ≥30%.

Results: In 1,366 patients, 46 LREs developed over a median follow-up of 2.80 years (IQR: 1.18–4.77). 404 (29.6%) and 555 (40.6%) patients experienced ≥5 kPa and ≥30% decreases from baseline LSM, whereas 129 (9.4%) and 167 (12.2%) experienced ≥5 kPa and ≥30% increases from baseline. Relative reduction of 30% had higher time-dependent specificity than absolute decrease of 5 kPa (30%: 44.6 [40.7–48.4], 5 kPa: 33.7 [30.2–37.5]), while the time-dependent sensitivity was similar (30%: 89.5 [79.4–97.7], 5 kPa: 87.9 [77.5–96.0]). Consistently, a ≥30% relative decrease (adjusted subdistribution hazard ratio [aSHR] 0.29, 95% CI 0.12–0.71, p = 0.007), but not an absolute 5 kPa decrease in LSM (aSHR 0.54, 95% CI 0.23–1.09, p = 0.160), was associated with a significant reduction in LREs. In contrast, both absolute increase of 5 kPa and relative increase of 30% in LSM were associated with an increased risk of LREs (5 kPa: aSHR 2.68, 95% CI: 1.34–5.36, p = 0.006; 30%: aSHR 2.12, 95% CI: 1.10–4.08, p = 0.024).

Conclusion: Both 30% and 5 kPa increase in LSM are reliable indicators of disease progression, while 30% relative decrease is more effective in capturing risk reduction in LREs.

WED-119

Steatotic liver disease phenotypes in inflammatory bowel disease: a screening study identifying masld as the primary driver of liver fibrosis

Dana Kablawi[1], Riccardo Righetti[1], Raman Agnihotram[1], Faisal Aljohani[1], Chiara Saroli Palumbo[2], Alain Bitton[1], Waqqas Afif[1], Talat Bessissow[1], Giada Sebastiani[1]. *[1]McGill University, Montreal, Canada; [2]Montreal, Canada*
Email: giada.sebastiani@mcgill.ca

Background and aims: Steatotic liver disease (SLD) seems common in people living with inflammatory bowel disease (IBD). The newly

proposed definition of metabolic dysfunction-associated steatotic liver disease (MASLD) highlights metabolic drivers of hepatic steatosis while recognizing its frequent coexistence with other chronic liver diseases, including alcohol and drug-induced liver injury. The purpose of this study was to characterize the distribution of SLD phenotypes in people with IBD and evaluate the association of coexisting MASLD and IBD with liver fibrosis.

Method: As part of a MASLD screening program, transient elastography was performed in consecutive people with IBD from a prospective cohort in Montreal, Canada. SLD was defined as hepatic steatosis with a controlled attenuation parameter ≥275 dB/m. MASLD was defined by presence of steatosis with at least 1 cardiometabolic risk factor: BMI, prediabetes or diabetes, hypertension, or dyslipidemia. Significant liver fibrosis was defined as liver stiffness measurement ≥8 kPa. Factors associated with fibrosis were assessed using logistic regression models.

Results: A total of 495 patients (mean age 45, 54% male, 64% CD, mean IBD duration 14 years, mean BMI 25.4). SLD was identified in 35% of patients, of which 57% met criteria for MASLD, 5% had alcohol-related SLD, and 38% had other forms. The overall prevalence of significant liver fibrosis was 8%, increasing to 13% and 22% in patients with 1–2 or 3–4 cardiometabolic risk factors, respectively. The prevalence of liver fibrosis was higher in patients with MASLD vs. those without. Patients with non-MASLD SLD phenotypes (4.5%) and those with liver fibrosis (7.5%) had a higher prevalence of methotrexate exposure vs. those without SLD (1.9%) or liver fibrosis (2.3%). After adjusting for IBD type, biological sex and IBD duration, MASLD remained independently associated with 3-fold higher odds of fibrosis (aOR 3.1, 95% CI 1.5–6.1). No significant association was observed for non-MASLD SLD phenotypes. Notably, 3.5% of IBD patients had significant fibrosis in the absence of SLD.

Conclusion: MASLD is the most frequent phenotype of SLD in people with IBD and is strongly associated with liver fibrosis. A proportion of patients also exhibit SLD without metabolic comorbidities or significant alcohol intake, suggesting a potential role for chronic medication exposure. Clinicians should prioritize the identification and management of cardiometabolic risk factors in IBD care to mitigate liver-related complications.

WED-120

Utility of ELF compared with VCTE in guideline-based fibrosis assessment pathways using MRE as reference

Cecilia Katzenstein[1], Anna Mageras[1], Mark Miller[1], Victor Llanes[1], Xiaotao Zhang[1], Meena Bansal[1]. [1]*Icahn School of Medicine at Mount Sinai, New York, United States*
Email: cecilia.katzenstein@icahn.mssm.edu

Background and aims: EASL guidelines recommend stepwise fibrosis assessment using FIB-4 followed by second-line testing when risk is indeterminate or elevated. While VCTE is commonly used, the role of the Enhanced Liver Fibrosis (ELF) blood test within guideline-based pathways remains uncertain.

Method: We prospectively analyzed 157 patients evaluated for MASH who underwent FIB-4, ELF, VCTE, and MRE as part of routine care. Significant fibrosis was defined as MRE ≥3.1 kPa, and cirrhosis as MRE ≥5.0 kPa. Performance was assessed using ROC analysis, sensitivity and specificity, and Spearman correlation with MRE. Sequential pathways reflecting EASL FIB-4 categories followed by ELF or VCTE were evaluated.

Results: The cohort was metabolically high risk, with median BMI 33.6 kg/m^2 and diabetes in 44.8%. Median MRE was 3.1 kPa (IQR 2.4–4.2), and 33.8% had significant fibrosis (MRE 3.1–5.0 kPa). In kPa ≥3.1, ELF and VCTE demonstrated similar discrimination (AUC 0.76 vs 0.75; p = 0.84). For kPa ≥5.0, VCTE showed higher discrimination (AUC 0.92 vs 0.81; p = 0.033). ELF correlated moderately with MRE (rho = 0.52, >0.001), comparable with VCTE, and remained correlated across subgroups, including patients with BMI >40 kg/m^2 (rho = 0.40, p = 0.019) whom VCTE was not significantly correlated. After FIB-4≥1.3, ELF and VCTE showed identical sensitivity for MRE ≥3.1 kPa (56.4%), with higher specificity for ELF (82.3% vs 77.2%). For MRE ≥5.0 kPa, VCTE was more sensitive (88.0% vs 76.0%), while ELF was more specific (88.6% vs 82.6%). In the indeterminate FIB-4 subgroup (1.3–2.67), cirrhosis prevalence was 16.4%. ELF classified fewer patients as positive, with lower sensitivity but higher specificity than VCTE (54.5% vs 81.8%; 92.9% vs 78.6%). Among patients with significant fibrosis (33.8%), ELF had higher specificity than VCTE as a standalone test in the full cohort (64.4% vs 50.0%) and within FIB-4 pathways (67.3% vs 60.6%), with similar sensitivity.

Conclusion: In a high-risk cohort assessed using EASL-recommended stepwise pathways and MRE as reference, ELF and VCTE showed comparable discrimination for significant fibrosis, while VCTE remained more sensitive for cirrhosis. ELF consistently improved specificity when used as a reflex test after FIB-4, particularly in patients with indeterminate FIB-4, non-cirrhotic fibrosis, obesity, and diabetes. These findings support ELF as a pragmatic, blood-based reflex alternative to VCTE within guideline-based pathways to improve risk stratification and avoid uneccesary referrals to specialists.

AI-based non-invasive prediction of liver fibrosis in a multicenter biopsy-proven MASLD cohort in Korea

Soon Sun Kim[1], Young-Sun Lee[2], Charmgil Hong[3], Young Chang[4], Su Jong Yu[5], Jeong-Ju Yoo[6], Eileen Yoon[7], Hyo Young Lee[7], Young Joo Jin[8], Do Seon Song[9], Won Sohn[10], Byoung Kuk Jang[11]. [1]*Ajou University School of Medicine, Suwon, Korea, Rep. of South;* [2]*Korea University College of Medicine, Seoul, Korea, Rep. of South;* [3]*Handong Global University, Pohang, Korea, Rep. of South;* [4]*Soonchunhyang University Seoul Hospital, Seoul, Korea, Rep. of South;* [5]*Seoul National University College of Medicine, Seoul, Korea, Rep. of South;* [6]*Soonchunhyang University Bucheon Hospital, Bucheon, Korea, Rep. of South;* [7]*Hanyang University College of Medicine, Seoul, Korea, Rep. of South;* [8]*Inha University School of Medicine, Incheon, Korea, Rep. of South;* [9]*St. Vincent's Hospital, The Catholic University of Korea College of Medicine, Suwon, Korea, Rep. of South;* [10]*Sungkyunkwan University School of Medicine, Seoul, Korea, Rep. of South;* [11]*Keimyung University School of Medicine, Daegu, Korea, Rep. of South*
Email: cocorico99@gmail.com

Background and aims: Fibrosis stage is the key determinant of long-term prognosis in metabolic dysfunction–associated steatotic liver disease (MASLD). Recent guidelines define "at-risk MASH" as biopsy-proven disease with fibrosis stage ≥F2, underscoring the need for accurate non-invasive tests. This study aimed to develop an artificial intelligence (AI)–based model to predict liver fibrosis using routinely available clinical and laboratory variables from a Korean multicenter biopsy-proven MASLD cohort (STAR-K).

Method: The STAR-K retrospective cohort comprises 1,000 patients with biopsy-proven MASLD enrolled from 10 tertiary hospitals in South Korea. The dataset was divided using 5-fold cross-validation for model training, validation, and testing. Predictive performance for significant (≥F2) and advanced fibrosis (≥F3) was evaluated and compared with conventional scores, including the fibrosis-4 (FIB-4) index and NAFLD fibrosis score (NFS). Machine learning (Random Forest) and deep learning (DL; FT-Transformer, TabM, ExcelFormer) models were developed using base variables (age, AST, ALT, platelet count, BMI, diabetes status, albumin, and AST/ALT ratio). Additional analyses incorporated extended variables (INR, GGT, uric acid, LDL, and HDL). In a subset of patients (n = 810), model performance was compared with liver stiffness measurement (LSM) by transient elastography (TE).

Results: Under identical variable conditions, DL-based models showed superior performance compared with FIB-4 and NFS. The AUROC for predicting ≥F2 fibrosis was 0.7508 for FIB-4, 0.7587 for NFS, and 0.7947 for the DL model, while for ≥F3 fibrosis it was 0.7962, 0.8195, and 0.8446, respectively. Corresponding negative predictive

values were also higher for the DL model (≥F2: 0.7901 vs. 0.7083 and 0.6937; ≥F3: 0.8791 vs. 0.8176 and 0.7827 for FIB-4 and NFS, respectively). Incorporation of extended variables resulted in similar AUROC and NPV compared with the base-variable DL model. However, ML and DL models did not demonstrate clear superiority over LSM-based TE for fibrosis prediction.
Conclusion: In this multicenter biopsy-proven MASLD cohort, DL-based non-invasive models outperformed conventional clinical scores in predicting clinically meaningful fibrosis (F2–F3). These AI-based NITs may be useful for risk stratification and longitudinal monitoring in MASLD, although they currently serve best as complementary tools rather than replacements for TE.

WED-122
Optimal cut-off of 2D shear wave elastography for ruling out significant hepatic fibrosis in MASLD: a meta-analysis and machine learning
Mimi Kim[1], Eileen Yoon[2], Hyo Young Lee[2], Sang Bong Ahn[3], Joo Hyun Oh[4], Bo-Kyeong Kang[1], Chul-min Lee[1], Jihyun An[2], Ha Il Kim[2], Eun Chul Jang[5], Hye-Lin Kim[6], Jeong-Yeon Cho[7], Dae Won Jun[2]. *[1]Department of Radiology, Hanyang University College of Medicine, Seoul, Korea, Rep. of South; [2]Department of Internal Medicine, Hanyang University College of Medicine,, Seoul, Korea, Rep. of South; [3]Department of Internal Medicine, Nowon Eulji Medical Center, Eulji University, Seoul, Korea, Rep. of South; [4]Department of Internal Medicine, CHA University College of Medicine, Seongnam, Korea, Rep. of South; [5]Department of Occupational and Environmental Medicine, College of Medicine, Soonchunhyang University, Chunan, Korea, Rep. of South; [6]College of Pharmacy, Sahmyook University, Seoul, Korea, Rep. of South; [7]Department of Pharmacotherapy, University of Utah College of Pharmacy, Salt Lake, United States*
Email: noshin@hanyang.ac.kr

Background and aims: Two-dimensional shear wave elastography (2D-SWE) is a practical alternative for assessing liver fibrosis in primary care, where elastography devices are often unavailable. However, an optimal cut-off value to rule out significant fibrosis (≥F2) in metabolic dysfunction–associated steatotic liver disease (MASLD) remains unclear. This study aimed to determine the optimal cut-off through systematic review and meta-analysis.
Method: A comprehensive systematic review was conducted to identify studies evaluating the diagnostic performance of 2D-SWE for detecting significant hepatic fibrosis in MASLD, with liver biopsy as the reference standard. Pooled sensitivity and specificity were estimated using a bivariate random-effects model, and summary receiver operating characteristic curves were generated. Machine learning models were applied to define the optimal rule-out cut-off, which was validated using real-world clinical data.
Results: Twenty studies were included, encompassing 2,924 adults with biopsy-proven MASLD. The meta-analysis showed good diagnostic performance of 2D-SWE for significant fibrosis, with a summary area under the curve of 0.87 (95% confidence interval: 0.79–0.93). No significant differences were observed across different 2D-SWE manufacturers. Using a machine learning approach, the optimal cut-off value for ruling out significant fibrosis (defined as sensitivity >0.80 and negative predictive value (NPV) >0.95) was identified as 7.5 kPa. This threshold was validated using individual participant data across a range of thresholds (7.0–9.0 kPa). At 7.5 kPa, the model achieved a sensitivity of 0.88, specificity of 0.86, and NPV of 0.94, meeting key clinical criteria for a rule-out strategy.
Conclusion: 2D-SWE demonstrated good diagnostic performance in identifying hepatic fibrosis in patients with MASLD. A 7.5 kPa cut-off value was suggested as the optimal cut-offs for ruling out significant hepatic fibrosis. Two-dimensional shear wave elastography (2D-SWE), optimal cut-off, metabolic dysfunction–associated steatotic liver disease (MASLD).

WED-123
Data-driven identification of an IgA-enriched high-risk subtype in MASLD
Takefumi Kimura[1], Shun-Ichi Wakabayashi[1], Naoki Tanaka[1]. *[1]Shinshu University, Matsumoto, Japan*
Email: kimuratakefumii@yahoo.co.jp

Background and aims: Metabolic dysfunction-associated steatotic liver disease (MASLD) is a heterogeneous condition in which liver-related events (LRE) cannot be fully explained by fibrosis severity alone. Improved risk stratification requires identification of biologically distinct disease subtypes. We aimed to define prognostically relevant MASLD subgroups using a data-driven approach and to elucidate their underlying immune mechanisms.
Method: Unsupervised clustering was performed in biopsy-proven MASLD patients using routine clinical and biochemical variables. Multi-omics analyses, including hepatic qPCR, spatial transcriptomics, single-cell RNA sequencing, and immunohistochemistry, were applied to characterize high-risk subgroups. Prognostic findings were validated in independent cohorts.
Results: Four distinct MASLD clusters were identified. One cluster exhibited a markedly increased incidence of LRE (22% at 5 years, $P < 0.005$), which was not fully attributable to fibrosis stage. This high-risk subgroup was characterized by excessive IgA expression. Elevated serum IgA (≥318 mg/dL) independently predicted LRE (hazard ratio 2.02, $P = 0.01$), a finding consistently reproduced across validation cohorts. Immunohistochemistry demonstrated increased IgA-positive plasma cells in MASLD livers, correlating with serum EndoCAb IgG levels, suggesting enhanced gut permeability. Spatial transcriptomics and single-cell analyses revealed portal enrichment of IGHA1-expressing plasma cells, with associated activation of B-cell receptor signaling and extracellular matrix remodeling pathways.
Conclusion: A data-driven clustering strategy identified an IgA-enriched MASLD subtype with a high risk of liver-related events independent of fibrosis severity. IgA-driven immune activation along the gut–liver axis may represent a key pathogenic mechanism and a clinically relevant target for risk stratification in MASLD.

WED-125
Diagnostic performance of the FibroScan-AST (FAST) score for biopsy-proven metabolic dysfunction-associated steatohepatitis
Jaouhara Lahsini[1], Mohamed Borahma[1], Fatima Zahra Chabib[1], Nawal Lagdali[1], Fatima Zahra Ajana[1], Maryeme Kadiri[1]. *[1]Mohamed V University, Ibn Sina Hospital, Department C of hepato-gastroenterology, Rabat, Morocco*
Email: jaouhara.lahsini@gmail.com

Background and aims: Metabolic dysfunction-associated steatohepatitis (MASH) is the progressive form of metabolic dysfunction-associated steatotic liver disease (MASLD) and requires liver biopsy for definitive diagnosis. Non-invasive tools, including the FibroScan-AST (FAST) score, have been developed to improve risk stratification. This study aimed to evaluate the diagnostic accuracy of the FAST score and compare it with FibroScan parameters for predicting biopsy-proven MASH.
Method: This retrospective, single-centre study included 33 patients with MASLD who underwent both liver biopsy and FibroScan at a tertiary hepatology centre in Morocco between 2022 and 2025. MASH was defined according to histological criteria. FibroScan parameters included liver stiffness measurement (LSM) and controlled attenuation parameter (CAP). The FAST score was calculated using validated cut-offs: rule-out < 0.35, grey zone 0.35 to 0.67, rule-in ≥ 0.67. Diagnostic performance was assessed using ROC curve analysis with biopsy as the reference standard.
Results: Among 33 patients (mean age 46 ± 11 years, 78.8% women), 19 (57.6%) had biopsy-confirmed MASH. The FAST score demonstrated good diagnostic accuracy (AUROC 0.812), superior to LSM (AUROC 0.727) and CAP (AUROC 0.665). At the rule-out threshold,

sensitivity was 78.9% and specificity 85.7%; at the rule-in threshold, sensitivity was 47.4% and specificity 92.9%. CAP showed high sensitivity but limited specificity, particularly in patients with moderate steatosis (S1-S2).
Conclusion: The FAST score effectively identifies biopsy-proven MASH and outperforms CAP and LSM used alone. By integrating steatosis, fibrosis, and inflammatory activity, FAST is a clinically useful non-invasive tool for patient stratification and may refine the indication for liver biopsy in MASLD.

WED-126
Unmasking hidden risk: machine learning reveals ethnic-specific predictors of hepatocellular carcinoma in non-cirrhotic MASLD
Jeril Lasington[1], Lawin Steve Mathew Lasington[2]. *[1]New York Medical College, Valhalla, United States; [2]Rutgers University-Newark Arch, Newark, United States*
Email: lawinsteve.ls@gmail.com

Background and aims: Hepatocellular carcinoma (HCC) can develop in metabolic dysfunction-associated steatotic liver disease (MASLD) without cirrhosis, yet screening guidelines for this population remain absent. We developed an explainable machine learning (ML) model to identify HCC risk factors in non-cirrhotic MASLD and characterize ethnic-specific risk patterns.
Method: This cross-sectional study used the National Inpatient Sample (2019–2022) to identify adults with MASLD/MASH plus ≥1 metabolic risk factor (obesity, type 2 diabetes, hypertension, dyslipidemia) without cirrhosis, viral hepatitis, or alcohol-related liver disease. The primary outcome was concurrent HCC diagnosis. Four ML algorithms (Logistic Regression, Random Forest, XGBoost, LightGBM) were trained using temporal validation (2019–2021 training; 2022 testing) with SMOTE for class imbalance. SHAP analysis provided model interpretability, stratified by race/ethnicity.
Results: Among 287,517 non-cirrhotic MASLD patients (mean age 56 years; 58% female; 67% White), 711 (0.25%) had HCC. Logistic Regression achieved highest discrimination (AUC 0.848), followed by LightGBM (0.826). SHAP analysis identified age as the dominant predictor, followed by NASH histology, obesity, concurrent non-hepatic malignancy, and alcohol use disorder. Female sex was protective. HCC prevalence varied significantly by ethnicity: Asian/Pacific Islander patients had the highest rate (0.40%)—nearly three-fold higher than Black patients (0.14%)—with White (0.27%) and Hispanic (0.20%) patients intermediate. Ethnicity-stratified SHAP revealed distinct risk profiles: heart failure and hypokalemia predominated in Black patients, while sepsis emerged as a key predictor in Asian/Pacific Islander patients.
Conclusion: This ML model achieved strong discrimination for HCC in non-cirrhotic MASLD. Age and NASH histology are dominant predictors across all groups. Asian/Pacific Islander patients demonstrate the highest HCC prevalence and may warrant prioritized surveillance. These findings support development of ethnicity-informed, risk-stratified screening strategies for non-cirrhotic MASLD, addressing a critical gap in current guidelines.

WED-127
Emerging indices outperform traditional fibrosis scores in young MASLD across divergent screening goals
Ahlim Lee[1,2], Jaejun Lee[1,3], Hyun Yang[1,3]. *[1]The Catholic University Liver Research Center, The Catholic University of Korea, Seoul, Korea, Rep. of South; [2]St. Vincent's Hospital, The Catholic University of Korea, Suwon, Korea, Rep. of South; [3]Eunpyeong St. Mary's Hospital, The Catholic University of Korea, Seoul, Korea, Rep. of South*
Email: pwln0516@gmail.com

Background and aims: Although numerous noninvasive indices have been proposed to assess significant fibrosis (SF), none have been validated specifically in young adults with metabolic dysfunction-associated steatotic liver disease (MASLD). This study evaluated their performance in younger patients across two cohorts with distinct screening goals.
Method: We retrospectively analyzed two MASLD cohorts: a primary-care (PC) cohort from Armed Forces Goyang Hospital (n = 972) and a tertiary-care (TC) cohort from Eunpyeong St. Mary's Hospital (n = 342). SF was defined as liver stiffness ≥7.0 kPa on vibration-controlled transient elastography. The diagnostic performance of emerging indices (FIB-8, SAFE, MAF-5) was compared with traditional scores (FIB-4, APRI, NFS).
Results: Baseline comparisons showed significant differences in liver stiffness and other liver-related parameters, which were generally higher in the TC cohort. Across both settings, emerging indices consistently outperformed traditional scores for SF discrimination. In the PC cohort, the area under the receiver operative characteristic curves (AUROCs) were 0.735 for FIB-8, 0.766 for SAFE, and 0.812 for MAF-5, compared with 0.528 for FIB-4, 0.659 for APRI, and 0.608 for NFS. In the TC cohort, AUROCs were 0.691 for FIB-8 and 0.719 for SAFE, exceeding those of FIB-4 (0.572), APRI (0.635), and NFS (0.621). Decision curve analyses demonstrated that emerging indices provided greater net clinical benefit and larger reductions in unnecessary procedures, with thresholds differing by setting such that lower thresholds favored referral in the PC cohort, whereas higher thresholds were more appropriate for biopsy decisions in the TC cohort. Conventional cutoffs widely used in practice demonstrated limited sensitivity in this population, while thresholds optimized in this study yielded more balanced diagnostic accuracy, suggesting refinement may be required in clinical practice.
Conclusion: Traditional NITs showed limited performance in young adults with MASLD, whereas emerging indices such as FIB-8, SAFE, and MAF-5 appeared more suitable for achieving the screening goals of referral in PC and biopsy decision-making in TC. Nonetheless, refined cutoff values might be necessary for younger adults when applying both traditional and emerging indices.

WED-131
The sequential use of LiverPRO and ADAPT enhances fibrosis detection in at-risk populations
Diana Julie Leeming[1], Ida Lønsmann Sorribes[1], Cecilie Bager[1], Frederik Christiansen[1], Julie Astono[2], Bruno Golding[3], Morten Karsdal[1], Aleksander Krag[4], Katrine Lindvig[2], Maja Thiele[2,4]. *[1]Nordic Bioscience, Biomarkers & Research, Herlev, Denmark; [2]Evido Health, Copenhagen, Denmark; [3]Roche Diagnostics International, Rotkreuz, Switzerland; [4]FLASH – Centre for Liver Research, Department of Gastroenterology and Hepatology, Odense University Hospital and University of Southern Denmark, Odense, Denmark*
Email: djl@nordicbio.com

Background and aims: With approval of therapies for metabolic dysfunction–associated steatohepatitis (MASH), reliable non-invasive tests (NITs) are required to identify patients with fibrotic MASH for referral and treatment. We evaluated sequential blood-based NIT strategies combining the LiverPRO score, FIB-4, and the PRO-C3–based ADAPT algorithm to detect significant liver fibrosis in a population-based cohort.
Method: This single-centre liver fibrosis screening cohort included Danish participants recruited from the general population (n≈3,400) or with self-reported risk factors for steatotic liver disease (n≈3,000). All underwent same-month blood sampling and liver stiffness measurement (LSM by FibroScan®). Participants with LSM ≥8 kPa were invited for repeat LSM and liver biopsy. Significant fibrosis was defined as biopsy ≥F2 at visit 2. Diagnostic performance was assessed by sensitivity/specificity (sens/spec). LiverPRO combines up to nine routine blood tests to estimate fibrosis risk. ADAPT includes Elecsys® PRO-C3 as part of ADAPT, platelet count, age, and diabetes. We compared two-tier strategies, LiverPRO (≥0.25) or FIB-4 (≥1.3/2.0), followed by ADAPT (≥9.0), against FIB-4 alone.
Results: Among 6,443 participants, median age was 57 years (IQR 52–63), 48% male, BMI 28 kg/m^2 (25–33), and 9.7% had diabetes. Biopsy

was performed in 3.7% of the population of whom 70% had significant fibrosis (n = 168/242). Biopsy data showed 1.3% (n = 81) F2, 0.3% (n = 52) F3, and 0.5% (n = 35) F4 fibrosis. After exclusions, 5,639 participants were analysed. FIB-4 alone referred 27% with sens/spec 63%/74% and missed six F4 cases. LiverPRO referred 40% with sens/spec 92%/61%, missing one F4. LiverPRO followed by ADAPT improved sens/spec to 82%/81%, referred 21%, missed two F4 cases, and reduced referrals by 47% versus LiverPRO alone. FIB-4 followed by ADAPT referred 17%, achieved sens/spec 61%/84%, missed six F4 cases, and reduced referrals by 35% versus FIB-4 alone.
Conclusion: Sequential testing with LiverPRO and ADAPT provides high sensitivity for detecting significant fibrosis, minimizes missed cirrhosis, and reduces unnecessary referrals. This strategy outperformed FIB-4–based approaches, supporting advanced multivariable algorithms for fibrosis risk stratification.

WED-132
Evaluating the uptake of fibrosis-4 index as a screening tool for liver fibrosis in patients with type 2 diabetes
Calven Fu-Hao Lim[1], Min Chow[1], Jess Jie-Ying Ng[1], Hak-Keith Leung[1], Guo-Jeng Tan[1], Lee-Ling Lim[2,3,4,5,6], Jeyakantha Ratnasingam[2], Shireene Ratna Vethakkan[2], Pavai Sthaneshwar[7], Wah-Kheong Chan[1].
[1]Gastroenterology and hepatology Unit, Department of Medicine, Universiti Malaya, Kuala Lumpur, Malaysia; [2]Endocrine Unit, Department of Medicine, Universiti Malaya, Department of Medicine, Kuala Lumpur, Malaysia; [3]Department of Research, Development, and Innovation, Universiti Malaya Medical Centre, Kuala Lumpur, Malaysia; [4]Department of Medicine and Therapeutics, The Chinese University of Hong Kong, Hong Kong SAR, China; [5]Asia Diabetes Foundation, Hong Kong SAR, China; [6]Baker Heart and Diabetes Institute, Melbourne, VIC, Australia; [7]Department of Pathology, Universiti Malaya, Kuala Lumpur, Malaysia
Email: s2188754@siswa.um.edu.my

Background and aims: Metabolic dysfunction–associated steatotic liver disease is common among patients with type 2 diabetes (T2D), who are at increased risk of progressing to cirrhosis, yet fibrosis often remains clinically silent until hepatic decompensation occurs. This study aimed to evaluate the uptake of Fibrosis-4 index (FIB-4) as a risk stratification tool in patients with T2D.
Method: This was a retrospective study of consecutive patients with T2D who were seen in the Diabetes Clinic of University of Malaya Medical Centre between 1 January 2023 and 31 December 2023. Patients were identified as having higher risk of future cirrhosis based on elevated FIB-4 ≥1.3.
Results: The data for 1009 patients were analysed, median age 62 (52–71) years, 40.7% male. Elevated FIB-4 was seen in 28.8% (291/1009). Only 12.0% (35/291) with elevated FIB-4 were referred for further hepatology evaluation. Patients with elevated FIB-4 who were referred for further hepatology evaluation (compared with those who were not referred) were more likely known to have hepatic steatosis, had higher alanine aminotransferase, aspartate aminotransferase, gamma glutamyl transferase, and lower low-density lipoprotein cholesterol and platelet count. Among patients with low FIB-4, 3.3% (24/718) were referred for further hepatology evaluation.
Conclusion: Despite the incorporation of automatically calculated FIB-4 into laboratory report, this risk stratification tool was found to be under-utilised in patients with T2D, with the majority of patients at higher risk of future cirrhosis not referred for further hepatology evaluation, translating to missed opportunities for timely identification and management of patients with more severe liver disease.

WED-133
The metabolic body risk index (MBRI) based on anthropometric composite and machine learning for non-invasive diagnosis of MASLD
Yingying Lin[1], Yuyun Song[1], Ke Yin[1], Xu Cong[1], Ran Fei[1], Wang Zilong[1], Xin Ai[1], Minjun Liao[1], Xiaoxiao Wang[1], Huiying Rao[1], Feng Liu[1].
[1]Peking University People's Hospital, Peking University Hepatology Institute, Infectious Disease and Hepatology Center of Peking University People's Hospital, Beijing, China
Email: linyingying0123@163.com

Background and aims: Metabolic dysfunction-associated steatotic liver disease (MASLD) is closely linked to obesity and abnormal fat distribution, but single anthropometric indices show limited and inconsistent diagnostic performance. We derived a composite anthropometric index, the metabolic body risk index (MBRI), to enhance the identification of MASLD.
Method: We analysed 5,297 adults from NHANES 2017–2020, which was divided into training and test sets, and utilized the NHANES 2020–2023 cohort (n = 2,427) for external validation. In the training set, 17 anthropometric variables were entered into LASSO regression; selected variables were linearly combined to construct MBRI. Multivariable logistic models with restricted cubic splines assessed the association between MBRI and MASLD. Diagnostic performance for MASLD and MASLD with severe steatosis was evaluated by receiver operating characteristic (ROC) curves and area under the curve (AUC), and compared with each component index. To further improve discrimination, we applied LASSO and Boruta feature selection to MBRI and routine biochemical markers to develop machine learning models, utilizing SHAP values for interpretability.
Results: LASSO regression selected waist circumference, waist-to-height ratio, waist-to-hip ratio, TyG, conicity index and lipid accumulation product to form MBRI. Restricted cubic splines showed a significant non-linear association between higher MBRI and MASLD risk (p for non-linearity < 0.001). Across training, test and validation cohorts, AUCs of MBRI were 0.736–0.762 for MASLD and 0.776–0.798 for MASLD with severe steatosis, all higher than those of individual component indices. After inclusion of selected biochemical markers, machine-learning models achieved further improvement; in the validation cohort, the best model (GBM) reached AUCs of 0.770 for MASLD and 0.806 for MASLD with severe steatosis, outperforming FIB-4, NFS, APRI and HSI (AUC 0.532–0.714 and 0.546–0.752, respectively). SHAP analysis demonstrated that MBRI was the most significant predictor across models.
Conclusion: MBRI, a composite index derived from routine anthropometry, enables non-invasive identification of MASLD and MASLD with severe steatosis. Combining MBRI with a small panel of biochemical markers in interpretable machine-learning models significantly enhances diagnostic performance, proving beneficial for population screening and risk stratification.

WED-134
Development, validation, and longitudinal monitoring of a machine learning model for prediction of liver fibrosis and liver-related events in community-dwelling adults: a prospective, multicohort study

Email: qixiaolong@vip.163.com

Background and aims: Noninvasive tests (NITs) for detecting liver fibrosis in the community remain limited in accuracy and generalizability across global regions. This study aimed to develop and validate a novel score for predicting liver fibrosis, liver-related events (LREs), and longitudinal changes in risk in community-dwelling adults.
Method: We conducted a prospective, multicohort study including adults aged ≥ 18 years from community-based populations in China, Denmark, the United States, and the United Kingdom. Among several candidate machine learning models evaluated, extreme gradient boosting (XGBoost) achieved the best overall performance and was therefore selected for development of the LiverHealth score (free access: https://liverhealthscore.shinyapps.io/chess/). The LiverHealth score was derived in a community-based cohort and externally validated in three independent cohorts, all of whom underwent liver stiffness measurement (LSM) by transient elastography (Fibroscan®). Clinically significant fibrosis was defined as LSM ≥ 8 kPa or histological stage ≥ F2. Prognostic performance for liver-related events (LREs) was evaluated in a large population-based cohort, and longitudinal risk changes were assessed in a dynamic cohort with repeated measurements.
Results: We included 27601 participants: 10790 in the derivation cohort and 9154, 3004, and 4653 in validation cohorts 1, 2, and 3, respectively. The prognostic and dynamic cohorts included 454415 and 17379 participants, respectively. The LiverHealth score showed superior performance for predicting LSM ≥8 kPa in the derivation cohort (AUROC = 0.85 [0.83–0.86]) and validation cohorts 1 (0.81 [0.78–0.83]), 2 (0.85 [0.82–0.87]), and 3 (0.80 [0.78–0.82]), significantly outperforming LiverRisk, LiverPRO, CORE, FIB-4, APRI, and NFS (all $p < 0.001$). In the biopsy-assessment subgroup (n = 2929), the AUROC was 0.91 (0.88–0.93) for histological stage ≥ F2. Using rule-out and rule-in thresholds, participants were stratified into low-, medium- and high-risk groups, achieving highest sensitivities of 91.5%, 81.3%, 97.3%, and 88.7% across the derivation and validation cohorts. In the prognostic cohort, medium- and high-risk groups had significantly higher LRE incidence than the low-risk group. In the dynamic cohort, risk progression was associated with higher LRE incidence, whereas risk regression was associated with lower incidence.
Conclusion: The LiverHealth score accurately predicts liver fibrosis and liver-related events in community-dwelling adults.

Email: eka-lusina@yandex.ru

Background and aims: Metabolic dysfunction-associated steatotic liver disease (MASLD) is a growing global health concern. While metabolic risks are well-established, the contribution of occupational factors remains insufficiently addressed. This study aimed to evaluate the association between occupational hazards (physical, chemical, and organizational) and MASLD prevalence and biochemical activity in a large Russian cohort.
Method: This investigator-initiated, multicenter, cross-sectional study was conducted across 27 Russian cities (43 outpatient centers) between March and June 2025. Out of 3,748 consecutive patients screened (aged 18–90 years), 1,510 participants had sufficient data to be evaluated for MASLD based on 2023 criteria. Data on occupational hazards and work environment were available for 1.323 participants, of whom 147 (11.1%) reported exposure. Hazards were assessed via patient self-reports and defined as regular contact with chemical or physical agents, as well as irregular work schedules, including night and 24-hour shifts.
Results: Patients exposed to occupational hazards exhibited a significantly worse metabolic profile, with a median BMI 28 kg/m^2 (IQR 24–31) vs. 26 kg/m^2 (IQR 23–30) ($p < 0.001$) and waist circumference of 98 cm (IQR 88–105) vs. 92 cm (IQR 80–102) ($p < 0.001$) together with marginally higher liver enzyme levels of ALT 23 U/L (IQR 17–35) vs. 21 U/L (IQR 14–32) ($p < 0.05$); GGT 31.8 U/L (IQR 21.5–69.5) vs. 24 U/L (IQR 16–39) ($p < 0.05$). Systolic and diastolic blood pressure values were also higher in the exposed group ($p < 0.001$). In the cohort 686 patients met MASLD criteria. The prevalence of MASLD was significantly higher among patients exposed to occupational hazards (61.9% vs. 50.6%, p = 0.01; OR 1.58, 95% CI 1.12–2.25). Irregular working hours alone were also associated with increased MASLD risk (61.1% vs. 47.8%, p = 0.031; OR 1.714, 95% CI 1.062–2.76). However, in the multivariate logistic regression model adjusted for age, BMI, and blood pressure, the occupational factor did not retain statistical significance.
Conclusion: Our results suggest that occupational hazards and irregular working schedules may contribute to an increased risk of MASLD and a metabolic phenotype of abdominal obesity. Multivariate analysis indicates that this effect is mediated by the deterioration of BMI and blood pressure rather than acting as an independent risk factor. These results highlight the importance of considering occupational history as a potential factor in MASLD risk assessment.

WED-136

Prevalence and characteristics of patients with lean metabolic dysfunction-associated steatotic liver disease: data from a Russian real-world cohort

Igor Tikhonov[1], Ekaterina Liusina[2], Anna Sheptulina[2], Valeriy Lunkov[3], Natalia Trofimovskaya[1], Stanislava Zakharova[4], Elena Novitskaia[5], Viktoriya Vorobeva[6], Raisa Kapitova[3], Elena Sadomova[7], Yuliia Churkina[8], Yulia Egorova[9], Evgeniia Zakharova[10], Andrey Lipov[11]. *[1]Sechenov University, Moscow, Russian Federation; [2]National Medical Research Center for Therapy and Preventive Medicine, Moscow, Russian Federation; [3]Medsi Group JSC, Moscow, Russian Federation; [4]Lomonosov Moscow State University, Moscow, Russian Federation; [5]LCC Women's Clinic "Alpha", Chelyabinsk, Russian Federation; [6]CDC "Viveya", Chabarovsk, Russian Federation; [7]V.I. Email: antihbs@gmail.com

Background and aims: Metabolic dysfunction-associated steatotic liver disease (MASLD) in individuals with normal body weight is an emerging phenotype. Lean MASLD differs from obesity-associated disease and presents diagnostic and treatment challenges. We aimed to characterize the clinical and biochemical features of lean MASLD compared to "non-lean" MASLD in a large Russian cohort.
Method: This multicenter, cross-sectional study was conducted at 43 Russian outpatient clinics. Out of 3,748 consecutive patients screened (aged 18–90), 1,510 had sufficient data for evaluation based on 2023 criteria. Participants were categorized by BMI (cut-off 25 kg/m^2) and the presence of MASLD into lean MASLD (BMI <25 kg/m^2 with liver steatosis diagnosed by US), non-lean MASLD (BMI ≥25 kg/m^2 with steatosis), and lean healthy controls (BMI <25 kg/m^2 without steatosis). Clinical and biochemical data and FIB-4 scores were analyzed.
Results: MASLD prevalence was 51.9% (n = 784). Within the MASLD cohort, 9.8% (n = 77) were classified as lean MASLD (5.1% of the total population). The lean MASLD group had a median age of 57 years (IQR 45–67) and a BMI of 23.6 kg/m^2 (IQR 21.8–24.1). Lean and non-lean MASLD groups showed no significant differences in age or sex distribution. While the frequency of diabetes mellitus and arterial hypertension was similar, the total cardiometabolic risk burden was higher in the non-lean group (5 vs. 3 factors, $p < 0.001$). In the MASLD group, lean MASLD patients had significantly lower waist circumference (83.5 vs. 102.0 cm, $p < 0.001$), ALT (20.65 vs. 27.7 U/L, $p = 0.029$), glucose (5.14 vs. 5.6 mmol/L, $p < 0.001$), and triglycerides (1.10 vs. 1.55 mmol/L, $p = 0.0036$) compared to non-lean patients. Hyperuricemia was 0% in the lean group vs. 8% in the non-lean group ($p < 0.005$, Fisher's exact test). No significant difference in FIB-4 scores was found between the groups. Compared to lean healthy controls, the lean MASLD group demonstrated significantly higher values across all parameters: age, waist circumference, blood pressure, and all laboratory markers ($p < 0.05$).
Conclusion: In our cohort, lean MASLD represents up to 10% of cases. Despite normal BMI and waist circumference, these patients exhibit a metabolic profile significantly worse than lean healthy controls. This highlights the need for MASLD screening regardless of weight status and mandates further research into underlying drivers, such as microbiota composition and genetic polymorphisms.

WED-137

Real-life evaluation of the FIB-4 two-step fibrosis screening strategy in MASLD: measurement of waist circumference might make the difference

Rosa Lombardi[1], Andrea Dalbeni[2], Felice Cinque[1], Annalisa Cespiati[1], Cristina Bertelli[1], Giovanna Oberti[1], Giuseppina Pisano[1], Erika Fatta[1], Edoardo Pulixi[1], Gabriele Maffi[1], Francesca Alletto[1], Daniel Smith[1], Anna Mantovani[2], David Sacerdoti[2], Anna Ludovica Fracanzani[1]. *[1]Fondazione IRCCS Ca' Granda Ospedale Maggiore Policlinico di Milano, University of Milan, Milan, Italy; [2]Azienda Ospedaliera Universitaria Integrata of Verona, Verona, Italy*
Email: rosalombardi@hotmail.it

Background and aims: Accurate detection of advanced fibrosis in metabolic dysfunction–associated steatotic liver disease (MASLD) is crucial for timely referral to hepatology care. Current guidelines recommend a two-step screening strategy using FIB-4 (cut-off 1.3 or 2.0 if >65 years) followed by liver stiffness measurement (LSM ≥8 kPa). We aimed to assess the real-life performance of FIB-4 in MASLD patients referred to hepatology clinics and to identify factors influencing misclassification.
Method: Multicenter study including 1,484 MASLD patients (mean age 53 ± 13 years, 61% males) referred to two hepatology clinics (Milan and Verona) and fulfilling criteria for guideline-recommended screening (diabetes, obesity with comorbidities, or elevated transaminases).
Results: Fibrosis prevalence (LSM ≥8 kPa) was 29%. FIB-4 <1.3/2 and ≥1.3/2 were observed in 1,049 (71%) and 435 (29%) patients. Using the reccomended cut-off, 224/1,049 (21%) patients were false negatives and 224/435 (51%) false positives. FIB-4 showed good specificity (79%) and negative predictive value (NPV) (79%) but low sensitivity (48%), with an accuracy of 70% (AUC 0.70; 95% CI 0.68–0.74). Patients misclassified as non-fibrotic (FIB-4 <1.3/2; LSM ≥8 kPa) compared to those correctly classified (FIB-4 <1.3/2; LSM <8 kPa) were significantly older, more hypertensive and diabetic, with higher HOMA, BMI, waist circumference (WC), triglycerides and fasting glucose. In multivariable analysis WC remained the only independent factor associated with LSM≥8 kPa (OR 1.07, 95% CI 1.02–1.12).Conversely, patients misclassified as fibrotic (FIB-4 ≥1.3/2; LSM <8 kPa) compared to those correctly classified (FIB-4 ≥1.3/2; LSM ≥8 kPa), were younger and with lower WC, BMI, fasting glucose and HOMA index; WC remained independently and inversely associated with LSM>8 kPa (OR 0.95, 95% CI 0.92–0.99). Incorporating WC into patients classified as low risk by FIB-4(FIB<1.3 plus increased WC equal to FIB4≥1.3) markedly increased sensitivity and NPV up to 82%, reducing the number of patients with LSM≥8 kPa who would have been missed by FIB-4 alone, but with a reduction in specificity (34%).
Conclusion: In this real-life MASLD cohort referred to the hepatology clinic, FIB-4 may lead to misclassification. The integration of waist circumference, an easily obtainable marker of visceral adiposity, enhanced the performance of a stepwise screening strategy, improving sensitivity for advanced fibrosis and reducing missed referrals.

WED-138

Metabolome analysis revealed red flag signatures for the identification of MASLD risk across patients with dysmetabolic traits

Miriam Longo[1], Marica Meroni[1], Erika Paolini[1], Giulia Paolella[1], Rosa Lombardi[1,2], Valentina Flagiello[3], Jessica Avagliano[3], Carola Garavaglia[2], Elisa Polledri[2], Rosa Mercandate[2], Paolo Gallo[3], Francesca Terraciani[3], Silvia Fustinoni[1,2], Carlo Agostoni[1], Monica Gomaraschi[2], Umberto Vespasiani-Gentilucci[3,4], Anna Ludovica Fracanzani[1,2], Paola Dongiovanni[1]. *[1]Fondazione IRCCS Cà Granda, Ospedale Maggiore Policlinico, Milano, Italy; [2]Università degli Studi di Milano, Milano, Italy; [3]Fondazione Policlinico Universitario*

Campus Bio-Medico di Roma, Roma, Italy; [4]Research Unit of Clinical Medicine and Hepatology, Università Campus Bio-Medico di Roma, Roma, Italy
Email: paola.dongiovanni@policlinico.mi.it

Background and aims: Adolescents and adults with dysmetabolic traits can either develop MASLD or show no evidence of fatty liver despite comparable cardiometabolic burden. However, it is still unclear whether patients with MASLD exhibit a specific circulating metabolic fingerprint compared to non-MASLD dysmetabolic subjects. Therefore, we aimed to analyze the serum metabolomic profile in a dysmetabolic cohort (n = 383), including adolescents with MASLD (n = 100, A-MASLD), adults with biopsy-proven (n = 95, B-MASLD) or non-invasive MASLD (n = 88, NI-MASLD) diagnosis, and a control group of dyslipidemic patients (n = 100, Dys) without MASLD.
Method: Targeted metabolomics (TM) was performed by UHPLC and analyzed through MetaboAnalyst 6.0.
Results: Serum TM analysis revealed two main hierarchical clusters across dysmetabolic patients, highlighting that A/B-MASLD and NI-MASLD/Dys showed a similar metabolic pattern, respectively. In particular, ~100 species were dysregulated (adjusted $p < 0.05$ FDR) in A/B-MASLD *vs* NI-MASLD/Dys patients. Among them, 64 metabolites were shared between the A/B-MASLD groups, suggestive of a conserved signature across pediatric and adult biopsied cases potentially due to a comparable rate of severe disease. To discover candidate MASLD-specific biomarkers, we performed the intersection analysis of differentially abundant species across the 4 groups. Sixteen metabolites were consistently altered in all MASLD patients (A- B- NI-MASLD) vs Dys. Two of them, glutamic acid and phosphatidylcholine (PC) O-40:6, accurately discriminated MASLD from non-MASLD with 94% AUC (sens: 95%, spec: 88%), remaining stable after 10-fold cross-validation. Next, in the attempt to identify compounds with potential prognostic value, we stratified the dysmetabolic cohort according to MASLD severity. Nine metabolites were mainly dysregulated in severe disease vs controls (Dys). At multivariate and cross-validation analyses, a 5-metabolite model (Decanoylcarnitine, Ocatnoylcarnitine, Leucine, LysoPC 18:2, SM 41:2) achieved the best performance in distinguishing between severe MASLD vs controls (AUC 93%; sens: 87%; spec: 88%).
Conclusion: Serum TM analysis captured a specific circulating profile shared across young and adult MASLD patients, possibly linked to an advanced clinical phenotype, which may be a red flag for cardiometabolic complications in pediatric cases. Furthermore, we disclosed 2 compounds specific for MASLD and 5-metabolites highly predictive of severe MASLD.

WED-139
Machine learning models of non-invasive tests to predict MASH and fibrosis stage based on MAESTRO-NAFLD-1 and MAESTRO-NASH liver biopsies

Rohit Loomba[1], Rebecca Taub[2], Dominic Labriola[2], Jan Priel[3], Krishna Padmanabhan[3], W. Ray Kim[4]. *[1]University of California San Diego School of Medicine, La Jolla, United States; [2]Madrigal Pharmaceuticals, Inc., West Conshohocken, United States; [3]Cytel, Inc., Berlin, Germany; [4]Mayo Clinic, Stanford, United States*
Email: roloomba@health.ucsd.edu

Background and aims: Fibrosis stage in patients with Metabolic Dysfunction-Associated Steatohepatitis (MASH) is currently diagnosed by liver biopsy for the purpose of staging in clinical trials. Although non-invasive tools have emerged, no consensus method exists for staging fibrosis and/or diagnosing MASH with moderate to advanced liver fibrosis, a progressive liver disease. We aimed to develop machine learning (ML) methods to predict fibrosis stage and MASH with F2/F3 Fibrosis using non-invasive biomarkers.
Method: Data from 1,970 biopsy-confirmed patients who screened for phase 3 resmetirom trials (MAESTRO-NASH, MAESTRO-NAFLD-1) were retrospectively analyzed. Outcomes included predictions of fibrosis stage and "MASH with F2/F3 Fibrosis" (NAS ≥4 and moderate-to-advanced noncirrhotic fibrosis) based on thirty-seven predictors (including clinical, laboratory, and imaging measures). Models using random forest were developed, selected for accuracy and stability, in two settings: full predictor models (using all 37 variables) and "lean" models (a subset of predictors routinely available in clinical practice). Performance was evaluated with 4-fold cross-validation via area under the curve (AUC).
Results: Random forest models to predict three classes of fibrosis stages (F0/F1 vs. F2/F3 vs. F4) resulted in one-vs-rest cross-validation mean AUCs for the full data model (0.76, 0.75, and 0.94, respectively) and best performing lean model (0.83, 0.78, and 0.89, respectively). The most important factors included liver stiffness measures (MRE (magnetic resonance elastography), TE (transient elastography)) and MASH composite algorithms. In a model predicting MASH with significant (i.e., Stage 2/3) liver fibrosis, the full and lean models achieved AUCs of 0.75 and 0.79, respectively.
Conclusion: ML models using non-invasive biomarkers, with routinely available clinical predictors, accurately predict fibrosis stage and MASH with F2/F3 Fibrosis, supporting their potential to identify patients with MASH and moderate to advanced liver fibrosis for clinical trials or clinical practice.

WED-140
AI based cell free DNA methylation blood test for semaglutide response in patients with at-risk MASH: Results from SAMARA randomized control trial

Rohit Loomba[1], Egbert Madamba[1], Seema Singh[1], Leila Bazargan[2], Chong Lu[2], Hamed Amini[2], Soheil Damangir[2]. *[1]University of California, San Diego, La Jolla, United States; [2]Hepta Bio, Inc., Foster City, United States*
Email: soheil@hepta.bio

Background and aims: GLP-1 receptor agonists are emerging as effective treatments for metabolic dysfunction-associated steatohepatitis (MASH), yet tools to characterize their biological effects remain limited. We analyzed plasma cell-free DNA (cfDNA) methylation from the SAMARA trial to determine whether semaglutide induces distinct epigenetic changes compared to placebo and whether baseline methylation can distinguish treatment responders.
Method: Twenty-seven SAMARA participants with paired plasma samples (13 semaglutide, 14 placebo) were analyzed at baseline and end of treatment (~1 year; dose up to 2.4 mg subcutaneous weekly). A whole-methylome assay and AI model (LiquidTransformer) were used to segment the genome into biologically meaningful units and characterize methylation patterns. For each patient, we computed methylation change (end-of-treatment minus baseline) and identified regions differing between arms using the Mann-Whitney U statistic. Separately, we compared baseline methylation between responders and non-responders within the semaglutide arm. Pathway enrichment analysis was performed on significant regions.
Results: Semaglutide-treated patients exhibited methylation trajectories distinct from placebo, demonstrating a treatment-specific biological signal in cfDNA. Pathway analysis identified 28 significantly enriched GO terms: lipid metabolism including cholesterol biosynthesis and fatty acid transport; fibrosis and ECM remodeling including collagen signaling and SMAD regulation; neuronal development including axon guidance and CNS axonogenesis; cardiovascular function including nitric oxide and VEGF signaling; tissue repair including Wnt/catenin signaling; and renal development. Baseline methylation also distinguished responders from non-responders, with enrichment in Wnt/catenin signaling, immune regulation including T cell activation, and tyrosine kinase pathways. Notably, Wnt/catenin was enriched in both analyses, suggesting its role in GLP-1 response biology in MASH.
Conclusion: AI-enabled cfDNA methylation profiling distinguished semaglutide from placebo and identified baseline signatures associated with treatment response. Treatment-associated changes independent of clinical response magnitude were present even in

partial responders, suggesting cfDNA captures upstream biological effects not yet reflected in clinical outcomes. This approach may support precision strategies for predicting and monitoring GLP-1 agonist response.

WED-141

Patients with compensated MASH cirrhosis and Fibroscan® VCTE score <15 kPa: baseline data from a phase 3, double-blinded, randomized clinical trial assessing the safety and efficacy of pegozafermin (ENLIGHTEN-Cirrhosis)

Rohit Loomba[1], Naim Alkhouri[2], Quentin M. Anstee[3], Hank Mansbach[4], Cynthia L. Hartsfield[4], Laura Contreras[4], Jasmine Dowlat[4], Jennifer B Kang[4], Shibao Feng[4], Maya Margalit[4]. [1]*University of California San Diego, San Diego, CA, United States;* [2]*Summit Clinical Research, San Antonio, TX, United States;* [3]*Newcastle University, Newcastle upon Tyne, United Kingdom;* [4]*89bio Inc, San Francisco, CA, United States*
Email: maya.margalit@89bio.com

Background and aims: The Fibroscan® VCTE-LSM score is increasingly replacing liver biopsy in the assessment of patients with MASH. The diagnosis of cirrhosis in patients with MASH carries important prognostic and practical implications. In recent updates to the AASLD MASLD guidelines following the approval of drugs for non-cirrhotic MASH, no further evaluation to exclude cirrhosis is advised for patients with VCTE-LSM scores ≤15 kPa. ENLIGHTEN-Cirrhosis (NCT06419374) is an ongoing Phase 3 trial designed to assess the efficacy and safety of pegozafermin in MASH-cirrhosis. This analysis explores the baseline characteristics of randomized subjects with VCTE-LSM score < 15 kPa.
Method: Presence of metabolic risk factors and biopsy-proven MASH cirrhosis (within 6 months of screening, biopsies are scored by consensus read of 3 expert pathologists) are inclusion criteria in the ENLIGHTEN-cirrhosis study. The entry criteria do not have a minimal VCTE cutoff. Baseline data from subjects with VCTE-LSM score <15 kPa of the first 337 randomized subjects were analyzed.
Results: 122 randomized subjects (36%) had VCTE scores <15 kPa. In this subgroup, mean age was 61.5 years, 66% of subjects were female, 80% were diabetic, and 43% were taking a GLP-1RA. Mean BMI was 33.2 kg/m^2. Mean VCTE-LSM, ELF and FIB-4 were 11.0 (range 4.6–14.9) kPa, 10.1 and 1.9, respectively. The mean platelet count was 199×10^3, and 20% of subjects had small varices. The liver biopsy Laennec score was 4a, 4b and 4c in 38%, 57% and 5% of subjects, respectively. The mean NAS score was 2.7; 16% of subjects had no steatosis and 61% had no ballooning on liver biopsy. Mean liver fat by MRI-PDFF was 9.3%.
Conclusion: Cirrhosis would have been missed in >1/3 of randomized subjects in this large cohort of well-characterized subjects with biopsy-proven MASH-cirrhosis if a VCTE score <15 kPa been used to exclude cirrhosis. Although data from a clinical trial may not be fully representative of patients with MASH cirrhosis in general, they suggest that exclusion of cirrhosis by a VCTE-LSM score ≤15 kPa cut-off may lead to inadvertent initiation of drugs for non-cirrhotic MASH and failure to initiate indicated standard-of-care management in a substantial proportion of patients with MASH cirrhosis.

WED-142-YI

Development of an indigenous clinical risk model for early detection of liver fibrosis in an indian community cohort

Sundaresan Mohanraj[1], Vijaya Prakash Madesh[2], Abirami Perumal[1], Sibithooran Karmegam[2], Aravindh Somasundram[2], Arulraj Ramakrishnan[1,2]. [1]*KMCH research Foundation, Dr.NGP Arts and Science College, Coimbatore, Tamilnadu, India;* [2]*Liver Unit, Kovai Medical Center and Hospital, Coimbatore, Tamilnadu, India*
Email: mohanrajs.kmchrf@gmail.com

Background and aims: Non-invasive fibrosis scores such as FIB-4, APRI, SAFE, MAF-5, and Liver Risk Score are widely used for liver fibrosis assessment, but their performance in the Indian general population is suboptimal. In our earlier community cohort, these scores showed only moderate accuracy against FibroScan. This highlighted the need for an indigenous, population-specific tool. We therefore aimed to develop and internally validate a clinical model to predict clinically significant liver fibrosis in an Indian population.
Method: Phase I (KMCH-NCD Study-I) evaluated established fibrosis scores in a community cohort of 1,952 adults (2017–2018), using FibroScan liver stiffness measurement (LSM) as the reference. Phase II (KMCH-NCD Study-II) included 2,379 adults (2022–2023) to develop the new model. Clinically significant fibrosis was defined as LSM ≥7.0 kPa. Participants were randomly divided into derivation (70%, n = 1,665) and validation (30%, n = 714) cohorts.A multivariable machine-learning clinical model was developed using age, BMI, AST, platelet count, HDL cholesterol, and creatinine. The risk equation was: Fibrosis Risk Score = −5.834 + (0.0268 × Age) + (0.1011 × BMI) + (0.0387 × AST) − (0.00157 × Platelet) + (0.00064 × HDL) + (0.0763 × Creatinine). Model performance was compared with FIB-4, APRI, and NFS using AUROC.
Results: In the validation cohort, clinically significant fibrosis was present in 21.5%. The indigenous model showed good discrimination (AUROC 0.73; 95% CI 0.68–0.77; $p < 0.001$). At the Youden-optimal cut-off, sensitivity was 71% and specificity 68%. For community screening, the negative predictive value exceeded 90%, supporting rule-out utility. Under hospital-based prevalence assumptions (30%), PPV increased to 46%, indicating improved rule-in capability. The random forest model showed similar discriminatory performance and provided higher net clinical benefit across a wide range of decision thresholds. In comparative analysis, the new model outperformed traditional fibrosis scores (FIB-4 AUROC 0.60; APRI 0.63; NFS 0.62), with forest-plot comparison demonstrating consistently higher point estimates for the indigenous model.
Conclusion: Traditional fibrosis scores showed limited accuracy in Indian community screening. Using an independent population cohort, we developed an indigenous clinical fibrosis prediction model with improved discrimination and practical rule-out capability. External validation, including biopsy-based confirmation, is needed before routine clinical adoption.

WED-147

Ethnic variation in FibroScan-detected fibrosis and steatosis in a large multi-ethnic cohort: implications for MASLD screening

Ilya Abedi[1], Jumshaid Qureshi[1], Elkhashab Magdy[1], Marzena Magnes[1], Gabriel Bishara[1], Katarina Kangrga[1], Marianthi Masri[1], Michelle Guerrero[1], Gabriel Tarzi[1], Jillian Ho[1], Nada Elzahabi[1]. [1]*Toronto Liver Centre, Toronto, Canada*
Email: ilyaabedi2@gmail.com

Background and aims: FibroScan ® allows non-invasive assessment of liver fibrosis and steatosis through LSM and CAP, Ethnic differences in metabolic risk and liver disease burden, influenced by genetic and social determinants recognized internationally, but real-world data are limited. We evaluated ethnic variation in FibroScan-derived fibrosis and steatosis in a large, diverse cohort.
Method: Retrospective analysis of 11,286 patients undergoing FibroScan® between January 2020-May 2025. Fibrosis and steatosis stages were classified using validated cut-offs. Distribution across ethnic groups was analyzed, and percentages reported within each group.
Results: Advanced fibrosis (F3-F4) was highest in Northern European (7.4%), Jewish (5.2%), and Southern European (3.4%) populations. Cirrhosis (F4) was most prevalent in Caribbean (8.6%), Southern European (6.3%), and Western European (6.3%) groups. Advanced steatosis (S3) was most common in Northern European (37.0%), Caribbean (29.3%), Iberian (27.5%), and Southern European (27.1%) populations. Lower rates of S3 were observed in Hispanic, South Asian, and MENA populations.

Conclusion: FibroScan®-detected fibrosis and steatosis vary significantly across ethnic groups. These findings highlight the need for ethnicity-informed MASLD screening and interpretation of non-invasive liver assessments in diverse populations.

WED-148
Risk stratification by longitudinal FIB-4 biomarker measurements in patients with MASLD/MASH

Suraj Mahida[1], Amy Lou[1,2], Eric Liu[1], Ian Epstein[1], Jordan Francheville[1], Tasha Kulai[1], Julie Zhu[1]. *[1]Dalhousie University, Halifax, Canada; [2]Nova Scotia Health, Pathology, Halifax, Canada*
Email: suraj.mahida@dal.ca

Background and aims: MASLD/MASH affect 25–30% of Canadians and are linked to adverse outcomes. The primary aim of this study was to determine whether time-varying changes in FIB-4 predict AHEs including HCC, first decompensation, and all-cause mortality, among patients with MASLD/MASH. Secondary aim was to assess cumulative AHE incidence across FIB-4 tertiles and test whether associations persist after adjusting for age and sex.
Method: This retrospective cohort study analyzed longitudinal FIB-4 scores in 795 out of 1239 patients from Halifax Fatty Liver Disease Clinic (2010–2023), excluding 444 patients for non-MASLD causes or lack of fibrosis/staging confirmation. A total of 3380 FIB-4 scores were obtained, and FIB-4 dynamics were examined using an Extended Cox Proportional Hazards Model treating FIB-4 as a time-varying covariate with age and sex as fixed effects. Primary outcomes were incident HCC, first decompensation, and all-cause mortality; a composite "any hepatic event" endpoint was also modeled. Time 0 corresponded to the earliest of first FIB-4 or AHE date. Kaplan–Meier cumulative incidence curves were generated by tertiles of FIB-4. Ethics approval was obtained.
Results: Over a median follow-up of 7.4 years (IQR 3.5–10.1), 58 patients developed HCC, 189 experienced afirst hepatic decompensation event, and 91 died. In time-updated Cox models adjusted for age and sex, each 1-point increase in FIB-4 was associated with a 23% higher risk of HCC (HR 1.23, 95% CI 1.13–1.33), an 18% higher risk of decompensation (HR 1.18, 95% CI 1.14–1.23), and a 17% higher risk of death (HR 1.17, 95% CI1.12–1.23; all $p < 0.001$). The composite endpoint of any hepatic event demonstrated a similar association (HR1.17, 95% CI 1.13–1.22). Kaplan–Meier curves revealed a stepwise increase in cumulative incidence across FIB-4 tertiles, with the highest tertile showing >60% event probability at 15 years.
Conclusion: Previous analyses of this cohort demonstrated a stepwise increase in FIB-4 scores being strongly associated with AHE independent to that of age. Extending these findings, the time-varying Cox model revealed that longitudinal increases in FIB-4 dynamically predict hepatic complications and mortality, independent of age and sex. Time-varying modeling underscores the value of longitudinal FIB-4 monitoring for real-time risk stratification and could guide individualized surveillance and intervention strategies in MASLD care.

WED-149
Prevalence and risk factors of steatotic liver disease among secondary public-school students in Chattogram, Bangladesh

Abdullah Al Mahmood[1,2], Subash Mazumder[3], Aniruddha Ghose[1], Aloke Kumar Raha[4], Tarek Shams[1], Pritam Dasgupta[5], Mehrunnissa Khanom[6], Kamrun Nahar[1], Mohammed Salahuddin Shahed Chowdhury[1]. *[1]Chittagong Medical College, Chittagong, Bangladesh; [2]Chittagong Medical College Hospital, Chittagong, Bangladesh; [3]Rangpur Medical College, Rangpur, Bangladesh; [4]Rangamati Medical College, Rangamati, Bangladesh; [5]CSCR Hospital, Chittagong, Bangladesh; [6]Southern Medical College and Hospital, Chittagong, Bangladesh*
Email: almahmoodhepato@yahoo.com

Background and aims: Steatotic liver disease (SLD) is an increasingly important adolescent health concern with potential long-term cardiometabolic consequences, yet school-based evidence from Bangladesh remains limited. This study aimed to estimate the prevalence of SLD and identify associated risk factors among secondary public-school students in Chattogram, Bangladesh.
Method: A cross-sectional study was conducted among 2,000 students aged 11 to 17 years using a multistage sampling technique. Data were collected through questionnaires and clinical assessments, including anthropometric measurements and ultrasound imaging. Students with known liver disease or high alcohol intake were excluded. Associations were examined using chi-square tests and Student's t-tests. Binary logistic regression was performed and adjusted odds ratios (AOR) were calculated to identify factors associated with SLD.
Results: The prevalence of SLD was 16.8%. The mean age was 13.61 years with a standard deviation of 1.44, and 56.3% of participants were male. Students with SLD had higher mean body mass index (26.18 vs 19.86 kg/m^2), waist circumference (81.76 vs 67.75 cm), and hip circumference (93.75 vs 81.90 cm) than those without SLD (all $p < 0.001$). Smoking and hypertension were associated with SLD in bivariate analysis ($p = 0.001$ and $p = 0.036$, respectively). Heavy activity frequency per week, sedentary time (excluding sleep and holidays), and sleep duration were also associated with SLD ($p = 0.049$, $p = 0.035$, and $p = 0.033$, respectively). In binary logistic regression, higher waist circumference (AOR 1.14; $p < 0.001$), higher body mass index (AOR 1.04; $p = 0.005$), age (AOR 0.81; $p < 0.001$), and smoking (AOR 6.52; $p = 0.047$) were independently associated with SLD.
Conclusion: SLD was common among the students. Higher waist circumference, higher body mass index, and smoking were independently associated with SLD. These findings support school-based prevention and early screening strategies focused on healthy weight management and tobacco use prevention among adolescents.

WED-150
Refining the EASL two-step strategy for referral of patients with MASLD: a prospective multicenter primary care study

David Marti-Aguado[1], Marta Hernández Conde[2], Rosa Murria[1], Elba Llop Herrera[2], Enrique Rodríguez[1], Ana Pérez[2], Marta López-Gómez[2], Javier Abad Guerra[2], Jesús Rivera Esteban[2], Cristina Montón[1], Desamparados Escudero-García[1], Isabel Pascual-Moreno[1], Arturo Carratalá[1], José Luis Calleja Panero[2], Paloma Lluch-García[1]. *[1]Incliva - Instituto De Investigación Sanitaria, Valencia, Spain; [2]Hospital Universitario Puerta De Hierro Majadahonda, Majadahonda, Spain*
Email: davidmmaa@gmail.com

Background and aims: The EASL-EASD-EASO guidelines recommends a two-step strategy to identify patients with significant fibrosis (F≥2) among individuals at risk of MASLD. A significant challenge of implementing the guidelines is the limited resources of VCTE, given the reported high rate of false positives (FP) among intermediate-risk FIB-4 group. The aims of this real-world study was to optimize referral pathways for patients with intermediate FIB-4 values from primary care.
Method: This prospective, multicenter study was conducted in primary care settings across two cities of Spain (Valencia, Madrid) between 2023 and 2024. All individuals aged 35–65 years with type 2 diabetes or obesity + ≥1 cardiometabolic risk factor undergoing routine blood testing were enrolled. FIB-4 was automatically calculated. The target population comprised patients with intermediate FIB-4 values (1.3–2.67). In these patients, additional serum-based fibrosis scores (ELF, LiverRisk, CORE, SAFE) were calculated and all cases were referred to the hospital in order to perform a VCTE. Thresholds for serum-based fibrosis scores were selected based on proved prognostic information. The primary endpoint was F≥2, defined as VCTE >8 kPa. The optimal referral strategy was selected as that maximizing the Youden index (J = Sn+Sp-1).

Results: A total of 2,488 individuals were included: 77% FIB-4 <1.3, 21% FIB-4 1.3–2.67, and 2% FIB-4 ≥2.67. The recommended algorithm FIB4–VCTE would refer 21% of subjects (n = 513), with an F≥2 prevalence of 16% and a false-positive rate of 84%. Alternative strategies significantly reduced unnecessary referrals among indeterminate FIB-4. Algorithm #1: FIB4–ELF would refer 8.1% (n = 201 ELF ≥9.8), with 29% F≥2 (71% FP) and J = 0.38. Algorithm #2: FIB4–LiverRisk would refer 1.5% (n = 40 LiverRisk ≥10), with 37% F≥2 (63% FP) and J = 0.11. Algorithm #3: FIB4-CORE would refer 1.7% (n = 43 CORE ≥5), with 45% F≥2 (55% FP) and J = 0.19. Algorithm #4: FIB4–SAFE would refer 5.3% (n = 133; SAFE ≥100), with 38% F≥2 (62% FP). This strategy achieved the most balanced diagnostic performance (J = 0.39).
Conclusion: In a real-world primary care setting, the recommended FIB4–VCTE algorithm leads to a high rate of unnecessary referrals. An alternative and sustainable two-step strategy combining FIB-4 with SAFE improves referral efficiency while maintaining diagnostic performance. These findings support refinement of current EASL-EASD-EASO pathways to optimize MASLD management within public healthcare systems.

WED-151
Repeatability of mri biomarkers for monitoring patients with metabolic dysfunction-associated steatotic liver disease

David Marti-Aguado[1], Amadeo Ten-Esteve[2], Matias Fernández-Patón[2], Irene Navarrete-Pérez[3], Cristina Garcia[4], Ana Crespo[4], Victor Merino[5], Leonor Cerda-Alberich[2], Sonia Ginés Cárdenas[2], Victoria Aguilera Sancho[3], Salvador Benlloch[4], Luis Marti-Bonmati[6]. [1]*Digestive Disease Department, Clinic University Hospital, INCLIVA Biomedical Research Institute, Valencia, Spain;* [2]*Instituto De Investigación Sanitaria La Fe, Valencia, Spain;* [3]*Hospital Universitari I Politècnic La Fe, València, Spain;* [4]*Hospital Arnau De Vilanova, Valencia, Spain;* [5]*Incliva - Instituto De Investigación Sanitaria, Valencia, Spain;* [6]*Instituto De Investigación Sanitaria La Fe, Biomedical Imaging Research Group (GIBI230) La Fe Health Research Institute, Valencia, Spain, Valencia, Spain*
Email: davidmmaa@gmail.com

Background and aims: There is a need for reliable noninvasive test to move from diagnosis to monitoring MASLD. Understanding precision is key when using a biomarker to assess meaningful longitudinal changes in disease. The aim of this study was to determine the same-day different-scanner repeatability coefficient (RC) of Magnetic Resonance Imaging (MRI) biomarkers in patients with MASLD.
Method: This prospective, multicenter cross-sectional study (2024–2025) included patients with biopsy confirmed MASLD who underwent two liver MRI within the same day (30 minutes difference). Standardized imaging protocols were implemented with two MRI scanners from different vendors (Philips and GE HealthCare), both at 3 T. After automatic segmentation of the liver, proton density fat fraction (PDFF, %), iron content (LIC-R2*, mg/g), and hepatic volume (cm^3) was measured for each participant. The primary outcome was the same-day, different-scanner, different-vendor, same field-strength RC (both absolute values and RC%) for each imaging biomarker. The secondary outcomes were the same-day, different-scanner, different-vendor, same field-strength intra-class correlation coefficient (ICC) and within-case coefficient of variation (wCV%) for each imaging biomarker.
Results: Same day repeat MRI exams were prospectively conducted in 28 participants (mean age 57 years, 57% women, mean BMI 28,7 kg/m^2), of which 25% had F0, 18% F1, 29% F2, 14% F3, and 14% F4 on biopsy.
Primary outcome: the RC absolute values were 1.7% for hepatic PDFF, 0.2 mg/g for LIC-R2*, and 188 cm^3 for liver volume. The RC% were 15.6% for hepatic PDFF, 27.8% for LIC-R2*, and 11.6% for liver volume. Secondary outcome: The ICC was 0.99 for hepatic PDFF, 0.80 for LIC-R2*, and 0.94 for liver volume. The wCV% was 5.6% for hepatic PDFF, 10.4% for LIC-R2*, and 4.2% for liver volume, respectively. These results indicates that LIC-R2* had 86% higher within-subject measurement variation than MRI-PDFF.
Conclusion: This preliminary study suggests that thresholds of 1.7% for MRI PDFF, 0.2 mg/g for LIC-R2*, and 188 cm^3 for liver volume, should be used to discern measurement variability rather than real change in patients with MASLD. These repeatability estimates may improve the qualification of MRI biomarkers in clinical practice.

WED-152
Improving identification of metabolic dysfunction-associated steatotic liver disease through integration of glycated haemoglobin into established liver assessment pathways

Holly Martin[1,2], Jennifer Nobes[1,2], Damien Leith[1,2], Ruairi Lynch[1,2], John F Dillon[1,2]. [1]*University of Dundee, Dundee, United Kingdom;* [2]*Ninewells Hospital & Medical School, Dundee, United Kingdom*
Email: hollymartin2804@gmail.com

Background and aims: Metabolic Dysfunction-Associated Steatotic Liver Disease (MASLD) occurs in 38% of the population and is the most common cause of abnormal liver function tests. The pathogenesis of this condition centres on the interaction of obesity and insulin resistance (IR). Patients with abnormal alanine aminotransferase (ALT) identified through liver assessment pathways often remain without a definitive aetiological diagnosis, limiting risk stratification and management. Glycated haemoglobin (HbA1c) is a routine measure of average glycaemia used to diagnose type 2 diabetes, IR and features in the diagnostic criteria for MASLD. We hypothesised that integration of HbA1c into an established liver assessment pathway (intelligent liver function test [iLFT]) would identify patients with MASLD who thus far had been classified as abnormal ALT of unclear aetiology.
Method: We performed a retrospective analysis of patients assessed through the iLFT pathway between 2018 and 2023. Patients were categorised as abnormal ALT with fibrosis (cohort A; n = 260) or without fibrosis (cohort B; n = 4,753), with known MASLD cohorts with and without fibrosis used as controls (n = 1,039 and 1,335, respectively). HbA1c measured within 12 months of liver assessment was eligible for inclusion in the analysis, and patients meeting MASLD criteria (HbA1c > 39 mmol/mol) were identified.
Results: HbA1c data was available for 41 patients in cohort A and 529 patients in cohort B. 68.3% (n = 28) of patients in cohort A and 58.6% (n = 310) of patients in cohort B had an elevated HbA1c and therefore met criteria consistent with MASLD and could be reclassified accordingly. Mean (standard deviation [SD]) HbA1c in the cohorts were 56 mmol/mol (17.94) and 52 mmol/mol (16.42), respectively. In the control populations mean (SD) HbA1c for those with fibrosis and without fibrosis was 67 (20.84) and 66 (20.18), respectively.
Conclusion: Integrating HbA1c into an established liver assessment pathway enables clinically meaningful reclassification of patients with both early and advanced MASLD. This approach improves diagnostic precision, supports earlier identification of metabolically driven liver disease allowing tailored management to be delivered to patients to prevent disease progression and therefore impact on future clinical outcomes. For those with established fibrosis reclassification will potentially enable access to new MASLD treatments. Future work will involve a prospective trial of HbA1c assessment in the above cohorts.

WED-153

Accuracy of non-invasive tests for ruling out or in advanced fibrosis in MASLD patients across clinical settings: a systematic review and meta-analysis

Email: dmaya-ibis@us.es

Background and aims: Non-invasive tests (NITs) are widely used to screen for advanced fibrosis in patients with metabolic dysfunction-associated steatotic liver disease (MASLD). Patient characteristics such as age and metabolic comorbidities may modify NITs' diagnostic performance beyond their effects on fibrosis prevalence. We systematically quantified the impact of key demographic and metabolic factors on the accuracy of NITs for ruling out and ruling in advanced fibrosis in MASLD.
Method: A systematic literature search was performed to identify cohort, case-control, and cross-sectional studies evaluating the diagnostic accuracy of NITs (namely FIB-4, NFS, LSM-VCTE, APRI, AST/ALT, Agile 3+, ELF, MRE) in adults with MASLD. Eligible studies that reported fibrosis prevalence and at least one patient-level risk factor (age, sex, obesity, type 2 diabetes mellitus [T2DM], hypertransaminasemia), and that extracted diagnostic accuracy metrics (sensitivity [SE], specificity [SP], and predictive values [PPV, NPV]), were included. Mixed-effects meta-regression analyses were used to assess effect modification of diagnostic performance. Analyses were stratified by rule-out (low cutoff) or rule-in (high cutoff) strategies.
Results: Of 7,236 screened studies, 101 were included, comprising 28,017 and 30,527 patients in low- and high-cutoff analyses. Fibrosis probability was progressively overestimated with increasing age, driven by reduced SP (beta = – 0.048, p < 0.001). T2DM reduced SE (beta = – 0.003, p = 0.005) and NPV (beta = – 0.003, p = 0.007), increasing false negatives. Obesity modestly reduced SE (beta = – 0.01, p = 0.004) and PPV (beta = – 0.0021, p < 0.001), while hypertransaminasemia reduced SP (beta = – 0.019, p = 0.008) and PPV (beta = – 0.0199, p = 0.003), increasing false positives. Sex had minimal impact.
Conclusion: Age and T2DM were associated with the highest fibrosis prevalence and lowest NIT performance, followed by obesity and hypertransaminasemia. FIB-4, NFS, APRI, LSM-VCTE, and Agile 3+ were most sensitive to population differences, with greater influence from FIB-4, NFS, and LSM-VCTE due to higher study representation. Age-related performance decline was evident from 50 years onward, supporting context-specific thresholds, particularly in older and diabetic populations.

WED-154-YI

FIB-4 screening in primary care identifies one in five patients with diabetes mellitus at risk of fibrotic MASLD for specialist referral

Eva Katharina Messer[1], Olaf Bätz[2], David Petroff[3], Thomas Berg[1], Jan Kramer[2], Johannes Wiegand[1]. *[1]Division of Hepatology, Department of Medicine II, Leipzig University Medical Centre, Leipzig, Germany; [2]LADR Laboratory Group Dr. Kramer & Colleagues, Geesthacht, Germany; [3]Clinical Trial Centre Leipzig, Leipzig, Germany*
Email: eva.messer@medizin.uni-leipzig.de

Background and aims: Fibrosis-4 (FIB-4) index is the guideline recommended screening parameter for patients at risk for fibrotic metabolic dysfunction–associated steatotic liver disease (MASLD) and predicts clinical outcomes. Diabetes mellitus is a major risk factor for fibrotic MASLD. The majority of patients with diabetes mellitus are treated in primary care, but a structured FIB-4 screening has not yet been implemented, although it is essential for referral strategies to subsequent specialized care and for allocation of resources. To determine the feasibility of such a screening program, we tested a prospective FIB-4 reflex testing in Hb1Ac laboratory requests from primary care.
Method: At a central laboratory, alanine or aspartate aminotransferase and platelets were automatically added to Hb1Ac laboratory requests from primary care. Diabetes mellitus was defined by HbA1c levels ≥ 6.5%. FIB-4 categories for low, intermediate or high risk of hepatic fibrosis were classified by values < 1.3, 1.3–2.67, and > 2.67. For age > 65 years, the lower cut-off was 2.0. According to guidelines, FIB-4 results > 1.3 (> 2.0) indicate referral to specialized care.
Results: 17,988 laboratory requests from 360 primary care physicians were analyzed of which 7927 (44%) had HbA1c ≥ 6.5%. A low, intermediate or high risk for hepatic fibrosis was observed in 80% (n = 6335/7927), 17% (n = 1321/7927), and 3% (n = 271/7927), respectively, which resulted in a referral indication in 20% of cases. The distribution according to FIB-4 category was 97.5%, 2.5%, and 0% for women aged 35–44, but changed to 82.5%, 15.6%, and 1.9% at the age of 45–64, and to 87.7%, 8.8%, and 3.6% at the age of 65–74. In total, 459 (14.3%) women qualified for referral. In men, the corresponding results were 92.6%, 7.4%, and 0% at the age of 35–44, which changed to 70.9%, 26.7%, and 2.4% at the age of 45–64, and to 80.7%, 13.3%, and 6.0% at the age of 65–74. In total, 1133 (24.0%) men qualified for referral.
Conclusion: The study provides an estimate of referral rates from primary to specialized care for MASLD evaluation in patients with diabetes mellitus based on a large multicenter primary care cohort and allows calculation of resources. A FIB-4 screening in patients < 45 years may be postponed to later time points.

WED-155

Non-invasive test-driven modeling of patient eligibility for resmetirom therapy in MASLD: data from the German SLD-registry

Email: maurice.michel@uks.eu

Background and aims: Advanced Fibrosis related to metabolic dysfunction-associated steatotic liver disease (MASLD) is increasingly prevalent and associated with adverse outcomes and higher mortality. Non-invasive tests (NITs) are central to identify patients at increased risk of disease progression who may benefit from a pharmacological intervention. This study aimed to characterize patients eligible for resmetirom treatment based on NITs in a real-world cohort in Germany.

Method: The German SLD-Registry is a prospective, non-interventional registry study recruiting in secondary and tertiary care. The cohort included 1,308 patients at baseline with valid liver stiffness measurement (LSM; kPa) obtained by vibration-controlled transient elastography (VCTE) followed up to 3 years. Eligibility for resmetirom treatment was defined according to current German MASLD guidelines as VCTE 10–19.9 kPa and platelet count $\geq 140 \times 10^9$/L at baseline (eligible cohort: n = 276) and was compared with non-eligible patients (VCTE <10 kPa; n = 1,032). Demographic characteristics, clinical parameters, and cardiometabolic risk factors were analyzed.

Results: The overall cohort comprised 50.2% males with a mean age of 52.1 ± 13.4 years and 62.7% with obesity (BMI >30 kg/m^2). Resmetirom treatment eligibility criteria were met in 21.1% of patients. Mean LSM in the total cohort was 9.7 ± 8.2 kPa, compared with 12.6 ± 2.6 kPa in the eligible cohort and 8.9 ± 9.0 kPa in the non-eligible cohort. Mean FIB-4 was 1.5 ± 1.2 and did not differ between cohorts (p = 0.908). Obesity (72.1% vs. 60.2%, p < 0.001) and type 2 diabetes (53.3% vs. 38.7%, p < 0.05) were significantly more prevalent in the eligible cohort. Eligible patients also exhibited a higher burden of cardiometabolic risk factors, with a greater prevalence of more than four to five risk factors. Within the eligible cohort, 81.9% had LSM values of 10–15 kPa and 18.1% had values of >15–19.9 kPa. Over three years of follow-up, progression from 10 to 15 kPa to >15–19.9 kPa and from >15–19.9 kPa to >20 kPa occurred in 7.7% of patients with available longitudinal data.

Conclusion: In this large real-world MASLD cohort, approximately one in five patients met non-invasive criteria for resmetirom treatment eligibility. Identification of eligible patients using NITs may support risk stratification and guide pharmacological treatment strategies in routine clinical practice.

WED-156

A prospective multicenter study to examine the impact of acquired and genetic predictors on hepatocellular carcinoma risk in patients with advanced metabolic associated steatotic liver disease

Stefania Mira[1], Serena Pelusi[2], Lorenzo Miano[1], Francesco Malvestiti[1], Giulia Periti[2], Luisa Ronzoni[2], Marco Saracino[3], Roberta D'Ambrosio[2], Luca Miele[4], Antonio Liguori[5], Elisabetta Bugianesi[6], Chiara Rosso[6], Giorgio Soardo[7], Salvatore Petta[8], Grazia Pennisi[8], Umberto Vespasiani Gentilucci[9], Federica Tavaglione[10], Alessandro Federico[11], Francesco Paolo Russo[12], Paola Zanaga[12], Mario Masarone[13], Daniele Prati[2], Luca Valenti[1]. *[1]Università Degli Studi Di Milano, Milano, Italy; [2]Fondazione Irccs Ca Granda Ospedale Maggiore Policlinico, Milano, Italy; [3]Università di Pavia, Pavia, Italy; [4]Università Cattolica Facoltà di Medicina e Chirurgia, Roma, Italy; [5]Policlinico Gemelli, Roma, Italy; [6]Università Degli Studi Di Torino, Torino, Italy; [7]Università Degli Studi Di Udine, Udine, Italy; [8]Università Degli Studi Di Palermo, Palermo, Italy; [9]Campus Biomedico Via Alvaro del Portillo 200, Roma, Italy; [10]University of California San Diego, La Jolla, United States; [11]Università degli Studi della Campania Luigi Vanvitelli, Napoli, Italy; [12]Università degli Studi di Padova, Padova, Italy; [13]Università degli Studi di Salerno-Dip. Medicina Chirurgia e Odontoiatria, Baronissi, Italy*
Email: stefania.mira@unimi.it

Background and aims: Metabolic dysfunction and Metabolic and alcohol-associated steatotic liver disease (MASLD and MetALD) is a rising cause of hepatocellular carcinoma (HCC), but reliable prognostic tools for risk stratification strategies are still under definition. Aim was to examine the incidence of HCC and the impact of acquired and genetic factors in a prospective multicenter cohort of people at increased risk.

Method: Italian patients aged 45–75 years with MASLD/MetALD (alcohol intake <60/40 g/day in M/F), F3-F4 fibrosis (stiffness ≥8.0 kPa, FIB-4 ≥1.3) or family history of HCC were included. Clinical parameters and genotyping for *PNPLA3* rs738409, *TM6SF2* rs58542926, *GCKR* rs1260326, *MBOAT7* rs641738 and *HSD17B13* rs72613567 generated a polygenic risk score (PRS-5). Time to HCC progression was evaluated by Kaplan-Meier's estimates of cumulative incidence rates, and Cox regression.

Results: We enrolled 524 individuals (57% males) with median follow-up 44.5 months (IQR 15–57); 346 (65%) had cirrhosis, 280 (53%) Type 2 Diabetes (T2D), 100 (19%) MetALD. Twenty-nine (5.5%) developed HCC (28 cirrhotic; 5-year incidence 8.0%, 95%CI 5.2–11.8%; annual 1.5%, 0.9–2.1%). Liver-related events dominated mortality (37 deaths: 12 HCC, 10 decompensation, 7 CV, 7 extrahepatic cancer, 1 infection); competing-risk showed cirrhosis as major HCC driver (HR 15.98, 95%CI 2.17–117.6, p < 0.001). In 443 (85%) with genetics, PRS-5 higher in cirrhosis vs non-cirrhosis (0.47 ± 0.25 vs 0.38 ± 0.26, p < 0.001) and predicted cirrhosis (OR 1.42, 95%CI 1.12–1.81, p = 0.004) independent of age/sex/T2D/BMI (T2D strongest covariate: OR 3.10, 95%CI 1.94–5.00, p < 0.001). In cirrhosis, high PRS-5 (≥0.495, 90th centile) showed nominal HCC risk (HR 1.34, 95%CI 0.56–3.24, NS). Multivariable Cox (age/sex/T2D/BMI-adjusted) identified FIB-4 as independent HCC predictor (HR 1.34, 95%CI 1.20–1.49, p < 0.001; optimal cut-off 2.58: Sn 89%, Sp 65%, AUC 0.82). MetALD vs MASLD competing risk showed no difference in HCC incidence (p = NS). In MetALD, PRS-5 was higher in cirrhotic vs non-cirrhotic (0.51 vs 0.28, p = 0.01); strongly predicted cirrhosis (OR 3.16, 95%CI 1.31–9.22, p = 0.02) independent of age/sex/T2D/BMI.

Conclusion: In this multicenter prospective cohort of people with SLD, cirrhosis was confirmed as the strongest risk factor for HCC development. Genetic predisposition (PRS-5) was associated with cirrhosis presence, with an even large impact in the MetALD

subgroup. FIB-4 remains a robust HCC predictor. New genetic-clinical analysis are ongoing.

Application of EASL guidelines for the assessment of risk for MASLD-related advanced fibrosis in an outreach screening of underserved rural communities in central and northern Romania using hepatoscope

Andreea Mihaela Morariu-Barb[1], Ana Bilegan[2], Iulia Minciuna[1], Sigurdur Olafsson[3], Andrei Morariu[2], Fischer Petra[1], Irina-Maria Stoleru[2], Oana Nicoara-Farcau[1], Andreea Fodor[1], Mina Ignat[1], Bogdan Procopet[1], Einar S. Björnsson[3], Horia Ştefănescu[1].
[1]Regional Institute of Gastroenterology and Hepatology, Cluj-Napoca, Romania; [2]Caravana cu Medici, Cluj-Napoca, Romania; [3]Landspitali University Hospital, Reykjawik, Iceland
Email: horia.stefanescu@irgh.ro

Background and aims: Half of the Romanian population, known to be at risk for advanced liver fibrosis, resides in rural areas, with limited access to healthcare and education. With the availability of ultraportable medical devices to non-invasively assess liver health, screening programs to reach these populations become easier. The goal of this prospective study was to characterize the metabolic risk profile of the Romania's remote rural population including their risk of advanced liver fibrosis using non-invasive tests.
Method: Between 2022 and 2024, medical caravans were conducted in 17 villages across Central and Northen Romania. Caravans had two ultrasound machines: one dedicated to qualitative assessment, and one dedicated to the measurements of liver stiffness and quantitative ultrasound - the Hepatoscope, not CE-marked at the time of the study. Participants underwent hepatology clinical consultations, questionnaire, laboratory testing, and abdominal ultrasound with the two devices. MASLD was defined by the presence of hepatic steatosis on ultrasound and at least one cardiometabolic risk factor (obesity, diabetes or prediabetes, dyslipidemia or hypertension), and risk for advanced fibrosis was assessed using the EASL guidelines.
Results: 1935 inhabitants were screened, including 68.3% of females, with a median age of 56 years (45.0–68.0). Median BMI was 29.52 (25.5–33.8), and 46.8% had obesity, including 15.2% with severe obesity. Central obesity was found in 86.6% of participants. 17.4% self-reported type 2 diabetes (T2DM) while blood testing revealed that 18.2% had TD2M and 51.7% had pre-diabetes. 80.8% of participants had at least one cardiometabolic risk factor, including 23.7% with metabolic syndrome. 52.3% of participants had MASLD with a significantly higher LSM (4.9 vs 5.3 kPa, $p < 0.05$). FIB-4 was calculated for 1710 participants, with a median of 1.10 (0.76–1.62). 18.7% and 5.4% of participants had intermediate or high risk of advanced fibrosis. Among them, 46.11% had either T2DM and/or obesity with at least one cardiometabolic risk factor. 135 underwent an LSM, with 34 having an LSM > 8 kPa, representing 2% of the screened population.
Conclusion: MASLD affected more than half of the screened rural population. The risk of advanced fibrosis in these underserved populations highlights the need for continued outreach, early detection and integrated liver care strategies. Hepatoscope could be successfully used in this context.

WED-158

LIVERFAST outperforms FIB-4, in sequential combination with vibration controlled transient elastography (VCTE) for identifying ≥F3 Stages in patients with MASLD including patients with type 2 diabetes (T2D)

Marie Decraecker[1], Jean-Baptiste Hiriart[1], Marie Irles-Depe[1], Juliette Foucher[1], Jenny Yu[2], Ronald Quiambao[2], Amon Asgharpour[3], Mona Munteanu[4], Victor De Ledinghen[5]. *[1]Hepatology Unit, Hôpital Haut Lévêque, Pessac, France; [2]Fibronostics, New Orleans, United States; [3]Stravitz-Sanyal Institute for Liver Disease and Metabolic Health, Virginia Commonwealth University School of Medicine, Richmond, United States; [4]Fibronostics U.S., Inc, New Orleans, United States; [5]Hepatology Unit, Hôpital Haut Lévêque, Bordeaux University Hospital, INSERM U1053, Bordeaux University, Bordeaux, France*
Email: victor.deledinghen@echosens.com

Background and aims: FIB-4 followed by VCTE is recommended to detect advanced fibrosis (≥F3). LIVERFAST (Fibronostics U.S.,Inc.) is a novel blood-based test reimbursed in US to identify liver fibrosis. The study aimed to compare the performance of LIVERFAST and FIB-4, sequentially with VCTE, for the identification of ≥F3 fibrosis including analyses in patients with type 2 diabetes (T2DM).
Method: This retrospective study included MASLD patients from a tertiary hepatology center with LIVERFASt, FIB-4, VCTE, and liver biopsy within 6-month. Performances were assessed using sensitivity, specificity, PPV, NPV, and number needed to diagnose (NND).
Results: LIVERFASt outperformed FIB-4 for identifying ≥F3 fibrosis, showing almost twice higher sensitivity and higher NPV at the high FIB-4 cut-off (>2.67) and higher specificity and PPV at the recommended cut-off (≥1.3 [2.0]). The combination LIVERFASt and VCTE achieved higher PPV (90.4%) than FIB-4 and VCTE (76%) with similar NPV. LIVERFASt identified almost twice more of ≥F3 cases as FIB-4 at the >2.67 cut-off, NNDs 4.56 vs 7.98, respectively. LIVERFAST identified a similar number of ≥F3 cases as FIB-4 at the recommended ≥1.3 [2.0] cut-off with the number of required VCTEs referrals of 187/447 vs 243/447 ($p < 0.001$), respectively. Similar results have been observed in the T2DM subanalysis with a with a lower number of required VCTEs referrals of 118/228 vs 146/228 ($p < 0.01$), respectively. Another noteworthy result relates to the higher proportion of patients correctly classified without suspected fibrosis (true negatives) during the first step by LIVERFAST alone versus FIB-4 alone at the recommended cut-off: 42.7% vs 35.6%, $p < 0.05$, respectively.
Conclusion: LIVERFASt outperformed FIB-4 and its integration into MASLD pathways may enhance screening efficiency, including in high-risk T2DM patients. The study showed that LIVERFAST plays also crucial role in ruling out fibrosis in a higher proportion of patients than FIB-4, identifying those that do not require a second test as far as the first correctly classified fibrosis.

Positron emission tomography/magnetic resonance imaging with copper-64 DOTATATE identifies metabolic dysfunction-associated steatohepatitis and shows attenuated hepatic signal with glucagon-like peptide-1 receptor agonist treatment

Puria Nabilou[1], Helle Hjorth Johannesen[2], Thomas Lund Andersen[2,3], Camilla Bardram Johnbeck[2], Bryan Haddock[2], Sofie Boesgaard Neestrup Hansen[1], Anders Junker[1], Elias Rashu[1], Mira Thing[1], Mikkel Werge[1], Signe Wiese[1,3,4], Nicolai Wewer Albrechtsen[3,5], Andreas Kjaer[2,6], Lise Lotte Gluud[1,3].
[1]Gastro Unit, Medical Division, Copenhagen University Hospital - Amager and Hvidovre, Copenhagen, Denmark; [2]Department of clinical physiology and nuclear medicine, Rigshospitalet, Copenhagen University Hospital, Copenhagen, Denmark; [3]Department of clinical medicine, University of Copenhagen, Copenhagen, Denmark; [4]Zealand University Hospital - Køge, Køge, Denmark; [5]Bispebjerg and Frederiksberg, University of Copenhagen, Copenhagen, Denmark; [6]Cluster for molecular imaging, Copenhagen University Hospital Rigshospitalet, Department of biomedical sciences, University of Copenhagen, Copenhagen, Denmark
Email: purianabilou@hotmail.com

Background and aims: Liver biopsy remains the gold standard for diagnosing metabolic dysfunction-associated steatohepatitis (MASH), but its invasiveness limits routine use. With glucagon-like peptide-1 receptor agonists (GLP-1 RA) recently approved for treatment of MASH, there is a growing need for non-invasive alternatives. We investigated whether hepatic uptake of [^{64}Cu]Cu-DOTATATE, a positron emission tomography tracer targeting activated macrophages, can detect MASH non-invasively and whether GLP-1 RA treatment is associated with reduced hepatic uptake.

Method: 60 adults were prospectively included: 48 with biopsy-confirmed metabolic dysfunction-associated steatotic liver disease (MASLD) and 12 healthy controls. Participants underwent positron emission tomography/magnetic resonance imaging (PET/MRI) one hour after receiving a single dose 200 MBq [^{64}Cu]Cu-DOTATATE intravenously. Hepatic maximum standardized uptake values (SUV) and proton density fat fraction (PDFF) were calculated as the mean from three liver regions. Diagnostic discrimination for biopsy-defined MASH was evaluated using receiver operating characteristic analysis. The optimal uptake cut-off for MASH was determined using the Youden index.
Results: SUV was significantly higher in patients with MASLD than in healthy controls (8.9 vs 7.1; p = 0.002). Among patients, GLP-1 RA users (n = 11) had lower tracer-uptake than non-users (7.3 vs 9.4; p < 0.001). For identifying MASH, SUV yielded an area under the curve (AUC) of 0.75 in all participants and 0.83 in untreated participants. The optimal Youden-derived cut-off for SUV detecting MASH was 7.14, with sensitivity = 1.00, specificity = 0.53, positive predictive value = 0.83, and negative predictive value = 1.00. Combining SUV and PDFF improved diagnostic accuracy, with AUC-values of 0.88 and 0.90 in treated and untreated patients, respectively.
Conclusion: Hepatic [^{64}Cu]Cu-DOTATATE uptake on PET/MRI is elevated in patients with biopsy-confirmed MASH and is reduced in patients treated with GLP-1 RAs. These findings support its potential as a non-invasive tool for diagnosis and treatment monitoring of inflammation in MASLD.

WED-163
Metabolic dysfunction-associated steatotic liver disease as a risk factor for fibrosis progression in primary biliary cholangitis: a case-control study
Adela Navarro[1], María Escuín[1], Sandra García[1], Sara Lorente Perez[1], Alberto Lué[1], Luis Cortes Garcia[1], Trinidad Serrano[1], Marta Latre[1], Enrique Ceamanos[1], Guillén Bernal[1], Sergio García[1], Marta Fernández[1], María Galochino[1], Laura Andreu[1], Lucía Pérez[1], Victoria Pardo[1]. [1]*Hospital Clínico Universitario Lozano Blesa, Zaragoza, Spain*
Email: adnavarropu@gmail.com

Background and aims: Primary biliary cholangitis (PBC) is a chronic cholestatic disease that may coexist with metabolic dysfunction-associated steatotic liver disease (MASLD). The impact of MASLD on the course of PBC remains uncertain. We aimed to evaluate the influence of MASLD on treatment response and fibrosis progression in patients with PBC.
Method: We conducted a multicentre case-control study including 293 patients with PBC (219 isolated PBC, 74 PBC with MASLD). Clinical, biochemical, and follow-up variables were collected. Hepatic steatosis was assessed by ultrasound at diagnosis. Liver stiffness was measured by transient elastography, defining advanced fibrosis as values >10 kPa. Treatment response to ursodeoxycholic acid (UDCA) was assessed using Paris II criteria. The requirement for second-line therapy and prognosis, according to the UK-PBC score at 5, 10, and 15 years, were analysed. Progression to significant fibrosis, liver transplantation, and death were evaluated using Kaplan–Meier and Cox regression analyses.
Results: MASLD was present in 25.3% of PBC patients. UDCA response rates according to Paris II criteria were similar between groups. No differences were observed in the indication for second-line therapy or UK-PBC scores. Advanced fibrosis was more frequent in patients with PBC and MASLD (22.6% vs. 8.1%; p = 0.006). In multivariate Cox regression, MASLD was independently associated with a 3.5-fold higher risk of significant fibrosis (aHR 3.448; 95% CI 1.402–8.474; p = 0.007). Patients with PBC and MASLD showed a higher prevalence of hypertension and a less favourable metabolic profile, but no significant differences in mortality, liver transplantation, or cardiovascular/cerebrovascular events.
Conclusion: MASLD is common among patients with PBC and is independently associated with earlier and more advanced liver fibrosis. Transient elastography is a valuable tool for disease monitoring. These findings highlight the importance of a multidisciplinary approach and active management of metabolic risk factors in this subgroup.

WED-164
Comparison of transient elastography and shear wave elastography for MASLD screening in a population at risk
André Neves[1], Francisco Capinha[1], Ana Rita Fernandes[2], Maria do Mar d'Orey[3], Sofia Carvalhana[4], Helena Cortez-Pinto[5]. [1]*Gastroenterology and Hepatology service, Santa Maria Hospital, Santa Maria Local Health Unit, Lisbon, Portugal;* [2]*Gastroenterology and Hepatology service, Santa Maria Hospital, Santa Maria Local Health Unit, Lisboa, Portugal;* [3]*Centro de Investigação Clínica do Centro Académico de Medicina de Lisboa, Lisbon, Portugal;* [4]*Centro de Investigação Clínica do Centro Académico de Medicina de Lisboa, Serviço de Gastroenterologia, ULS Santa Maria, Lisboa, Portugal, Lisbon, Portugal;* [5]*Centro de Investigação Clínica do Centro Académico de Medicina de Lisboa, Clínica Universitária de Gastroenterologia, Faculdade de Medicina Universidade de Lisboa, Lisbon, Portugal*
Email: sofiacarvalhana@msn.com

Background and aims: Metabolic associated steatotic liver disease (MASLD) is a chronic progressive disease that may lead to fibrosis and cirrhosis. Early, non-invasive diagnosis using elastography techniques is essential. This study aimed to prospectively compare liver stiffness measurements (LSMs) obtained by transient elastography (TE) and shear wave elastography (SWE).
Method: Prospective analysis of 170 patients referred to a tertiary center for suspected MASLD, with metabolic risk factors. We evaluated clinical, anthropometric and biochemical parameters. LSM was evaluated using either Fibroscan(r) or Aixplorer ultrasound machine (SuperSonic Imagine, Provence, France).
Results: The study included 170 patients (mean age: 54.9 ± 13.6 years, 54.1% females), wtih a high prevalence of metabolic risk factors: 55.9% obesity, 53.5% hypertension, 50.6% dyslipidemia, 17.6% diabetes. Mean Body Mass Index (BMI) and waist circumference were 31.3 ± 5.6 Kg/m^2 and 100.3 ± 13.2 cm, respectively. Mean LSM: 5.07 ± 2.54 kPa (TE) and 5.40 ± 1.70 kPa (SWE). Most patients showed absent/mild fibrosis (< 8 Kpa): 95.3% by TE and 96.5% by SWE. A minority showed advanced fibrosis: 4.7% by TE and 3.5% by SWE. The correlation between TE and SWE was moderately positive (r = 0.48, p < 0.001), in those with absent/mild fibrosis (< 8 Kpa), while weak-to-moderate (r = 0.30, p < 0.001) in all advanced fibrosis cases. The ≥ F2 group, a significant difference in LSM was observed: mean 13.4 kPa for TE and 11.3 kPa for SWE (p < 0.001). When evaluating these patients, no statistically significant differences were observed regarding anthropometric or laboratory variables Multivariate analysis identified waist circumference as the only independent predictor for TE (beta = 0.073, 95% CI [0.002–0.150], p = 0.044). In contrast, for SWE, Diabetes (beta = 1.327, p = 0.003), GGT (beta = 0.019, p = 0.013), and Ferritin (beta = 0.002, p = 0.027) were the independent predictors.
Conclusion: Both Fibroscan and SWE are effective for the exclusion of advanced fibrosis. The clinical utility of using a complementary multistep strategy in cases with significant fibrosis is yet to be demonstrated, although our results suggest that possibility.

WED-165-YI
Back from the future? The original logistic FIB-4 model outperforms the current simplified FIB-4
TD Clara Nguyen[1], W. Ray Kim[1]. [1]*Mayo Clinic Arizona, Phoenix, United States*
Email: nguyen.thuy-duyen@mayo.edu

Background and aims: In pursuit of public health solutions to the metabolic dysfunction-associated steatotic liver disease (MASLD)

epidemic, guidelines recommend using the FIB-4 index for initial stratification. The current FIB-4 is an abbreviated form of the original model, derived from a logistic regression analysis (Sterling et al., 2006). We evaluated FIB-4 (the current form) versus FIB-4LR (the original logistic model) versus the SAFE score in the diagnosis of moderate and advanced fibrosis among US adults with MASLD.
Method: We analyzed National Health and Nutrition Examination Survey (NHANES) data, a population-representative sample of US adults. FIB-4 and FIB-4LR scores were calculated and correlated in adults meeting American Association of Clinical Endocrinology (AACE) MASLD screening criteria (age ≥40 with type 2 diabetes/prediabetes, overweight/obesity, or ≥2 cardiometabolic risk factors). Fibrotic MASH was defined as CAP ≥275 dB/m with LSM ≥8.0 kPa (moderate) or ≥12.0 kPa (advanced fibrosis) or LSM ≥15.0 kPa regardless of CAP. We generated ROC curves and determined sensitivity, specificity, predictive values, and number needed to screen (NNS) for FIB-4, FIB-4LR, and SAFE scores.
Results: The NHANES data is representative of 218 million US adults, which 59.8% met AACE screening criteria. 11.2 million met the fibrotic MASH definition, including 8.6% with moderate fibrosis and 3.9% with advanced fibrosis. Although FIB-4 and FIB-4LR were positively correlated, the R^2 was low at 43.8%. For moderate fibrosis, FIB-4LR demonstrated a higher AUROC (0.567) than FIB-4 (0.647). Equivalent to FIB-4 ≥1.3, FIB-4LR ≥1.63 achieved superior sensitivity (90.6%), NPV (96.1%), and PPV (10.8%) compared to FIB-4 (sensitivity 43.0%, NPV 92.2%, PPV 10.1%). SAFE performed best with an AUROC of 0.738, and at a cutoff of ≥0, demonstrated sensitivity (90.4%), NPV (98.0%), and PPV (13.2%) that matched or exceeded both FIB-4 models. Similar patterns were observed for advanced fibrosis.
Conclusion: Suffering from simplification, the current form of FIB-4 is an inferior substitute for the original model, which provides more statistically robust and clinically informative results using identical variables. The SAFE score, incorporating additional metabolically relevant variables, demonstrates superior discriminatory power for detecting both moderate and advanced fibrotic MASH.

Is perfection the enemy of good? A streamlined screening strategy for metabolic dysfunction-associated steatotic liver disease in the community

TD Clara Nguyen[1], W. Ray Kim[1], Eleana De Filippis[1], Blanca Lizaola-Mayo[1], David M. H. Chascsa[1], Nan Zhang[1], Alina M Allen[2]. [1]*Mayo Clinic Arizona, Phoenix, United States;* [2]*Mayo Clinic, Rochester, United States*
Email: nguyen.thuy-duyen@mayo.edu

Background and aims: Metabolic dysfunction-associated steatotic liver disease (MASLD) is a major source of cirrhosis-related morbidity and mortality globally. With newly approved therapies capable of reversing liver fibrosis, early identification of patients with fibrosis is critical. This study aims to correlate cardiometabolic risk factor (CMRF) profile with MASLD and fibrosis.
Method: We analyzed data from the National Health and Nutrition Examination Survey (NHANES), a population-representative sample of US civilians. CMRFs including overweight/obesity, prediabetes/type 2 diabetes (T2D), hypertension (HTN), hypertriglyceridemia (hyper TG), and low HDL cholesterol were correlated with steatosis and fibrosis, assessed by vibration-controlled transient elastography. Steatosis was defined as CAP ≥275 dB/m and steatotic fibrosis as LSM ≥8.0 kPa or ≥15.0 kPa regardless of CAP. Logistic regression analysis was used to evaluate associations between CMRFs and steatotic fibrosis.
Results: In NHANES 2017–20, 36.9% of U.S. adults had steatosis and 6.8% had steatotic fibrosis. T2D showed the highest prevalence (17.1%), while obesity, HTN, dyslipidemia, and prediabetes had intermediate risks (4.0–12.7%). Among non-T2D individuals, obesity was the strongest independent predictor of steatotic fibrosis with an odds ratio of 11.0. Simplifying screening criteria to T2D or obesity identified 92.8% of steatotic fibrosis cases with a number needed to screen (NNS) of 7.9, outperforming current guidelines; adding HTN (NNS 9.2) may enhance screening. NHANES 2021–23 data confirmed these findings.
Conclusion: Compared to current complex, inconsistent guidelines, a streamlined screening strategy focusing on T2D or obesity is more implementable while capturing most subjects with MASLD and fibrosis.

WED-167

The influence of stress factors on the state of the intestinal microbiota and intestinal epithelial permeability in patients with metabolic dysfunction-associated steatotic liver disease

Yana Nikiforova[1], Galina Dmitrievna Fadieienko[1], Inna Kushnir[1], Alexey Evheniyovych Gridnyev[1], Valentina Chernova[1], Tetyana Solomentseva[1]. [1]*L.T.Mala Therapy National Institute of the National Academy of Medical Sciences of Ukraine, Department of the Study of Digestive System Diseases and their Comorbidity with Non-communicable Diseases, Kharkiv, Ukraine*
Email: dr.jana@email.ua

Background and aims: The problem of metabolic dysfunction - associatted steatotic liver disease (MASLD) has remained relevant for many years. Modern conditions open a new focus for research into triggers factors of the disease, namely the influence of stress factors on the course of MASLD.
Method: 108 patients with MASLD were examined in the war period. Serum levels of chronic stress hormones - brain-derived neurotrophic factor (BDNF), prolactin and the epithelial permeability marker (zonulin) were determined by solid-phase immunoassay. The intestinal microbiota was determined by quantitative real-time polymerase chain reaction. The visceral adipose tissue (VAT) - a monitor scale "Omron BF-511". The obtained data were compared with data in the pre-war period.
Results: In patients with MASLD a direct relationship of moderate strength was found between zonulin levels and VAT ($r = 0.32$, $p < 0,05$). After the start of the war, zonulin levels were recorded that were 3.7 times higher compared to the group of healthy individuals and 1.5 times higher compared to the group of MASLD patients examined in the pre-war period ($p < 0.05$, respectively). The maximum increase in zonulin content was observed in high-grade steatosis ($p < 0.05$). Moderately strong associations were obtained between zonulin and HOMA indices and low-density lipoprotein ($r = 0.38$ and $r = 0.37$, $p < 0.05$ respectively), and a weak correlation with triglyceride indices ($r = 0.28$, $p < 0.05$). In patients with MASLD, who were exposed to the stress factors of the war period, a significant imbalance of the intestinal microbiota (IM) was observed, which was manifested by an increase in the content of Firmicutes (up to 57%) and a decrease in the pool of Bacteroidetes (8%). The F/B index was almost 4 times higher than in the group of MASLD patients who were examined in the pre-war period and was 25.9 and 6.43, respectively ($p < 0.05$). A direct correlation was found between prolactin levels and zonulin content in patients with MASLD of the main group ($r = 0.43$, $p < 0.05$). A direct correlation of moderate magnitude was found between the level of prolactin and BDNF with the content of Firmicutes ($r = 0.44$ and $r = 0.31$, $p < 0.05$ respectively), and an inverse correlation between prolactin and the content of Bacteroidetes ($r = -0.34$ and $r = -0.22$, $p < 0.05$ respectively).

Conclusion: The obtained data on the influence of chronic stress hormones on intestinal microbiota, intestinal permeability and further progression of MASLD.

Background and aims: Accurate fibrosis stage assessment in subjects with metabolic dysfunction–associated steatotic liver disease (MASLD) in specialized care remains challenging, mainly due to the non-negligible rate of fibrosis misclassification by transient elastography (TE). The Enhanced Liver Fibrosis® (ELF) test has been proposed as a complementary tool to improve risk stratification. This study aimed to characterize subjects with discordant versus (vs) concordant TE and ELF results and to describe ELF-guided clinical decision making.
Method: A prospective cohort study including patients referred to MASLD clinic at Vall Hebron Hospital between June 2024 and November 2025 with TE and ELF assessed within 3 months. Concordant patients were defined as LSM ≥ 8 kPa with ELF ≥ 9.8 or LSM < 8 kPa with ELF < 9.8; discordant patients as LSM ≥ 8 kPa with ELF < 9.8 or LSM < 8 kPa with ELF ≥ 9.8. Demographics, cardiometabolic risk factors, alcohol use, bioelectrical impedance measures, laboratory data and clinical decisions were analysed.
Results: A total of 188 patients, with a median follow-up of 2.4 [1.1–8.1] months, were included: 68 (36.1%) with LSM ≥ 8 kPa and 120 (63.8%) with LSM < 8 kPa. Among those with ≥ 8 kPa, 33 (48.5%) had concordant ELF results, while 35 (51.5%) were discordant. Discordant patients were younger (54.7 ± 12.9 vs 63.5 ± 9.7 years; $p < 0.01$), had lower median alcohol intake (0 [0–0] vs 0 [0–20] grams/day; $p = 0.02$), higher body mass index (39.6 ± 8.5 vs 35.3 ± 6.6 kg/m^2; $p = 0.02$), greater visceral fat index (18.3 ± 6.9 vs 14.1 ± 3.8; $p = 0.01$) and lower FIB-4 (1.23 [0.70–1.71] vs 2.14 [1.52–3.23]; $p < 0.01$). Follow-up and discharge rates were similar between groups, while referral for bariatric surgery was more frequent in discordant patients (22.9% vs 3%; $p = 0.03$). Among patients with < 8 kPa, 89 (74.2%) had a concordant ELF result while 31 (25.8%) were discordant. Discordant patients were older (61.8 ± 13.7 vs 53.0 ± 12.7 years; $p < 0.01$) and had higher FIB-4 values (1.41 [0.97–2.23] vs 1.09 [0.71–1,46]; $p < 0.01$). Follow-up (74.2% vs 42.7%; $p < 0.01$) and clinical trial assessment (19.4% vs 1.1%; $p < 0.01$) rates were higher.
Conclusion: Obesity may contribute to discordance between LSM and ELF by overestimating fibrosis stage in MASLD patients with LSM ≥ 8 kPa and ELF < 9.8. Patients with LSM < 8 kPa and ELF ≥ 9.8 may have significant fibrosis and benefit from further evaluation. The additive use of ELF in specialized care could improve risk stratification and support clinical decision-making.

WED-169

Validation and clinical performance of a liver proton density fat fraction measurement using artificial intelligence

Wenjie Pang[1]. [1]*Resonance Health, Burswood, WA, Australia*
Email: wenjiep@resonancehealth.com

Background and aims: Steatotic liver disease (SLD) is closely associated with metabolic syndrome and increased cardiovascular risk. Magnetic Resonance Imaging (MRI)–based methods for measuring hepatic steatosis have become the new gold standard due to several advantages over liver biopsy and other non-invasive modalities. The aims of this study were to validate and evaluate the performance of an FDA-cleared Artificial Intelligence (AI)–based MRI processing method that automatically quantifies multiple hepatic steatosis metrics in real time.
Method: 300 quarantined datasets previously analysed over a 5-year period using the FDA-cleared HepaFatScan manual method were selected as the reference standard. These datasets included scans acquired on various MRI makes, models, and field strengths (1.5 T and 3 T). They were used to validate the FDA-cleared AI method (HepaFatSmart), which simultaneously measures proton density fat fraction (PDFF) and steatosis grade. Additional 41 subjects with repeat scans were analysed using the AI method to evaluate repeatability and compare performance with manual HepaFatScan analysis.
Results: HepaFatSmart PDFF measurements closely matched those produced by the reference standard. A small bias of 0.22% was observed in the validation dataset; although statistically significant due to low standard deviation, the difference is clinically negligible, which demonstrates that the AI-based device provides accurate and reliable liver-fat quantification consistent with the reference standard. HepaFatSmart repeatability coefficients ranged narrowly from –2.0% to 1.7%, with a small bias of 0.17%. This indicates strong robustness and consistent performance. Repeatability was slightly better than that of the historical manual HepaFatScan measurements without suggesting an inherent superiority of the AI method. The AI system also incorporates an anomaly-assessment mechanism capable of detecting excessive liver iron levels, estimating their impact, and determining when analysis should be halted as a safety measure.
Conclusion: The AI-based method demonstrates accuracy and precision comparable to the established reference standard, with interchangeable results. Its automated workflow eliminates the need for specialized image-analysis expertise and enables near real-time reporting, supporting potential point-of-care screening and reducing costs. As part of a quantitative MRI analytic realm, its results remain transparent and visible to help mitigate any residual risks associated with AI-based methods.

WED-170

High prevalence of hepatic steatosis in adolescence and young adults: a cross sectional survey from Sindh Pakistan

Om Parkash[1], Aysha Almas[1], Suneel Piryani[1], Arjumand Rizvi[1], Abhishek Lal[1], Areesha Ikram[1], Jai Das[1]. [1]*Aga Khan University, Pakistan, Karachi, Pakistan*
Email: om.parkash@aku.edu

Background and aims: Hepatic Steatosis and its Metabolic Dysfunction–Associated Steatotic Liver Disease (MASLD) are emerging as a global concern and have a major impact on health. The overall aim of the study was to estimate the prevalence of Hepatic Steatosis and MASLD in adolescents and young adults in the province of Sindh, Pakistan and report associated metabolic factors.
Method: It was a cross-sectional study using a multistage complex household sampling strategy conducted in all (31) districts of Sindh, Pakistan, in 2023–2024. Adolescents (10–19 years) and young adults (20–24 years) were included and those who were hepatitis B or C positive were excluded. The primary outcome 1 was Hepatic Steatosis and Primary outcome 2 was MASLD. Hepatic Steatosis was defined as

ultrasound attenuation parameter UAP > 244 dB/m using a Fibro touch: Shear-wave Elastography System. MASLD was defined as Hepatic Steatosis and any one of the cardiometabolic criteria (Obesity, hypertension, triglycerides >150 mg/dl, HDL <40 mg/dl, Fasting blood sugar>100 mg/dl,).
Results: A total of 2,200 participants were invited to participate, of whom 2,136 (97.1%) agreed. Among these, 1,651 (77.3%) were adolescents aged 10–19 years and 485 (22.7%) were young adults aged 20–24 years, with a mean (SD) age of 15.8 ± 4.0 years. Overall, 997 (43.7%) participants were from rural 1,053 (47.6%) were males. Of the total 456 (21.1%) were underweight, 162 (8.6%) were overweight, and 87 (4.3%) were obese, 519 (26.0%) had impaired fasting glucose, and 93 (8.8%) had diabetes. Overall, 1,053 (53.3%) participants had hepatic steatosis, including 802 (52.1%) adolescents and 251 (57.6%) young adults. Among adolescents with Hepatic steatosis 444 (55.08%) and 358 (44.92%) were in early (10–14) and Mid-Late Adolescence (15–19). On multivariate regression, overweight or Obesity (OR 2.52 (95% CI 1.19–5.31), central obesity (OR 3.37(95% CI 1.38–8.26) was associated with hepatic steatosis, while being in middle (OR 0.80(0.59–1.08) or rich (OR 0.87(0.58–1.30) socio economic index was protective for Hepatic steatosis. The prevalence of metabolic dysfunction–associated Steatotic liver disease (MASLD) was 717 (36.3%) overall, comprising 525 (34.9%) adolescents and 192 (41.4%) young adults.
Conclusion: High prevalence of hepatic steatosis and MASLD in adolescents and adults from Sindh, Pakistan indicating that the occurrence happens much early in life. Further studies are required to look at mechanisms that lead to hepatic Steatosis early in life.

WED-171
Assessment of waist-to-height ratio as a predictor of MASLD and advanced fibrosis

Nashla Hamdan[1], Yoshihiro Yamamoto[1], Magdalena Kuczynski[1], Radin Pakseresht[1], Maxwell Tong[1], Keyur Patel[1]. [1]*University Health Network, Toronto, Canada*
Email: nashla.hamdan@uhn.ca

Background and aims: Body Mass Index (BMI) is used to assess obesity, but fails to account for fat distribution and may misclassify muscular or normal-weight patients with metabolic dysfunction. The Waist-to-Height Ratio (WHtR) is an anthropometric tool used to measure visceral adiposity, which has a strong association with metabolic disease. and may be a better predictor of Metabolic Dysfunction-Associated Steatotic Liver Disease (MASLD) than BMI. Our Aim was to evaluate the association between WHtR, hepatic steatosis and fibrosis severity as assessed by non-invasive tests including Vibration Controlled Transient Elastography (VCTE) Controlled Attenuation Parameter (CAP), FIB-4, APRI and NFS score.
Method: Cross-sectional study of adults with MASLD referred for risk stratification at a single tertiary Canadian center. Other chronic liver disease were excluded through clinical and laboratory investigations.
Results: Our cohort included 304 MASLD patients with mean age 51 ± 14 years, 49.6% male, mean BMI of 30.27 ± 7 kg/m^2, waist-hip ratio1.26 ± 6, and WHtR 0.59 ± 0.09. Comorbidities included hypertension (48%), dyslipidemia (40%), and Type 2 Diabetes Mellitus (22%). Patients were stratified into three WHtR risk categories: Low Risk (0.4–0.5), Increased Risk (0.5–0.6), and Higher Risk (>0.6). WHtR demonstrated moderate correlation with markers of hepatic steatosis and fibrosis: CAP (rho = 0.45, p < 0.001) and VCTE (rho = 0.35, p < 0.001), and NFS (rho = 0.33, p <0.001), but weaker with atherosclerotic cardiovascular disease (ASCVD) score (rho = 0.22, p = 0.001). A greater proportion of severe steatosis (CAP >280 dB/m) were classified in high WHtR group (p < 0.001), but there were no WHtR group differences for those with advanced fibrosis VCTE >12 kPa. Multivariable analysis for high risk WHtR showed lower independent association for male gender (OR 0.11, CI 0.03–0.41; p = 0.001), and as expected, increasing BMI (OR 1.35, CI 1.10 – 1.67; p = 0.004 and waist circumference (OR 1.33, CI 1.19 – 1.48; p = <0.001). There was no independent association with dyslipidemia (OR 0.57;p = 0.30) or hypertension (OR 1.36; p = 0.55).
Conclusion: The WHtR is a simple anthropometric measure associated with MASLD severity, and complements BMI and Waist-hip ratio in identifying patients at risk for advanced metabolic liver disease. Incorporating WHtR into clinical practice may improve the identification of high-risk MASLD phenotypes, particularly in patients where BMI may underestimate visceral adiposity.

WED-172-YI
External validation and recalibration of the CORE risk score to predict 10-year risk of liver cirrhosis in patients with type 2 diabetes

Rajan Paudel[1], Rickard Strandberg[1,2], Hannes Hagström[1,3]. [1]*Department of Medicine Huddinge, Karolinska Institutet, Stockholm, Sweden;* [2]*Red Door Analytics, Stockholm, Sweden;* [3]*Division of Hepatology, Department of Upper GI Diseases, Karolinska University Hospital, Stockholm, Sweden*
Email: rajan.paudel@ki.se

Background and aims: Metabolic dysfunction-associated steatotic liver disease (MASLD) is the most common chronic liver disease globally. Type 2 diabetes (T2D) is a key risk factor for MASLD occurrence and progression to cirrhosis. Currently, the FIB-4 score is recommended as a first-line risk assessment tool for patients with T2D in primary care, but its performance and implementation is limited. Further, FIB-4 is not designed to identify the risk of future outcomes related to cirrhosis. Here, we aimed to evaluate the performance of the cirrhosis outcome risk estimator (CORE) and recalibrate it for a T2D population.
Method: We used data from the National Diabetes Register in Sweden to identify people with T2D diagnosed between 1 January 1998 and 31 December 2022. We calculated CORE based on the laboratory data obtained from primary care in the Stockholm region. We used national health registers to identify incident cases of major adverse liver outcomes (MALO). We evaluated the performance in terms of time-dependent area-under-curve (tAUC), calibration plots, and clinical utility using decision curve analysis. As the baseline risk of T2D population is higher than the general population, we recalibrated the model using cause-specific flexible parametric models. All performance measures were compared with FIB-4.
Results: We used data of 37,015 individuals with T2D who had laboratory data to calculate CORE score. 784 developed MALO over a median follow-up period of 6.2 years (10-year cumulative incidence = 2.7%). CORE performed better than FIB-4 in terms of discrimination with a 10-year AUC of 0.86 compared to 0.81 for FIB-4. CORE did not calibrate well and showed underestimation of the observed risk, requiring recalibration. The updated CORE model showed improved calibration and performed better than FIB-4 in terms of net benefit at risk-thresholds up to 30%.
Conclusion: CORE performs better than FIB-4 in estimating risk of MALO in patients with T2D. CORE better captures high-risk groups and reduces the need for referrals as compared to FIB-4.

WED-173
The relationship between liver stiffness measurement and all-cause mortality in patients with chronic liver diseases varies over time

Rajan Paudel[1], Hannes Hegmar[1,2], Axel Wester[1], Soo Aleman[3], Jens Backman[4], Erik Degerman[5], Åsa Lundgren[6], Patrik Nasr[7], Johan Vessby[8], Joan Westin[9], Hannes Hagström[1,2], Rickard Strandberg[1,10]. Falun Hospital, Falun, Sweden; [6]Department of Infectious Diseases, Central Hospital, Kristianstad, Sweden; [7]Department of Gastroenterology and Hepatology, Department of Health, Medicine and Caring Sciences, Linköping University, Linköping, Sweden; [8]Department of Medical Sciences, Gastroenterology Research Group, Uppsala University, Uppsala, Sweden; [9]Department of Infectious Diseases, Sahlgrenska University Hospital, Gothenburg, Sweden; [10]Red Door Analytics, Stockholm, Sweden
Email: rajan.paudel@ki.se

Background and aims: Patients with chronic liver disease (CLD) have increased risk of death from non-liver causes demonstrating extra-hepatic complications of liver diseases. Liver stiffness measurement (LSM) using vibration controlled transient elastography (VCTE) could be useful in estimating all-cause mortality risk in patients with CLD. In our study, we aimed to evaluate the association between LSM and all-cause mortality over time and the differences across age, sex and underlying liver disease etiologies.
Method: We used data from Fibroscan® machines from sixteen hospital units across Sweden. Individuals with CLD who had at least one successful LSM between June 2008 and October 2020 were included in the study. The LSM data was linked with national patient and population registers in Sweden to obtain individual characteristics such as age, sex, country of birth, comorbidities and underlying etiologies as well as to follow-up for the outcomes. We modelled the effect of LSM in a flexible parametric survival model (adjusted for age, sex, comorbidities and country of birth). Using the model, we report the cumulative incidence and hazard ratios (HRs) for all-cause mortality associated with LSM over time.
Results: 13,824 patients with CLD with a median LSM of 5.8 kPa (inter-quartile range: 4.6–7.9) were followed up for a median of 6 years (IQR: 4.3–8.2). 984 (7.1%) patients died during the follow-up period. Mortality rates were highest for LSM >12 kPa (29.9 per 1000 person-years). For all etiologies, increasing LSM was associated with an increase in hazard initially (at around 4–6 years after baseline), which attenuated over time (after 6 years). Having alcohol-associated liver disease was associated with highest 10-year risk of all-cause mortality regardless of LSM, while having metabolic-dysfunction associated steatotic liver disease was associated with the lowest 10-year risk.
Conclusion: LSM has a time-dependent association with all-cause mortality, and it varied across age and etiologies. The increased hazard ratios for all-cause mortality associated with increasing LSM diminish over time since measurement. Our results suggest a need of age- and etiology-specific LSM cut-offs while assessing risk of all-cause mortality in patients with CLD.

WED-174-YI

Machine learning prediction of liver fibrosis in patients with metabolic dysfunction associated steatotic liver disease (MASLD)

Email: graziapennisi901@gmail.com

Background and aims: Accurate staging of liver fibrosis is crucial for risk stratification in patients with metabolic dysfunction-associated steatotic liver disease (MASLD). Liver biopsy, the current reference standard, is invasive and subject to sampling variability, while non-invasive tests (NITs) such as vibration-controlled transient elastography (VCTE) are widely used. We aimed to develop and validate AI-based models capable of distinguishing fibrosis stages.
Method: We developed and validated machine learning models to predict fibrosis stages in more than 3,600 biopsy-confirmed MASLD patients using 22 clinical features, liver stiffness measurement (LSM), and controlled attenuation parameter (CAP). Models included Feature Tokenizer Transformer (FTT), TabNet variants with distance-aware losses, ordinal MLP with CORAL framework, and gradient boosting machines. Performance was evaluated using Rubin's Rules across 5 MICE imputed datasets.
Results: The FTT and TabNet achieved the highest performance in binary tasks: AUROC = 0.860 and 0.855 (F≥3 vs F0-F2) and AUROC = 0.800 and 0.788 (F≥2 vs F0-F1), significantly outperforming FIB-4. For F≥3, FTT had significantly higher AUROC than LSM (p = 0.014) but

only marginally higher than AGILE3+, and, together with TabNet, the highest accuracy and the lowest grey zone (8.2% and 8.4%, respectively). For multiclass staging, ordinal models performed best with MLP-CORAL achieving QWK = 0.616.
Conclusion: Deep learning models with ordinal-aware architectures can accurately predict liver fibrosis stages using routinely available clinical data, offering a scalable alternative to biopsy without requiring specialized biomarkers.

WED-175
The FIB-4 score has a stronger correlation with cardiovascular risk than other adiposity markers in patients living with obesity
Carolina M. Perdomo Zelaya[1], Estefanía Chumbiauca[1], Adrián Gil Korilis[1], Patricia Yarnoz[1], Javiera Concha[1], Lucía ÓConnor[1], Camilo Silva[1], Nerea Varo[1], Gema Frühbeck Martinez[1], Javier Escalada[1]. [1]*Clínica Universidad de Navarra, Pamplona, Spain*
Email: cperdomo@unav.es

Background and aims: Adiposopathy is characterized by metabolic dysfunction of adipose tissue and with progressive orthotopic and ectopic fat accumulation in various organs, including the liver. Adiposopathy is a key event in the pathophysiology of metabolic dysfunction-associated steatotic liver disease (MASLD); its progression is associated with a higher cardiometabolic risk. However, the relationship between different adiposity parameters and the estimation of cardiovascular risk has not been evaluated. This study compares different adiposity parameters for predicting cardiovascular risk.
Method: Evaluation of a cohort of 129 patients living with obesity between 40 and 69 years of age without anti-obesity pharmacological or surgical treatment who attended the outpatient clinic of the Endocrinology Department of the Clínica Universidad de Navarra. Adiposity parameters were measured using anthropometry (body mass index [BMI], neck circumference, abdominal circumference, hip circumference, waist circumference, waist-to-height ratio [WHtR]), Clínica Universidad de Navarra - Body Adiposity Estimator (CUN-BAE), bioimpedance (visceral fat and body fat percentage), nutritional ultrasound (subcutaneous and preperitoneal tissue), and non-invasive markers of MASLD status (Controlled Attenuation Parameter [CAP], liver stiffness [kPa], FIB-4 Score, Hepamet Fibrosis Score [HFS], and NAFLD Fibrosis Score [NFS]). The FIB-4 cutoff points were 1.3 (< 65 years) and 2.0 (≥ 65 years). Cardiovascular risk was estimated using SCORE2/SCORE2-Diabetes risk estimator.
Results: In patients living with obesity, SCORE2 showed a positive correlation with FIB-4 Score ($r = 0.55$; $p < 0.001$). No correlation was found between cardiovascular risk and abdominal perimeter ($r = 0.14$; $p = 0.11$) nor with the WHtR ($r = -0.01$; $p = 0.91$). FIB4 Score accounts for 23% of the variability in SCORE2, whereas abdominal perimeter and WHtR account for 1.6% and 1.4%, respectively. After adjusting for sex, a higher cardiovascular risk was found based on the FIB-4 Score quartiles (Q3: OR 10.64, 95% CI 1.21–93.35 [$p = 0.033$]; Q4: OR 58.85, 95% CI 6.84–506.51 [$p < 0.0001$]). Patients with an abnormal FIB-4 Score had a higher prevalence of hypertension, dyslipidemia, and hyperuricemia, as well as a greater proportion of men ($p < 0.05$).
Conclusion: Adiposopathy parameters, particularly liver status assessed through the FIB-4 Score, may complement the estimation of cardiovascular risk in patients living with obesity.

WED-179
Head-to-head comparison between FibroTest and ELF, for the fibrosis diagnostic in outpatients with type-2 diabetes, using Bayesian latent class models
Antoine Pilon[1], Michel Vaubourdolle[1], Valentina Peta[2], Dominique Valla[1], Laurent Castera[1], Pierre Bedossa[3], Vlad Ratziu[4], Olivier Deckmyn[2], Thierry Poynard[2,4]. [1]*Assistance Publique Hopitaux de Paris, Biochemistry Laboratory INSERM, Paris, France;* [2]*BioPredictive, Paris, France;* [3]*Liverpat, Paris, France;* [4]*Sorbonne University, Pitié Salpêtrière, ICAN, Paris, France*
Email: thierry@poynard.com

Background and aims: In patients with metabolic dysfunction-associated steatotic liver disease, (MASLD) two serum fibrosis panels with patented algorithms are among the most cited: the Nash-FibroTest combination (FT), known in the USA as Nash-FibroSure-Plus which integrates three tests to simultaneously assess fibrosis, steatosis, and inflammatory activity and the Enhanced Liver Fibrosis (ELF) score, which evaluates fibrosis only. Surprisingly no head-to-head one-step comparison has been published in type-2 diabetes. Our aim was to evaluate the comparative performance of FT and ELF for diagnosing significant fibrosis stages (F2-F3-F4), in 398 type-2 diabetes outpatients of the prospective ongoing QUID-NASH study, 57 years old median and 40% females.
Method: The standard reference, liver biopsy is misclassified in 25% of cases, inducing bias in sensitivity, specificity, and area under the receiver operating curve (AUC) in both magnitude and direction, distorting head-to-head differences. Therefore, to offer a solution relaxing the perfect-gold-standard assumption, we used Bayesian latent class models (BLCMs) which do not presuppose superiority of any test including the histological reference.
Results: BLCMs revealed that posterior mean AUC was 0.94 for FT and 0.76 for ELF, with a mean difference (FT-ELF) of 0.18, (95% credible interval, 0.12–0.25). Sensitivity analyses demonstrated similar results after stratification by age, sex or body mass index. The ELF components were tightly intercorrelated, with hyaluronic acid showing the strongest association with ELF ($r = 0.94$) and PIIINP also highly correlated ($r = 0.73$) and FT and ELF correlated only moderately ($r = 0.42$). In contrast with FT: markers relate to the score in mixed directions and magnitudes: alpha2-macroglobulin ($r = 0.80$), haptoglobin ($r = -0.35$), apolipoproteinA1 ($r = -0.19$), gamma-glutamyltranspeptidase ($r = 0.34$), and total bilirubin ($r = 0.44$). This less redundant signal contributes to the higher BLCM-estimated discrimination observed for FT.
Conclusion: These results highlight the importance of accounting for reference standard imperfection and support the use of head-to-head comparisons combined with latent class modeling.

Background and aims: Current EASL–EASD–EASO guidelines recommend fibrosis screening in a large proportion of the general population. Recently proposed refined screening indicators - based

on diabetes, obesity, transaminases, and cardiometabolic risk factors - substantially reduce the target population for screening, but their longitudinal performance remain unknown.
Method: This prospective, longitudinal study, conducted at three European centres (Barcelona, Rotterdam, Odense), is embedded within the LiverScreen consortium. Baseline and follow-up liver stiffness measurements (LSM) were assessed over an approximate four-year interval, excluding individuals with BMI<18.5 kg/m^2, excessive alcohol intake and insufficient data. Elevated LSM was defined as ≥8 kPa, persistent elevated LSM as ≥8 kPa at baseline and follow-up, and clinically significant LSM increase as an increase to ≥8 kPa from a baseline <8 kPa, with ≥30% rise.
Results: Among 3708 adults (mean age 61 years, 54% male) LSM ≥8 kPa prevalence was 4.6% (n = 169). The refined indicators reduced the proportion of individuals eligible for screening to 9.9%; which was 51% under prevailing guidelines, with the prevalence of elevated LSM in the eligible population increasing to 17% from 6.9%, while maintaining a high NPV of 97%. During a median follow-up of 4.4 years [IQR 4.2–8.7], 8.7% of the refined screening-eligible population had persistently elevated LSM, compared to 2.8% under prevailing guidelines, with comparable high NPVs (99.3% vs. 99.7%). Among individuals meeting refined indicators but who screened <8 kPa, 8.3% experienced a clinically significant LSM increase to LSM ≥8 kPa, and 4.3% to LSM ≥10 kPa, rates that were 2.4- and 2.5-fold higher than observed under prevailing guidelines (3.5% and 1.7%, respectively). Among individuals not selected by the refined indicators, only 1.7% experienced a clinically significant LSM increase (4.9-fold lower than the 8.3% in the refined screening eligible- group).
Conclusion: The EASL–EASD–EASO screening criteria identify 51% of European adults for screening, of which only 2.8% exhibit persistent LSM elevation. Refined screening indicators reduce the screening-eligible population to 9.9%, of which 8.7% had persistent LSM elevation. Clinically significant LSM progression occurred five-fold more frequently in individuals selected by the refined criteria than in those excluded (8.3% vs. 1.7%). These findings support a more targeted approach for liver disease screening.

AGILE 3+ enhances non-invasive detection of advanced fibrosis in MASLD: comparison with FIB-4 and liver stiffness measurement

Ismail Qarch[1], Mohamed Borahma[1], Fatima Zahra Chabib[1], Nawal Lagdali[1], Sabbah Selma[1], Fatima Zahra Ajana[1], Maryeme Kadiri[1]. [1]*Gastroenterology C Department, Ibn Sina University Hospital, Mohamed V University, Rabat, Morocco*
Email: ismail.qarch@gmail.com

Background and aims: MASLD is a major cause of chronic liver disease, with advanced fibrosis (≥F3) being a key prognostic factor. FIB-4 is commonly used for initial screening but has limited sensitivity. LSM reflects hepatic rigidity without standardized thresholds, while AGILE 3+ integrates elastography with clinical and biological variables for improved risk stratification.This study compared the diagnostic performance of FIB-4, LSM, and AGILE 3+ in a real-world MASLD cohort.
Method: We conducted a retrospective, single-center study over 7 years. Seventy MASLD patients with complete data were included. Advanced fibrosis was defined as ≥ F 3. Performance was assessed using sensitivity, specificity, NPV, PPV, and AUC. Standard cut-offs: FIB-4 (< 1.30; > 2.67) and AGILE 3+ (< 0.451; ≥ 0.679).
Results: The population (mean age 52.4 ± 10.9 years) was predominantly female (84.3%). Metabolic syndrome and type 2 diabetes were present in 68.6% and 28.6% of patients, respectively. Advanced fibrosis (F3–F4) was identified in 7 patients (10.0%). Liver stiffness measurement (LSM) alone showed excellent discrimination for advanced fibrosis (AUC = 1.00, 95% CI: 0.85–1.00), as all patients with F≥3 (7/7, 100%) exhibited higher liver stiffness values than those without advanced fibrosis, reflecting a marked separation of stiffness values in this cohort with a limited number of advanced fibrosis cases; however, LSM provided a continuous measurement without predefined decision thresholds. The AGILE 3+ score demonstrated high diagnostic accuracy (AUC = 0.914) and enabled standardized clinical stratification. Using validated cut-offs, AGILE 3+ classified most patients with advanced fibrosis into the rule-in category (6/7), with one false-negative in the rule-out zone. At the rule-in threshold (≥0.679), AGILE 3+ achieved a sensitivity of 85.7% and specificity of 87.3%, with an excellent NPV of 98.2%, and at the rule-out threshold (<0.451) reliably excluded advanced fibrosis, outperforming FIB-4 <1.30 (NPV 97.5% vs 92.9%). In contrast, FIB-4 >2.67 showed perfect specificity (100%) but low sensitivity (28.6%), supporting its role as a first-line triage tool rather than a definitive risk stratification method.
Conclusion: In this real-world MASLD cohort, AGILE 3+ and LSM outperformed FIB-4 for detecting advanced fibrosis. While LSM showed excellent discrimination in this limited sample, AGILE 3+ provided clinically actionable rule-in and rule-out stratification, supporting a stepwise non-invasive assessment strategy.

Background and aims: Obese status is closely associated with liver fibrosis and adverse hepatic outcomes. This study aimed to develop a reliable tool based on routine clinical indicators to assess liver fibrosis risk in populations with obesity.
Method: We developed a novel scoring system, termed the ObesityLiver score, which was validated using multiple independent, community-based cohorts of individuals with obesity from China, the United States, and the United Kingdom. We implemented a robust dual-training cohort strategy for model construction. In the training cohort 1 (n = 1,872), four machine learning algorithms were utilized to identify key features associated with advanced liver fibrosis (liver stiffness measurement ≥10), and 40 heterogeneous base learners were developed across 10 algorithms. In the training cohort 2 (n = 1,872), a genetic algorithm was employed to perform an automated heuristic search for the optimal ensemble configuration, culminating in the derivation of the ObesityLiver score. The model's predictive performance was validated across the training (cohorts 1 and 2) and testing cohorts (n = 3,214), while its long-term prognostic value was further ascertained in the prognosis cohort (n = 86,663).
Results: The ObesityLiver score demonstrated robust diagnostic accuracy for advanced liver fibrosis, with AUROCs of 0.931 (95% CI: 0.915–0.947) in the training cohort 1, 0.845 (95% CI: 0.810–0.880) in the training cohort 2, and 0.847 (95% CI: 0.823–0.871) in the test cohort, consistently outperforming established non-invasive tests including LiverRisk, CORE, FIB-4, APRI, and NFS. Utilizing optimized rule-out (0.035) and rule-in (0.097) thresholds, we stratified participants into low- medium- and high-risk groups. This approach yielded high diagnostic precision, with sensitivities ranging from 87.3% to 99.3% and specificities from 90.0% to 92.1% across the training and test cohorts. Furthermore, in the prognostic cohort, the medium- and high-risk groups exhibited a significantly higher cumulative incidence of liver-related events compared to the low-risk group.
Conclusion: The ObesityLiver score provides a robust and reliable tool for detecting advanced liver fibrosis and predicting liver-related events within community-based cohorts of individuals with obesity.

High burden of hepatic steatosis, fibrosis, and cardiometabolic risk in HIV-monoinfected adults on antiretroviral therapy: STEAT-HIV results

Giulia Quartini[1], Cinzia Di Giuli[1], Lavinia Maria Saraca[1], Luca Capogrossi[1], Elisabetta Svizzeretto[1], Giovanni Genga[1], Giulia Proietti[1], Marta Cordoni[1], Federica Gentili[2], Pierluigi Fiore[2], Giuseppe Vittorio Luigi De Socio[3], Claudio Ucciferri[4]. *[1]Infectious Disease Clinic, S. Maria Hospital Terni, Terni, Italy; [2]Hepatology, gastroenterology and digestive endoscopy structure, S. Maria Hospital Terni, Terni, Italy; [3]Infectious Disease Clinic, Department of Medicine and Surgery, University of Perugia, Perugia., Perugia, Italy; [4]Infectious Disease Clinic, Department of Medicine and Surgery, University of Perugia, Perugia, Infectious Disease Clinic, S. Maria Hospital Terni, Perugia, Italy*
Email: giulia.qu@outlook.it

Background and aims: Hepatic steatosis and fibrosis are increasingly recognized as major comorbidities in people living with HIV (PLWH), even without viral coinfections or metabolic syndrome. Chronic immune activation, metabolic dysfunction, and long-term antiretroviral therapy (ART) ART exposure contribute to progressive liver injury. The STEAT-HIV study aimed to assess the prevalence and determinants of hepatic steatosis and fibrosis using non-invasive tools and to explore their associations with metabolic and therapeutic variables.
Method: A retrospective and prospective cohort study (2021–2022) was conducted at the Infectious Diseases Clinic in Terni (Italy). Liver stiffness (LSM) and controlled attenuation parameter (CAP) were measured using FibroScan®. Biochemical (transaminases, lipids), anthropometric, and cardiovascular (ASCVD, SCORE) data were analyzed. Correlation and multivariate regression analyses were performed ($p < 0.05$).

Results: A total of 258 patients were analyzed, 115 PLWH on stable ART after excluding HBV/HCV coinfections, diabetes, alcohol abuse, and recent diagnoses (<6 months) were enrolled. Median age was 52 years (IQR 46–59), 73% were male, with median BMI 24.3 kg/m^2 (IQR 22.8–26.7) and HIV duration 14 years (IQR 10–19). ART regimens included 38% protease inhibitor (PI), 42% integrase inhibitor (INSTI), 15% Doravirine, and 5% two-drug regimens (2DR). Hepatic steatosis (CAP >248 dB/m) was observed in 42.6% (49/115), and significant fibrosis (LSM >7 kPa) in 18.9% (22/115). CAP correlated with total cholesterol ($r = 0.31$; $p = 0.002$), triglycerides ($r = 0.34$; $p < 0.001$), and ASCVD score ($p = 0.02$). Patients receiving PI-based regimens had higher CAP (285 dB/m, IQR 260–310) and LSM (7.4 kPa, IQR 6.1–8.8) compared to those on Doravirine or 2DR (CAP 245 dB/m, IQR 230–260; $p < 0.01$). FibroScan® parameters showed stronger correlations with metabolic indices than serum-based scores (FIB-4, APRI; $p < 0.001$).
Conclusion: Hepatic steatosis and fibrosis are highly prevalent in HIV-monoinfected patients,closely linked to metabolic dysregulation and ART exposure,particularly PI-based regimens. FibroScan®with CAP effectively identifies early hepatic injury and outperforms serum indices in this population. Integrating non-invasive liver assessment into PLWH care could enhance early detection,guide selection of metabolically favorable ART regimens and prevent long-term hepatic and cardiometabolic complications.

WED-184-YI
Referral strategies in intermediate-risk FIB-4 patients: can longitudinal monitoring reduce FibroScan® use without missing advanced fibrosis?
Ilaria Reiso[1], Kamela Gjini[1], Gian Paolo Caviglia[1], Angelo Armandi[1], Marta Guariglia[1], Eleonora Dileo[1], Francesca Saba[1], Elisabetta Bugianesi[1]. [1]*Division of Gastroenterology and Hepatology, Department of Medical Sciences, University of Turin, Turin, Italy, Turin, Italy*
Email: ilaria.reiso@unito.it

Background and aims: In patients with metabolic dysfunction-associated steatotic liver disease (MASLD), the Fibrosis-4 (FIB-4) score is the recommended first-line screening test for initial risk stratification of advanced fibrosis. Values in the intermediate-risk range (1.3–2.67) are associated with a high proportion of false positives, resulting in a substantial downstream second-line testing burden. Current guidelines suggests two possible approaches in this group: proceeding directly to liver stiffness measurement (LSM) or repeating FIB-4 in one year after a lifestyle change intervention. Since up to 40% of MASLD patients fall into this category, identifying strategies that optimise referral is needed.To compare two different referral strategies in patients with intermediate FIB-4 values and evaluate their ability to predict progression to advanced fibrosis over approximately 5–10 years.
Method: We retrospectively analysed 92 patients with baseline FIB-4 between 1.3 and 2.67. Advanced fibrosis at follow-up was defined by liver biopsy showing F3-F4, when available, or by LSM ≥12 kPa. Two referral strategies were compared: (1) immediate referral if baseline LSM ≥8 kPa; (2) referral if FIB-4 remained ≥1.3 at 1–2 years. Diagnostic performance was assessed through sensitivity (Se), specificity (Sp), positive predictive value (PPV), negative predictive value (NPV), and confusion matrices.
Results: Advanced fibrosis over a median follow up of 6 (2.7–13.2) years was detected in 25 patients (27%). When applied at baseline, LSM ≥8 kPa had the best diagnostic performance (Se 0.95; Sp 0.7, PPV 0.45, NPV 0.97) in predicting advanced fibrosis at last follow-up. In 19 (21%) patients, FIB-4 values declined below <1.3 at 1–2 years, despite no structured lifestyle change intervention, and none of these patients developed advanced fibrosis during follow up. Therefore, repeating FIB-4 at 1–2 years and performing LSM only if FIB-4 remains ≥1.3, would have avoided 21% of FibroScan® examinations, without any missed cases of advanced fibrosis (Se 1; Sp 0.22, PPV 0.25, NPV 1).
Conclusion: In FIB-4 intermediate-risk patients, repeating FIB-4 at 1–2 years prior to second-line testing can reduce unnecessary LSM by 21%, without missing advanced fibrosis cases at follow-up.

WED-185
Comparison of metabolic dysfunction-associated steatotic liver disease characteristics in patients with type 1 and 2 diabetes mellitus

Email: dh.richelle@student.maastrichtuniversity.nl

Background and aims: Metabolic dysfunction-associated steatotic liver disease (MASLD) is related to metabolic syndrome (MetS) and type 2 diabetes (T2DM). An association between type 1 diabetes (T1DM) and MASLD is not extensively investigated. Therefore, this study investigated the prevalence and risk factors for MASLD in T1DM compared to T2DM.
Method: In this Belgian prospective cross-sectional study, MASLD was evaluated via transient elastography (VCTE) for fibrosis and controlled attenuation parameters (CAP) for steatosis (FibroScan®, Echosens). The cut-off values >248 dB/m for steatosis and 8 kPa for fibrosis were used. MASLD was defined as steatosis with at least one cardiometabolic risk factor, not including the glucose criterium for the T1DM group. Excessive use of alcohol was excluded. Insulin sensitivity was calculated via estimated Glucose Disposal Rate (eGDR) and SEARCH estimated Insulin Sensitivity (eIS). Associations were explored separately in T1DM and T2DM through logistic regression and compared between groups via interaction analysis.
Results: 66 T1DM (mean age 57 ± 11.5 years, 61% male, body mass index (BMI) 26.6 ± 4.06 kg/m^2) and 290 T2DM patients (median age 61 [55.0–68.0] years, 57% male, BMI 31.7 [28.8–35.7] kg/m^2) were included. MASLD prevalence was 39% in T1DM and 83% in T2DM, with statistically significantly higher VCTE and CAP in T2DM ($p < 0.001$). eIS and eGDR were statistic significantly higher in T1DM compared to T2DM ($p < 0.001$). Waist circumference (OR 1.20 (95% CI 1.09–1.32), 1.18 (95% CI 1.08–1.29)), BMI (OR 1.59 (95% CI 1.23–2.06), 1.52 (95% CI 1.24–1.86)), and MetS (OR 3.11 (95% CI 0.73–12.23), 33.1 (95% CI 5.86–186.7)) were positively associated with MASLD in T1DM and T2DM, respectively. Better insulin sensitivity through eIS (OR 0.29 (95% CI 0.15–0.59), 0.48 (95% CI 0.29–0.79)) and eGDR (OR 0.68 (95% CI 0.52–0.90), 0.61 (95% CI 0.43–0.87)) was negatively associated with MASLD in T1DM and T2DM, respectively. Factors were adjusted for age, sex and diabetes duration.
Conclusion: MASLD is less prevalent and advanced in patients with T1DM compared to patients with T2DM. Classic metabolic risk factors are associated with MASLD in both T1DM with insulin resistance and T2DM. Further studies are needed to validate these findings and analyse the onset of double diabetes.

Combined serological testing to improve efficiency and sustainability in MASLD care

Jesús Rivera Esteban[1], Paula Iruzubieta[2], David Marti-Aguado[3], Marta Hernández Conde[1], Alba Jiménez-Masip[4], Elba Llop Herrera[1], Christie Perelló[1], María Teresa Arias Loste[2], Juan M. Pericàs[4], José Luis Calleja Panero[1], Javier Crespo[5]. [1]*Hospital Universitario Puerta De Hierro Majadahonda, Majadahonda, Spain;* [2]*Hospital Universitario Marqués de Valdecilla, Santander, Spain;* [3]*Hospital Clinico de Valencia, Valencia, Spain;* [4]*Hospital Universitario Vall d'Hebron, Barcelona, Spain;* [5]*Instituto de Investigación Valdecilla (IDIVAL), Santander, Spain*
Email: jesusriveraest@gmail.com

Background and aims: Sequential algorithms for diagnosing MASLD generate excessive referrals of patients without advanced disease, overloading specialized care. We evaluated whether combining first-line serological tests improves discrimination compared with single use and its impact on diagnostic pathways.
Method: FIB-4, NFS, and FLI were assessed individually and in combination in a Spanish population cohort (PREV-ETHON). Significant fibrosis was defined as liver stiffness ≥8.0 kPa by TE. Standard cut-offs for significant fibrosis were used (FIB-4 ≥ 1.30, NFS ≥−1.455, FLI ≥ 60). Combinations used AND (both positive) or OR (either positive) strategies. AUC, sensitivity, specificity, and predictive values were calculated.
Results: Among 6,190 participants, MASLD prevalence was 33.5% and significant fibrosis 3.9%. Individually, FIB-4, NFS, and FLI showed similar performance (AUC 0.66–0.71) for significant fibrosis detection, with moderate sensitivity (55–64%), specificity (<70%) and high NPV (97%),resulting in positive test rates—and thus referral rates—of approximately 32–33%. Combining FIB-4+FLI or the three tests (all positive) achieved 90% specificity, maintained 97% NPV, and reduced positives to 11.2% (FIB4+FLI) or 9.8% (FIB4+FLI+NFS), corresponding to a 60% reduction in hepatology referrals and second-line testing compared with single-test use. On the other hand, the OR strategy increased sensitivity (67–81%) but markedly reduced specificity (44–58%), leading to high referral rates (42–57%). Despite this, PPV remained low (5–6%), largely reflecting the low prevalence of significant fibrosis in the general population.
Conclusion: Combining first-line serological tests substantially reduces referrals while maintaining strong rule-out performance for significant fibrosis in low-prevalence populations, such as primary care. An automated, combined test could improve the efficiency and sustainability of MASLD diagnostic pathways.

Background and aims: In patients with metabolic dysfunction-associated steatotic liver disease (MASLD) and raised FIB-4 but normal vibration-controlled transient elastography (VCTE) < 8 kPa, current guidelines do not offer clear recommendations on optimal monitoring strategies. Demanding VCTE for all subsequent assessments could be excessive. We aimed to evaluate whether changes in routine markers can help prioritize patients for VCTE re-referral.
Method: The VCTE-Prognosis study was a global MASLD cohort (2004–2023) with serial routine markers and VCTE assessments. We modelled LSM trajectories over 36 months using latent growth mixture analysis in patients with a first LSM < 8 kPa. Linear mixed-effects models evaluated changes in 14 routine markers and two scores within each trajectory and their correlation with LSM progression.
Results: Among 10,789 patients (median age 54; 58% male) three LSM trajectories were identified. Despite distinct baseline LSM in Class 1 (62.4%; 4.6 kPa, 95%CI = 4.5–4.6) and Class 2 (35.8%; 6.5 kPa, 95%CI = 6.4–6.6), both classes showed stable trends over time (0.0 kPa/month, 95%CI = – 0.0–0.0), whereas Class 3 (1.8%; 7.6 kPa, 95%CI = 7.5–8.1) showed an increasing trend in LSM of 0.2 kPa/month (95%CI = 0.2–0.2). Within three years, 4 (0.0%), 416 (10.8%) and 197 (100%) patients across the respective classes exceeded 8 kPa. FIB-4 trajectories most closely mirrored LSM progression, increasing of 1% per month in Class 3.
Conclusion: In patients with MASLD and normal liver stiffness, progression to an LSM ≥ 8 kPa within three years was observed in less than 6%. Most patients exhibited stable LSM over time, suggesting that monitoring intervals may be extended to every three years or longer, while annual follow-up is advisable for those with baseline LSM between 6 and 8 kPa. A yearly FIB-4 increase of ~ 12% may indicate need for re-referral.

Email: diego93rojo@gmail.com

Background and aims: Social determinants of health (SDH) are increasingly recognised as modifiers of disease progression in metabolic dysfunction-associated steatotic liver disease (MASLD). However, their prognostic relevance in patients with compensated advanced chronic liver disease (cACLD) remains poorly defined. We aimed to evaluate the association of SDH with the risk of major adverse liver outcomes (MALO) and major adverse cardiovascular events (MACE) in patients with cACLD.
Method: Prospective multicentre cohort including patients with cACLD due to MASLD from nine tertiary hospitals in Spain. Demographic, clinical, laboratory and imaging data were collected. SDH were assessed at baseline using a structured questionnaire. Nine socioeconomic variables, including employment status, household economic role, income, housing conditions, educational level, marital status, country of origin, age and sex, were used to construct a composite LiverSocial score. Each variable was analysed using univariable logistic regression with a composite endpoint of MALO and/or MACE. A weighted LiverSocial score was constructed using β coefficients derived from univariable logistic regression. Binary logistic regression models assessed its association and predictive performance.
Results: A total of 325 patients were included (median age 65 years [59–70]), 170 (52%) women, followed for a mean of 2.7 years. Arterial hypertension and diabetes mellitus were present in 72.4% and 69.8% of patients, respectively. Previous cardiovascular disease was documented in 9.6%. At baseline, five patients (1.5%) were classified as Child–Pugh B, and 98.5% as Child–Pugh A. During follow-up, MALO occurred in 28 patients (8.6%) and MACE in 13 (4.0%). Hepatocellular carcinoma developed in 4 (1.2%), and 26 (8.0%) experienced hepatic decompensation. Three patients underwent liver transplantation (0.9%). In univariable analyses, increasing age was significantly associated with the composite endpoint, whereas other SDH variables were not. In contrast, the weighted LiverSocial score was associated with MALO and/or MACE (OR 2.21, 95% CI 1.23–3.99; p = 0.008), with moderate discrimination (AUC 0.64, p = 0.0083) and an optimal cut-off of 2.5.
Conclusion: In patients with cACLD due to MASLD, a composite SDH-based score was associated with major liver and cardiovascular events. These findings suggest a potential role for integrating social vulnerability into holistic risk stratification strategies for advanced MASLD, warranting further validation.

WED-189
Lysosomal acid lipase activity as a marker of advanced fibrosis in steatotic liver disease: a prospective study

Roni Nasser[1], Afif Yaccob[1], Rawi Hazzan[2], Tor Regev-Sadeh[3], Fadi Abu Baker[4], Tarek Saadi[5]. *[1]Rambam Health Care Campus, HAIFA, Israel; [2]Clalit Health Services, Northern Region, Israel, HAIFA, Israel; [3]Bruce Rappaport Faculty of Medicine, Technion-Israel Institute of Technology, Haifa, Israel, HAIFA, Israel; [4]Department of Gastroenterology and Hepatology, Hillel Yaffe Medical Center, Hadera, Israel, HAIFA, Israel; [5]Rambam Health Care Campus, ARRABA, Israel*
Email: dr.t.saadi@gmail.com

Background and aims: Lysosomal acid lipase deficiency (LAL-D) is a rare genetic disorder that may mimic steatotic liver disease (SLD), particularly in patients without typical metabolic dysfunction. Accurate diagnosis is critical due to the availability of effective enzyme replacement therapy. The objectives of this study are to assess the prevalence of LAL-D in a selected cohort of non-obese individuals with SLD accompanied by dyslipidemia, or with cryptogenic cirrhosis, and to evaluate the relationship between LAL activity and liver disease severity.
Method: In this prospective observational study, 102 adult patients with imaging- or biopsy-confirmed SLD and dyslipidemia or cryptogenic cirrhosis were enrolled at a tertiary liver center in Israel. Individuals with secondary causes of hepatic steatosis, including excessive alcohol consumption, viral hepatitis, and other chronic liver diseases, were excluded. LAL activity was measured via dried blood spot testing. Clinical, laboratory, imaging, and histological data were collected.
Results: None of the patients demonstrated LAL deficiency. Mean LAL activity was 0.48 nmol/punch/hour. A median LAL level of 0.445 nmol/punch/hour was associated with advanced fibrosis (F3–F4) as compared to mild/moderate fibrosis (F0–F2). AUC was 0.64 (p = 0.031), suggesting potential clinical relevance. However, no LAL activity threshold could distinguish between presence or severity of hepatic steatosis. Higher LAL levels were also positively correlated with white blood cell and platelet counts.
Conclusion: Our findings suggest a low prevalence of LAL-D even within a selected cohort of non-obese patients with SLD or cryptogenic cirrhosis. Nonetheless, reduced LAL activity—particularly levels below 0.445 nmol/punch/hour—was associated with advanced hepatic fibrosis and may serve as a non-invasive marker of disease severity. Targeted testing in individuals with compatible clinical features could aid in risk stratification and guide further evaluation.

WED-190
ACT on MASH: A multi-country cross-sectional online survey of awareness, disease perceptions, and cardiometabolic comorbidities among people at risk for or living with MASLD and MASH

Sahar Saeed[1], Husam Albarmawi[2], Edwige-Ludiwyne Balzac[3], Julio Burman[4], Nathalie Eklöf[5], Takumi Kawaguchi[6], Nobuyoshi Kosaka[7], Jeff McIntyre[8], Lauren Nephew[9], Arash Pakseresht[10], Jörn M. Schattenberg[11], Cyrielle Caussy[12]. *[1]Queens University, Ontario, Canada; [2]Novo Nordisk, Mainz, Germany; [3]Novo Nordisk, France, Paris, France; [4]European Liver Patients' Association, Brussels, Belgium; [5]Novo Nordisk, Soberg, Denmark; [6]Division of Gastroenterology, Department of Medicine, Kurume University School of Medicine, Kurume, Japan; [7]Novo Nordisk, Japan, Tokyo, Japan; [8]Global Liver Institute, Washington DC, United States; [9]Indiana University School of Medicine, Indianapolis, United States; [10]Novo Nordisk, Canada, Mississauga, Canada; [11]Department of Medicine, Saarland University Medical Center, Homburg, Germany; [12]Hospices Civils de Lyon, Département Endocrinologie, Diabète et Nutrition, Hôpital Lyon Sud, Univ Lyon, CarMen Laboratory, INSERM, INRA, INSA Lyon, Université Claude Bernard Lyon 1, Pierre-Bénite, France*
Email: sahar.saeed@queensu.ca

Background and aims: Globally, an estimated one in three people is living with metabolic dysfunction-associated steatotic liver disease (MASLD), yet the perspectives of those affected remain poorly characterized. This study assessed awareness, knowledge, and perceptions of MASLD and metabolic dysfunction–associated steatohepatitis (MASH) among people diagnosed with, or at risk for, these conditions.
Method: In 2025, a multidisciplinary team, including a patient advocacy representative, developed an online cross-sectional survey among people diagnosed with MASLD/MASH or at risk for MASH living in Canada, France, Germany, Japan, and the United States (US). "At risk" was defined as having ≥1 cardiometabolic risk factor or a blood test showing elevated liver enzymes. Survey respondents were recruited via online panels, databases, outreach, and social media.
Results: Among 516 people completing the survey, 252 had MASH, 132 had MASLD, and 132 were at risk for MASH. The median age of respondents was 48 years. 50% of respondents were female, and 49%

had a university degree or higher. Cardiometabolic comorbidities were common among people with MASLD (obesity, 72%; hypertension, 42%; type 2 diabetes, 25%), with MASH (obesity, 71%; hypertension, 45%; type 2 diabetes, 35%), and for people at risk for MASH (obesity, 67%; hypertension, 47%; type 2 diabetes, 29%). Most respondents agreed they received a timely diagnosis (MASLD, 62%; MASH, 60%); however, the proportion of respondents who were "very" or "extremely" familiar with disease progression was low (MASLD, 15%; MASH, 37%). 58% of at-risk people recognized they were at risk of MASLD/MASH, and 58% were "very" or "extremely" concerned about the possibility of developing MASLD/MASH. Only 9% of at-risk people reported being "very" or "extremely" familiar with MASH. Overall, 55% of respondents with MASH "agreed" or "strongly agreed" that there is stigma associated with having liver disease, with notable variation by country (Canada, 73%; France, 77%; Germany, 57%; Japan, 50%; United States, 56%).
Conclusion: Awareness and understanding of MASLD and MASH remain low among both diagnosed and at-risk people, despite high cardiometabolic comorbidity. Low familiarity with disease progression and widespread perception of stigma highlight the need for patient education, stigma-reduction initiatives, and improved patient-provider communication.

Identification of advanced fibrosis in MASLD through breath fingerprinting: clinical trial results
Osnat Sella Tavor[1], Orit Marom Albeck[1], Ilay Marom[1], Omer Meroz[1], Gilad Feinberg[1], Lenny Aharon[1], Rifaat Safadi[2]. *[1]NaNose Medical, Netanya, Israel; [2]Hadassah Medical Organization, Hadassah Hebrew University Medical Center, Jerusalem, Israel*
Email: osnatst@nanosemed.com

Background and aims: Metabolic dysfunction–associated steatotic liver disease (MASLD) is the most common chronic liver disease worldwide, with prevalence expected to increase alongside rising rates of obesity and diabetes. Fibrosis stage is key determinant of prognosis; however, identification of advanced fibrosis remains challenging in routine clinical practice. Although liver biopsy is the reference standard, its invasiveness, sampling variability, and cost limit widespread use. Existing non-invasive assessments suffer from low specificity (< 65%) and limited accessibility. This study aimed to evaluate the performance of volatile organic compound (VOC)–based breath analysis for identifying advanced fibrosis in MASLD and assess its ability to discriminate fibrosis stage in comparison with established non-invasive assessment approaches with the aim to advance an effective, accurate non-invasive test suitable for use in the primary care setting.
Method: Chemi-resistor, nanoparticle based sensors exposed to subjects expelled breath samples via the innovative NaNose Dianose device. DiaNose utilizes a disposable breath collection unit, a replaceable sensor and a measurement system. It is a unique and novel measurement device that enables breath sample analysis under standardized environmental conditions across different geographic locations. The time-series sensor responses were fed into an advance AI algorithm, analyzed and a classifier differentiating between F0/F1 and F3/F4 stage MASLD was created. Clinical data was collected from MASLD patients across fibrosis stages, confirmed by liver biopsy or FibroScan.
Results: Breath samples obtained from 71 individuals with MASLD were analyzed, including 40 participants with absent or mild fibrosis and 31 with advanced fibrosis. This data were used to develop a classification algorithm within the clinical trial framework. Cross-validation analysis yielded a sensitivity of 76.2%, specificity of 83.9%, and an overall classification accuracy of 80.7%. Participant recruitment and data collection are ongoing to further enhance model robustness and external applicability.
Conclusion: The findings suggest that DiaNose differentiates between early and advanced fibrosis in individuals with MASLD and may serve as a rapid, non-invasive point-of-care screening tool. This approach has the potential to optimize primary care management, improve accessibility in underserved and rural settings, and support trial stratification to advance treatment development.

WED-195
Dynamics of noninvasive tests (NITs) - LIVERFAST, FIB-4 and vibration-controlled transient elastography (VCTE, Fibroscan), during monitoring therapy with TNR-beta agonist Resmetirom (RT) in patients with MASH- update
Jeevin Sandhu[1], Shaheen Mehrara[2], Mona Munteanu[3], Akash Pagadala[4], Ashwini Mehta[1], John Lee[3], Obinna Okolo[2], Parker Woods[5], Parvez Mantry[2,6]. *[1]Methodist Dallas Medical Center, Division of Hepatology, Internal Medicine, Dallas, United States; [2]Methodist Dallas Medical Center, Liver Institute, Dallas, United States; [3]Fibronostics U.S., Inc, New Orleans, United States; [4]University of Southern California, Los Angeles, United States; [5]Methodist Dallas Medical Center, Liver Institute, Dallas, dallas, United States; [6]LIver Institute, methodist Dallas medical center, Dallas, United States*
Email: parvezmantry@mhd.com

Background and aims: LIVERFAST is a new blood-based NIT that assess quantitatively fibrosis, MASH-activity, and steatosis. **Aims:** To assess the dynamics of LIVERFAST, FIB-4 and VCTE and CAP in monitoring patients on-RT and its response on fibrosis and steatosis [≥10% regression rate (10%RR) from baseline to repeated NIT].
Method: On-RT patients with baseline (t0) and repeated (t1) NITs have been included retrospectively. Statistics included Kaplan Meier non-parametric censored at 10% RR from t0, Tukey-Kramer Multiple-Comparison Test and subgroup analysis for dose/GLP-1 receptor agonists (GLP-1RA) analysis.
Results: Eligible patients without RT discontinuation: n = 86, 62% 80mg-dose, 39% male, 55% T2D, 46% GLP-1RA, mean (se) age 62.4 (1.3), BMI 33.7 (0.7), ALT 44 (4), FIB4 1.79 (0.14). T0-prevalence of F2F3 were 61% (LIVERFAST) and 44% (VCTE). Median (max) delays (mths) t0-to-t1 were 3.4 (LIVERFAST), 7.6 (VCTE) and 6.7 (FIB4). 67pts. with t0-FIB4 had no change at t1, (1.85 vs 2.02), or AST (44 vs 36), platelets count (230 vs $224*10^9$), all p = ns, and ALT (53 vs 40, p < 0.05). 30 pts had repeated VCTE (median t0–10.7 vs t1–10.1 Kpa) and CAP (t0–301 vs t1–299 dB/m), all p = ns regardless the dose or the association with GLP-1RA. 44 pts achieved t1-LIVERFAST with median scores (t0 vs t1): fibrosis (0.48 vs 0.38, p < 0.001), steatosis (0.50 vs 0.42, p < 0.05), activity (0.45 vs 0.42, p = ns), mainly in the 80 mg group (n = 27) and in either groups of RT-alone or in combination to GLP-1RA for fibrosis (p < 0.05). LIVERFAST-fibrosis 10% RR from t0 has been achieved more within 80mg-RT group than within 100mg-RT at 3 and 6mths, respectively: 23.8% vs 20.7% and 79.2% vs 37.5%, overall logrank p < 0.05). LFAST-steatosis 10% RR from t0 has been achieved more within 80mg-RT group (overall logrank p < 0.05). The significant decrease t0-to-t1 in the total cholesterol has neither impacted the ApolipoproteinA1 [131 vs 146 mg/dl] or LIVERFAST fibrosis score.
Conclusion: RT-Initiation based on NITs is efficient and allows further non-invasive monitoring. LIVERFAST is an efficient monitoring test that reflects histology remodeling and provides earlier insights into disease progression and RT response. A significant improvement (≥10%) in LIVERFAST fibrosis and steatosis scores have been observed after the third month of RT mainly in the 80 mg group. FIB-4 and VCTE and CAP scores showed limited change at reassessment.

WED-196

Cell-free chromatin liquid biopsy for non-invasive MASH diagnosis and monitoring

Gavriel Fialkoff[1], Jenia Gutin[1], Israa Sharkia[1], Ronen Sadeh[1], Rifaat Safadi[2], Yael Milgrom[2], Münevver Demir[3], Frank Tacke[3], Cornelius Engelmann[3], Nofar Rosenberg[4], Ophir Hay[4], Eithan Galun[4], Esther Harpenas[5], Amon Asgharpour[6], Jennifer Sayne[6], Michael Idowu[6], Nir Friedman[5], Arun J. Sanyal[6]. [1]*Senseera LTD, Jerusalem, Israel;* [2]*Hadassah-Hebrew University Medical Center, The Liver Unit Institute of Gastroenterology and Liver Diseases, Jerusalem, Israel;* [3]*Charité - Universitaetsmedizin Berlin, Department of Hepatology and Gastroenterology, Berlin, Germany;* [4]*Hadassah-Hebrew University Medical Center, The Goldyne Savad Institute for Gene Therapy, Jerusalem, Israel;* [5]*Hebrew University of Jerusalem, Faculty of Medicine, Jerusalem, Israel;* [6]*Virginia Commonwealth University School of Medicine, Richmond, United States*
Email: nir.friedman@mail.huji.ac.il

Background and aims: While much progress has been made in development of non-invasive tests (NITs) for fibrosis assessment, there remains an unmet need for validated NITs to diagnose metabolic dysfunction associated steatohepatitis (MASH) and to improve upon existing fibrosis biomarkers. The aim of this study was to evaluate cfChIP-seq - cell-free chromatin immunoprecipitation followed by sequencing - for non-invasive profiling of MASH-specific transcriptional activity directly from plasma.
Method: cfChIP-seq directed to histone modifications associated with transcriptionally active genes serves as a non-invasive method to provide a genome-wide scale readout of transcriptional activity in the tissues of origin, including the liver. This was used to establish a MASH score for the diagnosis of MASH. MASH score discovery was performed in a cohort of 72 biopsy proven MASLD, 1230 undiagnosed general population samples and 102 biopsy proven non-MASLD liver disease patients to ensure high specificity. The score was validated in another cohort of biopsy proven MASLD (n = 258).
Results: In the biopsy proven validation cohort the MASH score achieved an AUC of 0.93 (CI: 0.91–0.95) for the identification of MASH compared to the general population cohort. The AUC for the identification of MASH with NAFLD activity score ≥ 4 and fibrosis stages 2–4 (at-risk MASH) was 0.97 (CI: 0.96–0.99). We also demonstrate acceptable specificity of the MASH score versus other liver etiologies. Our analysis indicates that the MASH score is related to the presence and severity of individual histological features (NAS components/fibrosis). We also identified biomarkers associated with independent histological components of the disease, including fibrosis, thereby potentially enabling decoupling of fibrosis staging from disease activity in future applications.
Conclusion: Here, we developed a chromatin liquid biopsy MASH score for the non-invasive detection of MASH. This technology provides a noninvasive window into the liver's physiological state, with promise not only for detection but also for guiding precision drug selection and monitoring responses in the evolving landscape of MASH therapy.

WED-197

Metabolic matters: real-world assessment of metabolic dysfunction–associated steatotic liver diseases in the United States by integrating international classification of diseases codes and non-invasive tests for improved detection

Jörn M. Schattenberg[1], Zuleika Aponte Torres[2], Lu Zhang[2], Katrine Lindvig[3], Mireia Raluy[4], Mark Yates[5], Claudio Sartini[6], Zobair M. Younossi[7]. [1]*Department of Internal Medicine II, University Medical Center Homburg, Homburg and Saarland University, Homburg, Germany;* [2]*West Sussex, United Kingdom;* [3]*Evido Health, Odense, Denmark;* [4]*Thermo Fisher Scientific, Stockholm, Sweden;* [5]*Thermo Fisher Scientific, London, United Kingdom;* [6]*Boehringer Ingelheim International GmbH, Ingelheim, Germany;* [7]*The Global NASH/MASH Council, Washington, DC, United States*
Email: zobair.younossi@cldq.org

Background and aims: There is an urgent need for game-changing strategies to identify, risk-stratify, and improve management of metabolic dysfunction–associated steatotic liver diseases (MASLD) such as metabolic dysfunction–associated steatohepatitis (MASH) in routine practice. Studies have consistently reported underdiagnosis of MASH using only International Classification of Diseases (ICD) codes, underlining the importance of empowering physicians to identify patients with the disease earlier. This study aimed to discover the size of the patient population diagnosed with, or at-risk for MASH in the United States by leveraging an integrated approach using ICD coding, non-invasive test (NIT) data, and a machine learning (ML)-based fibrosis assessment (LiverPRO, Evido Health, Denmark).
Method: This observational, non-interventional, retrospective study used electronic health record and claims data from the Optum® Market Clarity (OMC) US database between January 1, 2021, and December 31, 2023. Adults aged ≥ 18 years were eligible. Case definitions classified patients as diagnosed with MASH (ICD code K75.81) or at-risk for MASH using combinations of the ICD code for MASLD (K76); Fibrosis-4 Index (FIB-4) scores ≥ 1.3 calculated with AST, ALT, platelets, and age; and LiverPRO-defined ≥ F2 fibrosis. LiverPRO is a validated, algorithm-based tool that estimates liver fibrosis risk using NITs and patient age. Same-day lab values were required for FIB-4 and LiverPRO computations.
Results: In total, 42,596,381 patients were included from the OMC database. The total prevalence of patients with MASH diagnosis (0.5%) or at-risk for MASH (8.1%) was 8.5%. Among patients identified as at-risk for MASH, the prevalence of those with MASLD diagnosis was 5.2%, and that of patients without MASH/MASLD diagnosis but with FIB-4- or LiverPRO-defined fibrosis was 1.9% (of which, 40.0% with overweight/obesity, 27.2% with diabetes) or 1.0% (of which, 47.3% with overweight/obesity, 39.0% with diabetes), respectively.
Conclusion: Our findings indicate a gap in MASH disease recognition, as the diagnosed prevalence in OMC is very low compared with overall prevalence estimates in the literature. Diagnosis rates may be improved by leveraging the use of FIB-4 and other novel NITs, especially among patients identified as at-risk for MASH. Educating physicians on NIT use and interpretation, especially in the presence of metabolic factors, could empower them to diagnose MASH in an earlier stage.

WED-198

Velacur determined fat fraction as a tool to predict MRI-PDFF changes in patients receiving liver-directed treatment

Caitlin Schneider[1], Jim Hennan[2], Xiaomin Lu[2], Matthew Dauphin[2], Rebecca Taub[2]. [1]*Sonic Incytes Medical Corp, Vancouver, Canada;* [2]*Madrigal Pharmaceuticals, West Conshohocken, United States*
Email: caitlin@sonicincytes.com

Background and aims: As new treatments are becoming available for patients with MASLD and MASH, non-invasive methods at the point of care will be needed to assess patient response. MRI Proton Density Fat Fraction (MRI-PDFF) MRI-PDFF is the most well-validated non-invasive imaging biomarker associated with histologic improvement in MASH. Although still with limitations, MRI-PDFF responders were significantly more likely to have a histologic response. This study examines the efficacy of Velacur Determined Fat Fraction (VDFF) to identify patients demonstrating significant (>30%) changes in the MRI-PDFF which would indicate treatment response, as defined in AASLD and EASL recommendations.

Method: Patients enrolled in Madrigal's open label extension (OLE) study for resmetirom, who had a qualifying Velacur and MRI-PDFF scan at Day1, and at any follow-up visit (week 16 or week 52) were included. Each Day 1-follow-up visit pair was treated as an independent data point for change-over-time analyses. This study included cirrhotic and non-cirrhotic patients previously enrolled in other blinded resmetirom studies, but all patients received resmetirom during the OLE. The AUROC, sensitivity and specificity of changes in Velacur VDFF to predict ≥ 30% changes in MRI-PDFF were calculated.
Results: Data was collected between Aug 2021 and May 2024 from 9 sites in the US. A total of 626 paired visits were collected. From these visits, 127 unique patients, with 181 qualifying, paired visits were included in the analysis. The median Day1 MRI-PDFF was 9.4%. Of the included patients, 106 had received treatment in the previous study and 21 were treatment naïve at Day1. At Week 16, median percent change from Day 1 was −24.3% for MRI-PDFF and −27.3% for VDFF; at Week 52, corresponding changes were −24.5% and −28.3%, respectively. No statistically significant difference in median percent change was observed between MRI-PDFF and VDFF (p = 0.4). At 85 (47%) of the visits, a patient showed ≥ 30% decrease in MRI-PDFF. Using the same 30% change cutoff for VDFF, the AUROC was 0.76 [0.68, 0.82], with a sensitivity of 68% and specificity of 75%. The positive predictive value of VDFF was 70%.
Conclusion: Accurately monitoring changes in patients over time, in response to treatment, is important to understanding which patients are benefiting. In this study, Velacur VDFF tracked longitudinal changes in liver fat similar to MRI-PDFF and represents a promising point-of-care approach for identifying patients likely to be responding to therapy.

WED-199

Phenotype-dependent failure of FIB-4 to rule-out advanced fibrosis among patients with MASLD in primary care: four-cohort comparison with LiverPRO

Abdel-Aziz Shaheen[1], Katrine Lindvig[2], Georg Semmler[3], Julie Astono[2], Maja Thiele[4], Mark Swain[1], Aleksander Krag[5], M Mang[6], Bernhard Wernly[7], Christian Datz[8], Juan G Abraldes[6]. *[1]University of Calgary, Calgary, Canada; [2]Evido Health, Copenhagen, Denmark; [3]Medical University of Vienna, Vienna, Austria; [4]Centre for Liver Research, Copenhagen, Denmark; [5]Odense University Hospital, Odense, Denmark; [6]University of Alberta, Edmonton, Canada; [7]Center for Public Health and Healthcare Research, Clinic I for Internal Medicine, University Hospital Salzburg, Salzburg, Austria; [8]General Hospital Oberndorf, Teaching Hospital of the Paracelsus Medical University, Salzburg, Austria*
Email: az.shaheen@ucalgary.ca

Background and aims: EASL recommends FIB-4 score as first-line test in primary care to rule-out advanced fibrosis in individuals with suspected metabolic dysfunction-associated steatotic liver disease (MASLD), but external validation across general populations and clinical phenotypes is limited. We compared FIB-4 with LiverPRO across four EASL-eligible MASLD cohorts (based on EASL guidelines for MASLD risk-stratification).
Method: We analysed four primary-care MASLD cohorts: Calgary (two-dimensional shear wave elastography, n = 8,126), Edmonton (vibration-controlled transient elastography [VCTE], n = 985), Denmark (VCTE, n = 4,365) and Austria (VCTE, n = 704). Advanced fibrosis was defined as liver stiffness measurement (LSM) ≥8 kPa. Rule-out thresholds were FIB-4 < 1.30 or LiverPRO < 0.25. Outcomes were false-negative (FN) proportion among LSM≥8, missed LSM≥8 per 1,000 risk-stratified, and negative predictive value (NPV). Analyses were stratified by age (at 65), sex, body mass index (BMI at 30), alanine aminotransferase (ALT at 30 U male/ 25 U female) and diabetes status.
Results: In the primary-care cohorts, the median age was 43–59 years, BMI 28–31, diabetes 13–38%, and LSM ≥ 8 prevalence 8–14%. Overall, FIB-4 classified 67–77% as low risk yet FN rates were 41–55% (35–62 missed/1,000; NPV 92–95%). LiverPRO classified 32–60% as low risk with FN rates of 13–23% (12–32 missed/1,000; NPV 93–97%), corresponding to 22–32 percentage-point lower FN rates and 22–30 fewer missed cases per 1,000 across cohorts. Among patients with diabetes, FIB-4 missed 48–110 cases/1,000 screened versus 12–46 with LiverPRO. FIB-4 heterogeneity was most prominent by age, where FN rates were 54–67% in < 65 years vs 0–29% in ≥ 65 years, and increased with obesity and normal ALT (BMI ≥ 30 45–63% vs. BMI < 30 23–48%; normal ALT 20–67% vs. elevated ALT 36–51%). LiverPRO FN rate remained lower with narrower range among these subgroups (< 65 years 16–28%; ≥ 65 years 0–12%; BMI ≥ 30 16–24%; elevated ALT 9–24%). FN was higher within FIB-4 compared to LiverPRO in women (32–64% vs. 11–25%) and men (34–56% vs. 12–33%).
Conclusion: Across four EASL risk-stratification eligible primary care MASLD cohorts, the recommended FIB-4 rule-out threshold generated clinically relevant and phenotype-dependent false reassurance, particularly in younger individuals and patients with diabetes. LiverPRO provided more consistent rule-out and substantially reduced missed advanced fibrosis. This supports evaluating LiverPRO to optimise MASLD triage pathways.

WED-200

Diagnostic yield and efficiency of non-invasive two-tier pathways for liver fibrosis assessment in metabolic dysfunction-associated steatotic liver disease

Neha Sharma[1], Yasamin Farbod[1], Dana Kablawi[1], France Martineau[1], Sara Alessa[1], Amina Alsalmi[1], Adam Hassan[2], Aurgho Datta[1], Randy Ngalamulume Mukengeshayi[2], Philip Wong[1], Xun Zhao[1], Marc Deschenes[1], Tianyan Chen[1], Amine Benmassaoud[1], Giada Sebastiani[1]. *[1]Centre universitaire de Santé McGill, Montréal, Canada; [2]McGill University, Montréal, Canada*
Email: giada.sebastiani@mcgill.ca

Background and aims: The impact of redefining NAFLD as metabolic dysfunction–associated steatotic liver disease (MASLD) on first-tier non-invasive fibrosis testing is unclear. We compared the diagnostic efficiency of five two-tier pathways combining serum biomarkers (first tier) and transient elastography (TE; second tier) for detecting fibrosis (F2–F4) in MASLD.
Method: Patients with MASLD, without alcohol misuse or viral hepatitis, were consecutively enrolled at a tertiary hepatology program in Québec between 2015 and 2025. Five simple serum fibrosis biomarkers—fibrosis-4 index (FIB-4), BARD score, NAFLD fibrosis score, AST/ALT ratio, and AST-to-platelet ratio index (APRI)—were evaluated as first-tier tests to exclude fibrosis (F2–F4). All participants subsequently underwent TE (FibroScan®). For each pathway, we estimated the proportion of avoidable TE examinations based on low-risk biomarker results and the discordance rate between low biomarkers and high TE measurement (≥8 kPa). Diagnostic yield was defined as the difference between avoided TE examinations and discordance. A weight yield model ($\lambda = 3$) was applied to reflect the greater clinical impact of missed fibrosis, whereby each missed case was considered three times more detrimental than an avoided TE.
Results: A total of 233 patients with MASLD (mean age 57 years, 52% male, mean BMI 32 kg/m^2). Fibrosis by TE was present in 38%. First-tier testing would have reduced TE referrals by 35% using the NAFLD fibrosis score, 48% with BARD, 54% with FIB-4, 55% with AST-ALT ratio and 78% with APRI. However, discordance between low-risk biomarkers and high TE ranged from 14% with BARD to 25% with

APRI. Net diagnostic yield (avoidable TE minus discordance) was highest for APRI (53) and FIB-4 (39), but after applying the weighted penalty for missed fibrosis, FIB-4 achieved the highest overall weighted yield (+7.9). In contrast, APRI showed a markedly reduced weighted yield (+3.3), while the NAFLD fibrosis score resulted in a negative weighted yield (−17.5). FIB-4 reduced TE referrals by 53.8% while maintaining a relatively low discordance rate (15.3%), representing the most balanced performance across pathways.
Conclusion: In patients with MASLD, two-tier diagnostic pathways substantially reduced the need for TE. Incorporating a weighted yield analysis that penalizes missed fibrosis identified FIB-4 as the most efficient and clinically balanced first-tier test, supporting its preferential use for non-invasive fibrosis risk stratification in MASLD care pathways.

WED-201
aMAP score effectively stratifies HCC risk in the steatotic liver disease population in the UK biobank
Yaru Shi[1], Wenxin Xu[1], Ning Yu[1], Zhihong Liu[1], Ya Xu[1], Jinlin Hou[1], Rong Fan[1]. [1]*Department of Infectious Diseases, Nanfang Hospital, Southern Medical University, Guangzhou, China*
Email: rongfansmu@163.com

Background and aims: Steatotic liver disease (SLD), currently the most prevalent chronic liver disease worldwide, is associated with an increased risk of hepatic and extrahepatic complications, including hepatocellular carcinoma (HCC), highlighting the need for risk stratification to guide surveillance. The aMAP score, developed for HCC risk prediction mostly in patients with viral hepatitis across 11 global prospective studies, has been less studied in SLD. This study aimed to assess the predictive performance of aMAP for HCC risk in a large SLD cohort.
Method: Data were obtained from the UK Biobank, a prospective cohort. Patients with SLD were identified and categorized into metabolic dysfunction-associated steatotic liver disease (MASLD), metabolic alcohol-related steatotic liver disease (MetALD), and alcohol-related liver disease (ALD), excluding those with viral hepatitis. The aMAP score was calculated, and its performance for HCC prediction was evaluated using discrimination, risk stratification with adjustment for competing risk of death, and calibration. Cross-sectional and longitudinal associations between metabolic parameters and aMAP scores or risk categories were assessed, with longitudinal analyses performed using Generalized Linear Mixed Model.
Results: A total of 156415 patients with SLD were enrolled (121558 MASLD, 27593 MetALD, 7264 ALD) followed for a median of 13.64 years (IQR: 12.80–14.37), 237 HCC events and 17462 deaths occurred, with 15-year cumulative HCC incidence of 0.17%, accounting for the competing risk of death. The aMAP score showed strong discrimination for HCC prediction, achieving a C-index of 0.76, outperforming PAGE-B, mPAGE-B, CAMD, and AASL scores (0.68–0.74). Risk stratification by aMAP categorized patients into low- mid- and high-risk groups, with 15-year cumulative incidences of 0.05%, 0.21%, and 1.12%, respectively (high vs low adjusted HR: 29.69; 95% CI: 19.99–44.10). Calibration was robust (Brier score < 0.001). Metabolic parameters, including blood glucose, waist circumference (WC), and systolic blood pressure showed positive trend across aMAP. After adjusting confounding factors, changes in blood glucose (OR = 1.08, $p < 0.001$) and WC (OR = 1.01, $p = 0.01$) remained independently associated with changes in aMAP risk levels.
Conclusion: The aMAP score effectively stratified HCC risk in patients with SLD, with changes in blood glucose and WC statistically associated with concurrent changes in aMAP.

WED-202
Impact of sodium-glucose cotransporter 2 inhibitors on hepatic pathology and key biomarkers in type 2 diabetes with metabolic dysfunction-associated steatotic liver disease: a prospective study
Farah Khaznadar[1], Omar Khaznadar[2], Marija Hefer[1], Ana Jurić[3], Robert Smolic[1], Ana Hrzenjak[3], Kristina Kralik[4], Ana Petrovic[1], Justinija Steiner[5], Kristina Bojanić[1], Martina Smolic[1]. [1]*University of Osijek Faculty of Dental Medicine and Health Osijek, Osijek, Croatia;* [2]*Dr. Juraj Njavro National Memorial Hospital Vukovar, Vukovar, Croatia;* [3]*General County Hospital Našice, Našice, Croatia;* [4]*University of Osijek Faculty of Medicine, Osijek, Croatia;* [5]*Health Center Osijek, Osijek, Croatia*
Email: msmolic@fdmz.hr

Background and aims: Type 2 diabetes mellitus (T2DM) is commonly associated with metabolic dysfunction-associated steatotic liver disease (MASLD), for which approved therapies are scarce. Our objective was to evaluate the effects of SGLT2 inhibitors (SGLT2i) on liver fibrosis, steatosis, and metabolic biomarkers in T2DM-related MASLD in a real-world clinical setting.
Method: Sixty-seven T2DM patients, aged 37–89 years, were prospectively monitored for six months following the initiation of SGLT2i therapy. Serum levels of peroxisome proliferator–activated receptor (PPAR) α and γ, sterol regulatory element-binding protein 1 (SREBP1), and microsomal triglyceride transfer protein (MTTP) were assessed by ELISA. Non-invasive ultrasound methods, the two-dimensional shear wave elastography (2D-SWE) and ultrasound-guided attenuation parameter (UGAP), were used to assess liver fibrosis and steatosis, respectively, in addition to biochemical and anthropometric examinations.
Results: Following the six-month period, MTTP levels increased (198.4→428.9 ng/L, $p < 0.001$), while PPARγ levels decreased (895.0→565.4 ng/L, $p < 0.001$). Liver stiffness showed a significant improvement, with reduced 2D-SWE values (6.22→6.10 kPa, $p = 0.001$), which were inversely correlated with MTTP ($\rho = -0.268$, $p = 0.03$). UGAP values positively correlated with 2D-SWE ($\rho = 0.365$, $p = 0.002$) and demonstrated positive associations with leukocyte count, triglycerides, and liver enzymes, alongside an inverse association with HDL cholesterol ($p \leq 0.01$). Additionally, significant improvements were observed in fasting glucose, HbA1c, INR, waist circumference, and BMI ($p \leq 0.04$).
Conclusion: Treatment with SGLT2i is linked to early improvement in hepatic steatosis, liver fibrosis, and metabolic control in T2DM-associated MASLD. These changes were accompanied by beneficial regulation of PPARγ and MTTP, suggesting a role of SGLT2i in improving hepatic lipid metabolism and slowing MASLD progression, highlighting their therapeutic potential. Larger controlled trials are needed to affirm these findings.

WED-203
Two-step paediatric MASLD diagnostic approach: primary-care (PC) screening plus clinical fibrosis rule-out to select patients with progressive MASLD
Piotr Socha[1], Malgorzata Wajda-Cuszlag, Anna Swiader-Lesniak[1], Katarzyna Goclawska[1], Lukasz Szarpak[2], Sebastian Więckowski[1]. [1]*The Children's Memroial Health Instituite, Department Gastroenterology, Hepatology, Nutritional Disorders and Pediatrics, Warsaw, Poland;* [2]*The John Paul II Catholic University of Lublin, Technology Transfer Center, Lublin, Poland*
Email: p.socha@ipczd.pl

Background and aims: Paediatric MASLD is relatively common among obese children but significant liver fibrosis is not a common feature. Since fibrosis is the major indicator of progressive liver disease patients with fibrosis should be selected and referred to liver clinics for close follow up and therapy. As liver biopsy is rarely indicated and MR techniques are not commonly available to assess steatosis and fibrosis (PDFF and MR-elastography) other non-invasive markers need to be vaildated. Paediatric MASLD requires practical

two-step triage tools combining (1) primary-care screening for steatosis/fibrosis risk using routine tests and (2) bedside rule-out of clinically relevant fibrosis.
Method: In a prospective cohort of 402 children (10–18 years) with overweight/obesity, reference standards were MRI LiverLab PDFF for steatosis (S^+ ≥5.5%) and MR-elastography (MRE) for fibrosis (F^+ ≥2.7 kPa). Step-1 used the five-variable POZ^+ model (waist SDS, ALT, GGT, uric acid, TG/HDL) estimated with L2-penalised logistic regression and validated with nested patient-cluster cross-validation and 2000-resample bootstrap CIs. Step-2 used penalised logistic regression on FibroScan stiffness (E) and bioimpedance-derived body cell mass (BCM) to derive a continuous fibrosis risk equation and a 0–2 point score, with 10-fold cross-validation and bootstrap CIs.
Results: S^+ prevalence was 34.1% (137/402) and F^+ prevalence 12.5% (50/400). POZ^+ yielded AUC 0.76 (95% CI 0.70–0.81) for S^+ and 0.68 (0.58–0.76) for F^+, with high-sensitivity thresholds (Se ≥0.90) giving NPVs of 0.87 (S^+) and 0.92 (F^+). Benchmark fibrosis scores (PNFI, APRI, FIB-4, NFS) performed worse for F^+ (AUCs ranged from 0.49 to 0.66). For step-2 (n = 390), the E+BCM model achieved AUC 0.73 (95% CI 0.65–0.81). At a rule-out operating point (Se ≈0.92; Sp ≈0.30), NPV reached 0.96, with 25–30% of children assigned to a low-risk 'green zone' while maintaining NPV ≥0.95, in which MRE could usually be omitted.
Conclusion: A two-step pathway (PC^+ screening followed by non-MR E+BCM bedside triage) provides MRI/MRE-validated screening for MASLD-related steatosis and fibrosis and can substantially reduce MRE utilisation through a high-NPV fibrosis rule-out strategy based on widely available measurements.

WED-204

DM-LRE score: gradient boosting machine (GBM)-based machine learning model in predicting liver-related events (LREs) in type 2 diabetes mellitus (T2DM)

Email: 1155169298@link.cuhk.edu.hk

Background and aims: We aimed to develop a prediction model for LREs in patients with T2DM, given the close relationship between diabetes and liver disease progression.
Method: This retrospective cohort study included patients with T2DM from Hong Kong (HK-T2DM cohort) and patients with T2DM and metabolic dysfunction-associated steatotic liver disease (MASLD) from an international multicentre cohort undertaking vibration-controlled transient elastography (VCTE) examination (VCTE-Prognosis-T2DM cohort). The HK-T2DM cohort was randomly divided in an 80:20 ratio to form the development and internal validation cohorts. The VCTE-prognosis-T2DM cohort was used for external validation. The primary endpoint was incident LREs in 5 years, defined as hepatic decompensation, hepatocellular carcinoma, liver transplantation or liver-related deaths. The DM-LRE score was derived from s including cirrhosis status and routine serum markers at baseline. GBM demonstrated the highest concordance index (C-index) and time-dependent area under the receiver operating characteristic compared to XGBoost and random forest in predicting LREs. The score was applied for risk stratification using cutoffs at 90% sensitivity and specificity.
Results: 575,000 patients were included in the HK-T2DM cohort (mean age 61.9 years; 52.3% males), while 3,587 patients were included in the VCTE-Prognosis-T2DM cohort (mean age 56.0 years; 56.8% males). The incidence rates of LRE were 1.285 and 4.241 per 1,000 person-years for HK-T2DM and VCTE-prognosis-T2DM cohorts, respectively. In the development and external validation cohorts, the C-indices of the DM-LRE score in predicting 5-year LRE were 0.752 (95% CI: 0.742–0.763) and 0.864 (95% CI: 0.806–0.926), respectively, outperforming the Fibrosis-4 index (FIB-4, C-indices: 0.674 and 0.830). The DM-LRE score displayed a C-index similar to liver stiffness measurement in the external cohort (0.864 vs. 0.866). In the VCTE-prognosis-T2DM cohort, 1,866 (52.0%), 1,347 (37.6%) and 374 (10.4%) of patients were stratified into low- intermediate- and high-risk categories by the DM-LRE score. Low- intermediate- and high-risk subgroups exhibited a 5-year incidence rate of 0.880, 1.739, and 26.278 per 1000 person-years, respectively ($p < 0.001$).
Conclusion: The DM-LRE score could identify individuals at risk of LREs in patients with T2DM and facilitate early referral to specialty care.

WED-205

Comprehensive risk assessment for gastrointestinal cancers in steatotic liver disease (MASLD, MetALD, and ALD)

Nobuharu Tamaki[1], Takefumi Kimura[2], Shun-Ichi Wakabayashi[2], Naoki Tanaka[2], Namiki Izumi[1], Masayuki Kurosaki[1]. [1]*Musashino Red Cross Hospital, Tokyo, Japan;* [2]*Shinshu University School of Medicine, Nagano, Japan*
Email: nobuharu.tamaki@gmail.com

Background and aims: Steatotic liver disease and alcohol consumption are known risk factors for gastrointestinal cancers. Accordingly, the risk of gastrointestinal cancers may be increased in subgroups of steatotic liver disease (SLD), including metabolic dysfunction–associated steatotic liver disease (MASLD), MASLD with increased alcohol intake (MetALD), and alcohol-related liver disease (ALD). However, differences in gastrointestinal cancer risk among these subgroups have not been fully elucidated. This study aimed to investigate the incidence of gastrointestinal cancers in patients with MASLD, MetALD, and ALD.

Method: We conducted a nationwide, population-based cohort study using a Japanese health insurance claims database. A total of 978,607 individuals with MASLD, 366,152 with MetALD, 152,721 with ALD, and 4,884,398 controls were included. The primary outcome was the incidence of gastrointestinal cancers, including hepatocellular carcinoma (HCC), biliary tract cancer, esophageal cancer, gastric cancer, colorectal cancer, and pancreatic cancer.
Results: The 10-year cumulative incidence of HCC was 0.006% in the control group, 0.04% in the MASLD group, 0.05% in the MetALD group, and 0.09% in the ALD group. Similarly, the 10-year cumulative incidence of biliary tract cancer was 0.02% in controls, 0.05% in MASLD, 0.07% in MetALD, and 0.08% in ALD. After adjustment for age, sex, diabetes, dyslipidemia, hypertension, and smoking status, the adjusted hazard ratios (aHRs) for HCC ranged from 3.55 to 5.39 across the MASLD, MetALD, and ALD groups, while those for biliary tract cancer ranged from 1.45 to 1.66. The risks of both HCC and biliary tract cancer were significantly elevated in all SLD subgroups compared with controls. The 10-year cumulative incidence of colorectal cancer was 0.31% in the control group, 0.48% in MASLD, 0.73% in MetALD, and 0.97% in ALD. For esophageal, gastric, and colorectal cancers, aHRs ranged from 0.75 to 1.26 in MASLD, 1.09 to 1.44 in MetALD, and 1.13 to 2.48 in ALD, indicating a stepwise increase in risk with greater alcohol consumption. No significant association was observed between pancreatic cancer risk and alcohol consumption.
Conclusion: Patients with SLD have a significantly higher risk of gastrointestinal cancers compared with controls. The magnitude of risk differs according to the SLD subtype, particularly in relation to alcohol consumption. These findings highlight the importance of risk-stratified cancer screening strategies in individuals with SLD.

WED-206

Automated image analysis validation for MRI hepatic fat fraction quantification for steatotic liver diseases

Brendan Eck[1], Alvaro Jorge-Peñas[1], Vahan Sharoyan[1], Thomas Fuerst[1], Pohan Chen[1], Thomas Cajgfinger[1], Mark Tengowski[1]. [1]*Clario, Philadelphia, PA, United States*
Email: Mark.Tengowski@clario.com

Background and aims: Fatty liver analysis relies on expert readers defining manual regions of interest (ROIs) in nine Couinaud segments to determine individual segment and overall fatty liver values. In this methods development study, we validated known hepatic fat fraction (HFF) values generated by an automated solution against those values obtained manually by expert readers.
Method: Multi-center scan data (99 subjects with 252 exams, 1–3 time points per subject) collected using 6-echo MRI-PDFF techniques were processed with a proprietary fat-water separation algorithm to generate fat, water, R2*, goodness-of-fit, and fat fraction map series. We developed a computer-assisted yet human supervised image analysis solution that segmented the entire liver using the out-of-phase series and automatically identified the axial slice with the largest liver cross-sectional area. The median HFF was measured using the computer-defined ROI in this slice. The reader independently measured HFF using the standard manually defined ROIs in the nine Couinaud segments with overall HFF computed. Automated and manual measurements were compared using descriptive statistics, intra-class correlation coefficient (ICC) and Bland-Altman agreement.
Results: The accuracy of the fat-water separation algorithm was confirmed by comparison to an in-scan 0% to 40% fat calibration phantom (Calimetrix, Madison WI) yielding ICC = 0.999 (95% CI 0.991–1.000) with a mean bias of 0.4%. HFF manual measurements (0.9% and 34.6%) covered the clinically relevant ranges. The cross-sectional comparison of the automated algorithm with expert reader HFF results showed excellent agreement with ICC = 0.997 (95% CI 0.994–0.998). The mean method bias was 0.2% with Bland-Altman 95% limits of agreement of – 1.2 to 0.8%. In longitudinal analysis, manual method changes in HFF ranged from – 17.5 to +11.6%. Again the automated algorithm agreed well with the manual read (ICC = 0.992; CI 0.959–997; mean bias 0.1%; agreement limits were – 1.1 to +1.2%).
Conclusion: This study demonstrates outstanding correlation between manual HFF measurements and an automated overall single slice HFF solution. This analysis workflow retains the human reader to confirm or correct the algorithm output with high accuracy and HFF reproducibility. In studies evaluating change in liver fat over time, the overall HFF quantification by automated image processing with expert reader supervision is anticipated to serve as an alternative to fully manual methods.

WED-211

Prognostic value of liver stiffness measurement for liver-related events in metabolic dysfunction-associated liver disease-related compensated advanced chronic liver disease

Kitrawee Pisarnvorawat[1], Panarat Thaimai[2], Tassanun Jaihan[2], Kanokwan Sonsiri[2], Prooksa Ananchuensook[2], Supachaya Sriphoosanaphan[2], Sombat Treeprasertsuk[2], Kessarin Thanapirom[2,3]. [1]*Department of Medicine, Faculty of Medicine, Chulalongkorn University and King Chulalongkorn Memorial Hospital, Thai Red Cross Society, Bangkok, Thailand;* [2]*Division of Gastroenterology, Department of Medicine, Faculty of Medicine, Chulalongkorn University and King Chulalongkorn Memorial Hospital, Thai Red Cross Society, Bangkok, Thailand, Center of Excellence in Liver Fibrosis and Cirrhosis, Chulalongkorn University, Bangkok, Thailand., Bangkok, Thailand;* [3]*Center of Excellence in Liver Fibrosis and Cirrhosis, Chulalongkorn University, Bangkok, Thailand*
Email: nesskitrawee.p@gmail.com

Background and aims: Patients with compensated advanced chronic liver disease (cACLD) remain at risk of hepatic decompensation. Early risk stratification using non-invasive tests is therefore essential to enable timely intervention. This study aimed to evaluate the prognostic performance of liver stiffness measurement (LSM) for predicting liver-related events (LREs) in patients with cACLD due to metabolic dysfunction-associated steatotic liver disease (MASLD).
Method: Patients with MASLD-related cACLD were enrolled at Chulalongkorn University Hospital between 2015 and 2023. cACLD was defined as LSM ≥10 kPa by vibration-controlled transient elastography. Baseline LSM, Fibrosis-4 (FIB-4) index, AST-to-platelet ratio index (APRI), and NAFLD fibrosis score (NFS) were collected. LREs were defined as ascites, variceal bleeding, hepatic encephalopathy, spontaneous bacterial peritonitis, hepatocellular carcinoma, or death.
Results: Among 603 patients with MASLD-related cACLD, 74 (12.3%) developed LREs over a median follow-up of 58 months (IQR 39–80). Compared with those without LREs, patients who developed LREs were significantly older, had a lower body mass index, and a higher prevalence of diabetes mellitus and chronic kidney disease. They also exhibited more advanced liver dysfunction at baseline, as shown by lower platelet counts and albumin, and higher INR. Furthermore, baseline LSM [21.8 (14.1–31.2) vs 13.5 (11.6–17.1) kPa, p < 0.001], FIB-4 [3.27 (2.22–4.51) vs 1.42 (0.82–2.13), p < 0.001], APRI [0.75 (0.53–1.08) vs 0.42 (0.27–0.69), p < 0.001], and NFS [0.99 (-0.1–1.87) vs – 0.82 (-1.83–0.16), p < 0.001] were significantly higher in the patients who developed LRE than those without LRE. In multivariate analysis, age (HR = 1.060, 95%CI: 1.031–1.090, p < 0.001) and baseline LSM (HR 1.048, 95% CI 1.034–1.061, p < 0.001) were independently associated with LREs. Notably, LSM demonstrated the highest discriminatory performance at both 1 and 2 years (AUC = 0.871 and 0.842), outperforming FIB-4 (AUC = 0.783 and 0.836), APRI (AUC = 0.707 and 0.725), and NFS (AUC = 0.741 and 0.803). By maximizing

Youden's index, LSM > = 20 kPa predicts LRE with the sensitivity of 58.1%, specificity of 84.7% and AUC of 0.753.
Conclusion: Baseline LSM is an independent predictor of LREs in MASLD-related cACLD and demonstrates superior prognostic performance compared with FIB-4, APRI, and NFS. Integration of LSM into risk stratification may improve early identification of high-risk patients and guide timely surveillance and preventive interventions.

WED-212

Circulating extracellular vesicles and ferritin enable machine learning based detection of hepatic steatosis in metabolic dysfunction-associated steatotic liver disease

Eleni-Myrto Trifylli[1,2,3], Athanasios Angelakis[4], Anastasios Kriebardis[2], Nikolaos Papadopoulos[5], Sotirios Fortis[2], Vasiliki Pantazatou[2], Ioannis Koskinas[6], Hariklia Kranidioti[6], Spyridon (Spyros) Siakavellas[6], Spilios Manolakopoulos[6], Melanie Deutsch[6]. *[1]GI-Liver Unit, 2nd Department of Internal Medicine, National and Kapodistrian University of Athens, General Hospital of Athens "Hippocratio", Laboratory of Reliability and Quality Control in Laboratory Hematology (HemQcR), Department of Biomedical Sciences, Section of Medical Laboratories, School of Health & Caring Sciences, University of West Attica (UniWA), Athens, Greece, Athens, Greece; [2]Laboratory of Reliability and Quality Control in Laboratory Hematology (HemQcR), Department of Biomedical Sciences, Section of Medical Laboratories, School of Health & Caring Sciences, University of West Attica (UniWA), Athens, Greece; [3]417 Army Equity Fund Hospital, Athens, Greece; [4]Amsterdam University Medical Center, Epidemiology and Data Science, Amsterdam, Netherlands; [5]National Organization for the Prevention and Treatment of Addictions (EOPAE), Athens, Greece; [6]GI-Liver Unit, 2nd Department of Internal Medicine, National and Kapodistrian University of Athens, General Hospital of Athens "Hippocratio," Athens, Greece*
Email: trif.lena@gmail.com

Background and aims: Metabolic dysfunction–associated steatotic liver disease (MASLD) is the most prevalent chronic liver disease worldwide, yet non-invasive assessment of hepatic steatosis remains limited. Blood-based biomarkers are therefore needed for clinical risk stratification. Extracellular vesicles (EVs) are emerging candidates, while ferritin may provide complementary inflammatory information indicative of steatohepatitis and advanced fibrosis risk. We evaluated whether circulating EV features, alone or combined with ferritin, can identify hepatic steatosis in an independent multicenter cohort using machine learning (ML) and explainable artificial intelligence (XAI).
Method: In this prospective multicenter study, 96 eligible patients presenting exclusively metabolic dysfunction underwent steatosis assessment by transient elastography (iLivTouch FT100, Hisky), with the absence of steatosis (S0) defined by ultrasound attenuation parameter cut-offs (< 244 dB/m) and quality criteria. Circulating EVs were isolated from fasting plasma and characterized by nanoparticle tracking analysis, including mean size, total concentration, and size-based subpopulations. Ferritin was analyzed as a numeric biomarker. Data from one center were used for training with three-fold cross-validation (n = 58), and external validation was performed in an independent cohort from two centers (n = 38). A CatBoost classifier was trained to distinguish steatosis presence (S1–S3) from absence (S0), with interpretability assessed using SHapley Additive exPlanations. Ferritin associations were evaluated using univariate statistical tests.
Results: External validation for steatosis presence (S1–S3) vs absence (S0) showed robust performance, with sensitivity 0.78, specificity 0.76, and AUROC 0.82. Comparable performance was observed in three-fold cross-validation (AUROC 0.81 ± 0.15). SHAP analysis identified ferritin as the most influential predictor, followed by EV size and concentration, with higher ferritin values shifting predictions toward steatosis. In external validation, ferritin was moderately associated with steatosis presence (absolute $r \approx 0.41$, $p < 0.05$).
Conclusion: EVs enable robust ML-based detection of hepatic steatosis in MASLD. Ferritin adds complementary, biologically relevant information regarding inflammation through non-linear effects captured by XAI. The combined use of EVs and ferritin outperforms EV features alone, supporting a multimodal, ML-based approach for scalable, non-invasive MASLD risk stratification.

WED-213

Hepatic antifibrotic response by fibrogenesis markers in patients with MASLD undergoing a 6-month randomized dietary trial

Angelo Armandi[1], Lorenza Vaira[1], Rambabu Surabattula[2], Diana Julie Leeming[3], Gian Paolo Caviglia[1], Marta Guariglia[1], Chiara Rosso[1], Eleonora Dileo[1], Fabio Bioletto[4], Ilaria Goitre[5], Valentina Ponzo[5], Francesca Saba[1], Kamela Gjini[1], Davide Giuseppe Ribaldone[1], Sudha Rani Myneni[2], Simona Bo[5], Detlef Schuppan[2,6], Elisabetta Bugianesi[1]. *[1]Division of Gastroenterology and Hepatology, Department of Medical Sciences, University of Turin, Turin, Italy; [2]Institute of Translational Immunology, Johannes Gutenberg University, Mainz, Germany; [3]Nordic Bioscience, Herlev, Denmark; [4]Division of Endocrinology, Diabetes and Metabolism, Department of Medical Sciences, University of Turin, Turin, Italy; [5]Division of Clinical Nutrition, Department of Medical Sciences, University of Turin, Turin, Italy; [6]Beth Israel Deaconess Medical Center, Harvard Medical School, Boston, Massachusetts, United States*
Email: angelo.armandi@unito.it

Background and aims: Lifestyle intervention aiming at weight loss (WL) is the cornerstone of Metabolic Dysfunction-Associated Steatotic Liver Disease (MASLD) management, but treatment response by non-invasive tests (NITs) is not yet established. Here, we aim to assess antifibrotic response to WL by collagen and non-collagen fibrogenesis markers.
Method: We included 146 patients with MASLD (median age 52 [46–61] years, 63% male) undergoing 6-month randomized dietary trial (2021–2023): Mediterranean Diet (n = 49), Low-Charb Diet (n = 49) or nutritional advice (n = 48). Inclusion criteria: MASLD and LSM (VCTE) < 10 kPa, Body Mass Index (BMI) of 25–35 kg/m^2, age < 65 years. Exclusion criteria: HbA1c > 9.5%, type 2 diabetes (T2D) treated with insulin of GLP1-RA. All parameters were assessed at baseline and 6 months. Serum non-collagen (TSP2, CD163 and IGFB7 - Mainz) and collagen (C4M, PRO-C3, PRO-C4, PRO-C6 and PRO-C8 - Nordic Bioscience) markers were measured through in-house standardized ELISA assay. Primary endpoint was changes in NIT levels between patients achieving < 5% WL (group A n = 91), compared to those achieving 5 – 10% WL (group B n = 38) and ≥10% WL (group C n = 17).
Results: Median BMI was 30,4 [28,7–33,4] kg/m^2, T2D and PNPLA3 GG were present in 31% and 21,8% of cases. PRO-C4 levels fell significantly in group B (p = 0,041) and C (p = 0,015), but not in group A (p = 0,147). TSP2 levels fell substantially in group B (p = 0,046) and in group C (p = 0,004) but not in group A (p = 0,714). FIB-4 and VCTE did not show clinically significant changes. Delta PRO-C4 showed a stepwise negative increase across the 3 groups: from mean - 71,7 (SD 510,3) ng/ml to mean - 228,7 (634,2) ng/ml to mean – 695,5 (1735,8) ng/ml (ANOVA p = 0,011). Delta TSP2 varied from mean - 0,2 (13,5) ng/ml to mean - 4,2 (14,5) ng/ml to mean - 12,6 (15,8) ng/ml (ANOVA p = 0,004). PRO-C4 and TSP2 showed significant association with delta weight changes: R2 0,05 (p = 0,003) and 0,08 (p = 0,0002). Delta TSP2> - 1,96 ng/ml and delta PRO-C4> - 703 ng/ml (both by Youden

Index) were associated with WL> 5% after adjustment for age, male sex, obesity, T2D and PNPLA3 GG: aOR 0,16 (0,04–0,63, p = 0,008) and aOR 0,29 (0,29–0,96, p = 0,043) respectively.
Conclusion: In patients with MASLD without advanced fibrosis undergoing dietary intervention, serum TSP2 and PROC4 levels fell significantly in correlation to WL and were associated with WL> 5%. This evidence suggests their clinical utility to monitor attenuation of hepatic fibrogenesis.

WED-214
Validation of clinical care pathways for detecting significant fibrosis in metabolic dysfunction-associated steatotic liver disease (MASLD): an individual patient data meta-analysis

Email: k.m.vaneekhout@amsterdamumc.nl

Background and aims: To optimize the implementation of preventive hepatology within current cardiometabolic care structures, pathways using sequential non-invasive tests (NITs) are proposed to detect liver fibrosis due to metabolic dysfunction–associated steatotic liver disease (MASLD). These pathways aim to improve early detection while reducing referrals of mild cases. Despite growing interest in their application, large-scale, standardized evaluations of their performance are lacking.
Method: We conducted an individual patient data meta-analysis (IPDMA), pooling historic European cohorts of adults aged 18–80 years at cardiometabolic risk, with or without steatosis, excluding excessive alcohol use and other liver diseases. Clinically significant fibrosis was defined using a predefined hierarchical reference standard. We evaluated care pathways combining a blood-based NIT (FIB-4, MAF-5, NFS, APRI, or BARD) followed by a liver stiffness measurement (LSM)-based NIT (FibroScan, FAST, or AGILE-3+). Pathway performance was assessed using sensitivity, specificity, fibrosis detection rates, and numbers needed to screen (NNS) for referral and fibrosis identification. The best-performing pathway was defined by the highest sum of sensitivity and specificity.
Results: A total of 4,168 participants from 10 cohorts were included, with data available for 3,850 to assess clinically significant fibrosis. Clinically significant fibrosis was present in 19.5% (n = 752), based on: 1. histology (n = 507), 2. MRE (n = 15), 3. MRI-cT1 (n = 14) or, 4. VCTE-LSM (n = 216). Among 93 pathways, the two-tier MAF-5 followed by FibroScan ≥8 kPa or FAST >0.35 showed the best performance (sensitivity 0.80, specificity 0.93), with an NNS of 5 for referral and 9 for fibrosis detection. APRI with a cutoff > 0.5 was the best-performing one-tier pathway (sensitivity 0.61, specificity 0.81).
Conclusion: This IPDMA provides valuable insights into the performance of various one-tier and two-tier pathways for detecting clinically significant liver fibrosis in individuals at cardiometabolic risk. Two-tier pathways consistently outperformed one-tier pathways, particularly those combining MAF-5 with LSM-based NITs. These strategies optimize fibrosis detection while reducing unnecessary referrals with acceptable NNS. While awaiting prospective validation in large-scale, multinational cohorts, this IPDMA supports implementation of diagnostic clinical pathways for liver fibrosis detection in patients at cardiometabolic risk for MASLD.

WED-215
Simplified metabolic dysfunction associated fibrosis-5 (sMAF-5) score to identify at-risk liver fibrosis and to predict prognosis

Email: l.vankleef@erasmusmc.nl

Background and aims: Metabolic dysfunction Associated Fibrosis - 5 (MAF-5), a waist-circumference-based non-invasive test (NIT) for fibrosis risk stratification, has emerged as a well-performing test in low-prevalence populations. Waist circumference is often not available, which limits the utility of the MAF-5. Therefore, we

developed and validated the simplified MAF-5 (sMAF-5), which could be used when waist circumference is unavailable.
Method: US representative individuals from NHANES 2017–2020 with metabolic dysfunction were selected. Correlation between MAF-5 and sMAF-5 was assessed using Pearson's correlation coefficient. AUC analysis was used to compare sMAF-5 to other scores with the DeLong test for assessing statistically significant differences in detecting LSM ≥8 kPa. sMAF-5 was validated in US NHANES 2021–2023 and MASLD patients across a pooled cohort of 16 tertiary referral centres in the US, Europe, and Asia (VCTE Prognosis Study Group) for the presence of LSM ≥ 8 kPa and liver-related events (LRE) defined as hepatic decompensation and HCC.
Results: In three cohorts, 22,723 individuals were included. The derivation cohort included 6,191 adults (49% male, mean age 52 years) of whom 10.1% had LSM ≥ 8 kPa. The sMAF-5, comprising BMI, diabetes, AST, platelets, and sex, was strongly correlated with MAF-5 (r = 0.97). With sMAF-5, 61.6% were classified as low risk (sMAF-5 < 0), 14.0% as intermediate risk (0–1), and 24.4% as high risk (≥ 1), with observed LSM ≥ 8 kPa prevalence of 3.4%, 9.2%, and 27.7%, respectively. The AUC of sMAF-5 (AUC 0.803) did not significantly differ from the original MAF-5 (AUC 0.808), but was significantly better than SAFE (0.739), LiverRisk (0.715), LiverPRO (0.715), and FIB-4 (0.667). Results were validated in the independent NHANES 2021–2023 cohort (n = 4,202), yielding similar results. In the VCTE prognosis study group (12,330 MASLD patients), sMAF-5 was associated with LRE where the time-dependent AUC for LRE (all), hepatic decompensation, and HCC was 0.75, 0.79, and 0.71, respectively. AUC particularly increased with longer time to event. Among MASLD patients, the cumulative incidence of LRE was 0.6% and 0.7% in MASLD patients with sMAF-5 < 0 and 0–1 and 3.2% for sMAF-5 ≥ 1.
Conclusion: sMAF-5 is a valuable replacement for the original MAF-5 as a first-line test in screening algorithms when waist circumference is unavailable, enabling the identification of adult community-dwelling individuals at increased risk of liver fibrosis and future liver-related events.

WED-216
Evaluating non-invasive screening strategies for identifying treatment-eligible fibrotic MASH in MASLD patients

Laurens A. van Kleef[1], Maurice Michel[2], Katrine Lindvig[3], Maja Thiele[3], Harry L.A. Janssen[1], Christian Labenz[4], Jörn M. Schattenberg[2], Willem Pieter Brouwer[1]. *[1]Erasmus MC, Rotterdam, Netherlands; [2]Department of Internal Medicine II, Saarland University Medical Center, Homburg, Germany; [3]Odense University Hospital, Odense, Denmark; [4]University Medical Center Mainz, Mainz, Germany*
Email: l.vankleef@erasmusmc.nl

Background and aims: Non-invasive tests (NITs), particularly FIB-4, are increasingly used to detect advanced chronic liver disease. However, FIB-4 shows suboptimal performance as a stand-alone screening tool in the general population. We therefore evaluated the ability of FIB-4–based strategies to identify individuals with fibrotic MASH eligible for pharmacologic treatment.
Method: We analysed two cohorts: patients with biopsy-proven MASLD from \German tertiary care, and participants with MASLD defined by VCTE and CAP from US representative adults from NHANES 2017–2020. Individuals with presumed cirrhosis (F4 on biopsy or LSM ≥15 kPa) were excluded from the main analyses, consistent with AASLD resmetirom treatment criteria. We assessed the sensitivity and specificity of FIB-4 and LSM in the German cohort and extended this with newer NITs in NHANES.
Results: Among 365 patients with biopsy-proven MASLD (mean age 51 years; 53.2% male), 58.4% had F2–F3 fibrosis, indicating treatment eligibility. Using the EASL–EASD–EASO two-step screening strategy (FIB-4 ≥1.3, or ≥2.0 for those aged ≥65 years, followed by VCTE), only 31% of patients with biopsy-confirmed F2–F3 fibrosis would have been identified. FIB-4 alone resulted in a 50% points loss in sensitivity, and the addition of LSM caused a further 20% loss. Findings were consistent when including individuals with cirrhosis. In NHANES, among 2,785 community-dwelling individuals with MASLD (mean age 55 years; 53.5% male), 369 (13.3%) had an LSM between 8 and 15 kPa, meeting AASLD non-invasive criteria for resmetirom eligibility. Using age-specific cut-offs, FIB-4 demonstrated low sensitivity (19%) but high specificity (86%). Newer NITs outperformed FIB-4: LiverPRO (F2 model, threshold 0.25) had a sensitivity of 56% and specificity of 61%; SAFE (threshold 0), 77% and 45%; and MAF-5 (threshold 0), 86% and 45%. There were no meaningful changes including individuals with LSM ≥ 15 kPa. A two-step strategy using MAF-5 as the high-sensitivity screening test followed by FIB-4 confirmation yielded a sensitivity of 17% (69% points lower than MAF-5 alone) and a specificity of 91% (46% points higher), indicating that most true positives were excluded in the second step.
Conclusion: Detecting patients eligible for pharmacologic treatment due to fibrotic MASH remains challenging in both clinical and population-based settings. FIB-4–based screening strategies miss the majority of individuals who may benefit from resmetirom, highlighting the need for improved non-invasive algorithms.

WED-217
State-transition models of MASLD progression in economic evaluation: an updated systematic review

Rohan Vijjhalwar[1], Rohit Vijjhalwar[2,3], Naomi Hollings-Tenant[3], Mary Onoja[3], Keith Cooper[3], Chinonso Nwoguh[2,3], Tina Reinson[3], Josh Bilson[3], Chris D Byrne[3], Ryan M Buchanan[2,3]. *[1]Epsom and St Helier University Hospitals NHS Trust, London, United Kingdom; [2]University Hospital Southampton NHS Foundation Trust, Southampton, United Kingdom; [3]University of Southampton, Southampton, United Kingdom*
Email: rohan_vijjhalwar@hotmail.com

Background and aims: Metabolic dysfunction-associated steatotic liver disease (MASLD) affects over one-third of adults and is linked to obesity and type 2 diabetes. Economic evaluations rely on decision-analytic models to project long-term outcomes and assess new diagnostics and therapies, but approaches to modelling MASLD progression vary widely. This systematic review investigated how state-transition models published since June 2021 have represented the natural history of MASLD/NAFLD/MASH for economic evaluation.
Method: A systematic review was registered prospectively on PROSPERO (CRD420251237086) and conducted in PubMed, Scopus, Cochrane CENTRAL and INAHTA from June 2021 onwards. We included adult state-transition models (Markov or microsimulation) used in full economic evaluations or burden-of-disease analyses that explicitly modelled progression across fibrosis and advanced liver disease states. Model structures, transition and regression probabilities, mortality assumptions, utilities and diabetes adjustment were extracted. The probabilities of transition are considered low if they are smaller than 0.1, and high if the probability is greater than 0.6.
Results: 26 studies were included. All but one used cohort Markov models; one used agent-based microsimulation. Most evaluated screening or treatment strategies in high-income settings; three studies explicitly adjusted for diabetes. Model structures commonly included F0-F3, compensated and decompensated cirrhosis, hepatocellular carcinoma and liver transplantation. Forward transition probabilities varied markedly: annual F0-F1 ranged between 0.01–0.17, F1-F2 ranged between 0.03–0.60, F2-F3 ranged between 0.03–0.12 and F3-CC ranged between 0.06–0.19, CC-DC and DC-HCC were typically 0.04–0.10 and 0.02–0.07, respectively. Regression was

modelled in a minority of studies with small, mainly treatment-driven F1-F0 and F2-F1 probabilities; regression from cirrhosis was rare. Utilities and mortality specifications showed comparable heterogeneity.
Conclusion: Contemporary models remain highly heterogeneous and often rely on non-MASLD natural history, with limited metabolic risk stratification. These differences are likely to influence the estimated burden and cost-effectiveness of emerging MASLD therapies.

WED-219
LiverPRO prediction reflects fibrogenic activity in patients with metabolic dysfunction-associated steatohepatitis by identifying patients with elevated PRO-C3
Ying-Wooi Wan[1], Julie Astono[2], Andressa de Zawadzki[3], Diana Julie Leeming[3], Morten Karsdal[3], Regina Lemus[1], Andreas Sand[2], Paresh Thakker[1], Haakan Wennbo[1], Katrine Lindvig[2], Zoltan Derdak[1]. *[1]Takeda Development Center Americas, Inc., Cambridge, MA, United States; [2]Evido Health ApS, Copenhagen, Denmark; [3]Nordic Bioscience A/S, Herlev, Denmark*
Email: zoltan.derdak@takeda.com

Background and aims: Metabolic Dysfunction-Associated Steatohepatitis (MASH) is defined by progressive fibrotic remodeling of the liver, where fibrogenesis is a key determinant of disease progression and prognosis. Non-invasive measures of fibrogenesis are essential for selecting patients with high fibrogenic activity, a key requirement for antifibrogenic therapy trials. LiverPRO from Evido Health is a data-driven model predicting significant (F2), advanced (F3), and cirrhotic (F4) fibrosis using non-invasive clinical and laboratory parameters. PRO-C3, the N-terminal pro-peptide of type III collagen, is a circulating biomarker of active fibrogenesis. This study evaluated the association between LiverPRO predictions and PRO-C3 levels in MASH patients.
Method: Serum PRO-C3 (Roche-COBAS) and LiverPRO predictions for F2, F3, and F4 were assessed in a screening cohort of 121 participants with presumed MASH enrolled in a Takeda-sponsored Phase 1b clinical trial. The cohort was middle-aged (mean age 53 ± 10.9 years) and predominantly female (56%). Mean liver stiffness was 11.5 ± 6.0 kPa, the FAST score was 0.50 ± 0.26. PRO-C3 had a median value of 39.25 ng/mL (IQR, 35.08–48.73). Unadjusted associations between LiverPRO and PRO-C3 were assessed using Spearman correlation. High and low fibrogenesis groups were defined by median or fixed PRO-C3 cutoff (40 ng/mL). Discriminative performance was evaluated using area under the receiver operating characteristic curve (AUROC). Statistical significance was determined by two-sided Wilcoxon rank-sum tests.
Results: LiverPRO predictions correlated positively with PRO-C3 (F2: $\rho = 0.25$, $p = 0.0072$; F3: $\rho = 0.34$, $p = 0.00021$; F4: $\rho = 0.28$, $p = 0.0021$). Subjects with high PRO-C3 had significantly higher LiverPRO values than those with low PRO-C3 (all $p < 0.01$). The AUROC for LiverPRO distinguishing high versus low PRO-C3 groups was 0.65 (95% CI: 0.55–0.75) for F2, F3 and 0.64 (95% CI: 0.54–0.74) for F4, indicating moderate discrimination.
Conclusion: LiverPRO scores show a strong association with Pro-C3, a marker of active fibrogenesis, in screening MASH populations. These findings suggest LiverPRO may aid identification patients with high fibrogenic activity and support enrichment strategies in clinical trials with agents that target hepatic fibrogenesis. Incorporating LiverPRO alongside PRO-C3 could streamline patient selection and accelerate antifibrotic drug development in MASH.

WED-220
A distinct aromatic catabolism enterotype of the gut microbiome in metabolic dysfunction associated steatotic liver disease with type 2 diabetes
Jakob Weglage[1], Martin Kluge[1], Josephine Frohme[1], Sonja Lang[2], Anna Martin[2], Frank Tacke[1], Münevver Demir[1]. *[1]Charité Universitaetsmedizin Berlin, Department of Hepatology and Gastroenterology, Berlin, Germany; [2]University Hospital Cologne, Department of Gastroenterology and Hepatology, Cologne, Germany*
Email: jakob-hermann-josef.weglage@charite.de

Background and aims: Distinct changes in the gut microbiome have been associated with MASLD, but the functional interference between the gut microbiome and cardiometabolic comorbidities of MASLD remains incompletely understood. We investigated whether type 2 diabetes (T2D), obesity (OB), dyslipidaemia (DL) and arterial hypertension (HTN) are associated with compositional and/or functional microbiome signatures in MASLD.
Method: Stool samples from 130 adults with MASLD underwent 16S rRNA sequencing. Functional profiles were inferred using PICRUSt2 and aggregated into MetaCyc-based functional groups. Participants were stratified by T2D (n = 30), OB (n = 114), DL (n = 70) and HTN (n = 80). Predicted pathway abundances were CLR-transformed. Alpha/beta diversity, ordinations (PCA/PCoA/UMAP) and differential pathway abundance were assessed. Group differences were tested using linear regression adjusted for age and sex with FDR correction.
Results: Alpha/beta diversity and ordination analyses revealed no subgroup-specific clustering by cardiometabolic comorbidities. Only few bacterial genera differed by T2D. In contrast, 166 predicted pathways were differentially abundant in MASLD+T2D after covariate adjustment, but not in OB, DL, or HTN. The vast majority of T2D-associated pathways showed lower predicted abundance, spanning carbon/energy metabolism, amino acid and nucleotide biosynthesis, vitamin/cofactor metabolism and cell envelope functions (median $\beta \approx -0.5$). Conversely, pathways with higher predicted abundance in MASLD+T2D mapped to "aromatic degradation pathways" (10/11 pathways in the unadjusted model; 10/15 after adjustment; median $\beta \approx +5.6$), including catechol, gallate, salicylate, 4-hydroxyphenylacetate and p-cresol-related pathways.
Conclusion: Within MASLD, T2D shows no large-scale differences in bacterial community structure but a distinct predicted functional enterotype characterised by widespread reduction of core bacterial metabolic pathways alongside a selective enrichment of aromatic compound degradation. These changes were specific to T2D and were not observed for OB, DL or HTN. The enrichment of aromatic degradation aligns with prior mechanistic evidence linking microbial aromatic metabolites to impaired hepatic lipid handling and insulin signalling, suggesting that enhanced aromatic substrate turnover may contribute to the more progressive phenotype in MASLD with T2D.

WED-221
Understanding the metabolic burden among people with fibrosis and evaluating the implementation of the EASL clinical care pathway in China using the Meinian database
Lai Wei[1], Lixin Guo[2], Weihao Wang[2], Siyun Wang[3], Zewei Shen[3], Kwabena Opuni[4]. *[1]Hepatopancreatobiliary Center, Beijing Tsinghua Changgung Hospital, Tsinghua University, Beijing, China; [2]Department of Endocrinology, Beijing Hospital, National Center of Gerontology, Institute of Geriatric Medicine, Chinese Academy of Medical Sciences, Beijing, China; [3]Novo Nordisk (Shanghai) Pharma Trading Co., Ltd, Shanghai, China; [4]Novo Nordisk A/S, Bagsværd, Denmark*
Email: weelai@163.com

Background and aims: Metabolic dysfunction-associated steatotic liver disease (MASLD) is a major global health burden. Liver fibrosis, a

key prognostic factor, increases severe hepatic and cardiovascular risk. However, evidence on fibrosis prevalence and metabolic impact in China are limited. Updated EASL–EASD–EASO Clinical Practice Guidelines (CPG) recommend a clinical care pathway (CCP) for fibrosis screening and risk stratification in at-risk populations, but real-world CCP implementation in China remains unclear. This study assessed fibrosis prevalence, associated patient characteristics, and EASL CCP implementation in the Chinese population.

Method: We analyzed the Meinian health check-up database (~20 million Chinese adults, ≥18 years; Jan 1–Dec 31, 2023). The cohort met EASL CPG assessment criteria. We stratified characteristics by liver stiffness measurement (LSM) and assessed fibrosis-4 (FIB-4) performance with LSM in the EASL at-risk population (T2D, obesity plus ≥1 cardiometabolic risk factor, or elevated liver enzymes). Data were analysed descriptively.

Results: Overall, 1,124,132 individuals comprised the study cohort. Of these, 92% had no/mild fibrosis (LSM < 8 kPa), 7% had moderate fibrosis (MF; 8–12 kPa), and 1% had advanced fibrosis (AF; >12 kPa). Compared with the no/mild fibrosis group, the MF and AF groups had higher prevalences of obesity (18% vs. 49% and 64%), diabetes (9% vs. 19% and 27%), and ≥1 metabolic risk factor (81% vs. 96% and 97%), respectively. The number of concurrent metabolic risk factors increased with rising LSM. Of the cohort, 36% were identified as at-risk population to further screen for fibrosis according to EASL CCP (low 79%, intermediate 15%, high 6%). Using LSM as the reference, FIB-4 demonstrated a negative predictive value (NPV) of 86.3% (95% CI: 86.2–86.5), a positive predictive value (PPV) of 19.2% (95% CI: 18.9–19.5), sensitivity 27.5% (95% CI: 27.1–27.8), and specificity 79.9% (95% CI: 79.7–80.0). Notably, among the low-risk subgroup (n = 319,303) stratified by FIB-4, 12.0% had LSM ≥8 kPa (MF) and 1.6% had LSM >12 kPa (AF).

Conclusion: This study highlights the significant metabolic burden of liver fibrosis in the Chinese population. Although FIB-4 is recommended as the initial CCP step for its low cost and simplicity, its sensitivity and PPV are suboptimal, despite acceptable NPV. Optimizing screening strategy is needed to better identify and manage individuals at risk of fibrosis and improve clinical outcomes.

WED-225-YI

Real-world liver fibrosis screening patterns of adults with type 2 diabetes and cirrhosis: a population-based Canadian cohort

Cindy Wen[1,2], Jennifer Flemming[1,2,3], Maya Djerboua[3], Jessica Burnside[1,2], Giada Sebastiani[4], Sahar Saeed[1]. *[1]Department of Public Health Sciences, Queen's University, Kingston, Canada; [2]Department of Medicine, Queen's University, Kingston, Canada; [3]ICES, Queen's University, Kingston, Canada; [4]Department of Medicine, McGill University, Montreal, Canada*
Email: cindy.wen@queensu.ca

Background and aims: People living with type 2 diabetes (T2D) are at high risk of liver disease progression. The Fibrosis-4 (FIB-4) Index is recommended as the first step for risk stratification. We aimed to describe screening patterns from T2D to the diagnosis of incident cirrhosis.

Method: We conducted a population-based retrospective cohort study using laboratory and administrative health data in Ontario, Canada, linked through ICES between 2010 and 2022. Adults aged 40 + with incident T2D diagnosis and no history of liver disease were followed to their first cirrhosis diagnosis using validated identification algorithms. Patterns, frequencies, and timing of liver fibrosis screening were assessed using the FIB-4 Index categorized as low (< 1.3), moderate (1.3–2.67), and high risk (> 2.67).

Results: We identified 782,898 adults with incident T2D and no history of liver disease. Of whom 12,423 developed cirrhosis in a median of 4.74 [IQR: 2.34, 7.59] years. At baseline, 42.0% were female, median age 60 years [IQR: 52, 67], hemoglobin A1c 6.70% [6.20, 7.90], 22.7% lived in areas of the lowest income quintile, 27.5% reside in highly racialized or newcomer-dense regions, 78.2% have a primary care provider, and 56.9% were classified as having very high comorbidity using the Aggregated Diagnosis Groups System. Among the 41.3% who had no history of FIB-4 screening before their cirrhosis diagnosis, the median time to cirrhosis was 4.07 [IQR 1.89, 6.80] years. Among the 58.7% that were screened, the median time from T2D diagnosis to first screen was 1.34 [IQR: 0.39, 3.27] and 5.23 [IQR: 2.71, 8.02] years to cirrhosis. 57.9% were only screened once before cirrhosis diagnosis (FIB-4 risk: 23.1% low, 26.0% moderate, 50.9% high), with a median time of 1.70 [IQR: 0.50, 3.89] years to the first screen and 4.46 [IQR: 2.13, 7.24] years to cirrhosis. Differentially, among the 42.1% with > 1 FIB-4 screen, they had a median of 1.00 [IQR: 0.29, 2.43] years to first screen and 6.29 [IQR: 3.76, 9.91] years to cirrhosis (FIB-4 risk at first screen: 47.5% low, 52.5% moderate, none were high).

Conclusion: Among people with T2D diagnosed with cirrhosis, rapid progression was common, and nearly half had no history of FIB-4 screening despite having universal access to healthcare. Of those screened, about one-third were identified as low risk using the current cutoffs before a cirrhosis diagnosis. Future analyses will continue to explore the relationship between risk factors, screening patterns, and time to advanced liver outcomes.

WED-226

Social determinants of health shape all-cause mortality risk in steatotic liver disease: a machine learning analysis

Cindy Wen[1,2], Wei Tu[1,3], Giada Sebastiani[4], Jessica Burnside[1,2], Carmela Rapino[1,5], Alnoor Ramji[6], Mark Swain[7], Keyur Patel[8], Jennifer Flemming[1,2,9], Sahar Saeed[1]. *[1]Department of Public Health Sciences, Queen's University, Kingston, Canada; [2]Department of Medicine, Queen's University, Kingston, Canada; [3]Canadian Cancer Trials Group, Queen's University, Kingston, Canada; [4]Department of Medicine, McGill University, Montreal, Canada; [5]School of Medicine, Toronto Metropolitan University, Brampton, Canada; [6]Division of Gastroenterology, University of British Columbia, Vancouver, Canada; [7]Calgary Liver Unit, Cumming School of Medicine, University of Calgary, Calgary, Canada; [8]Division of Gastroenterology and Hepatology, University Health Network, Toronto, Canada; [9]ICES, Queen's University, Kingston, Canada*
Email: cindy.wen@queensu.ca

Background and aims: Risk-stratification for people with steatotic liver disease (SLD) relies on a "one-size-fits-all" approach that emphasizes clinical factors, despite increasing evidence on the impact of social determinants of health (SDoH). We aimed to evaluate the prognostic utility of adding SDoH to predict all-cause mortality among adults with SLD.

Method: We analyzed data from the Canadian Longitudinal Study on Aging, which follows aging adults (45 to 85 years) from 2012 to 2021. SLD was defined as hepatic steatosis (via the NAFLD Ridge Score) and 1 or more cardiometabolic risk factors (CMRFs). Our outcome was all-cause mortality. Data was split into 75% training, 25% testing, and 5-fold cross-validation was used for hyperparameter tuning. Predictors were selected via a Least Absolute Shrinkage and Selection Operator (LASSO) Cox Regression from clinical markers (n = 8), alcohol consumption (n = 2), sociodemographics (n = 8), and other lifestyle factors (n = 3). We used a Survival Classification and Regression Tree (CART) and Random Survival Forest (RSF). The best model was evaluated in the test set using the Concordance Index (C-Index), Integrated Brier Score (iBS), and Time-Dependent Area Under the

Receiver Operating Curve (AUC(t)). Prognostic factors were identified using Shapley Additive exPlanations values.
Results: We identified 9,239 adults with SLD (34.3% female) across a median follow-up of 7.67 years with 687 (7.4%) deaths. At baseline, 44.4% were 65 years or older, 93.4% were White, 30% had < $50,000 household income, 42.7% with education below Bachelor's degree, median alcohol consumption 26.9 g/week [IQR: 0, 94.2], and median alanine aminotransferase (ALT) 26 U/L [IQR: 20, 35]. The RSF provided the best model for all-cause mortality with a moderate test set performance: C-Index 0.780, iBS 0.0296, and mean AUC(t) 0.788. End of follow-up global importance indicates that after age, the most prognostic factors were smoking, number of CMRFs, sex, physical activity, hemoglobin A1c, waist circumference, household income, ALT, and education. The test set was stratified to 'high' and 'low' risk based on RSF predictions, showing strong separation in survival curves ($p < 0.001$).
Conclusion: An equity-oriented RSF meaningfully stratified 'high' and 'low' risk adults with SLD for all-cause mortality. Beyond clinical factors, the impact of income, education, and lifestyle underscore the value in integrating SDoH. Future work will integrate sex-stratification for more inclusive SLD risk-stratification.

WED-227
Macrophage caspase-8 deficiency promotes nonalcoholic steatohepatitis progression
Qiong Wu[1], Mingwei Sheng[2], Xiyun Bian[3], Fengmei Wang[2]. *[1]Tianjin First Central Hospital, Nankai University, Tianjin, China; [2]Tianjin First Central Hospital, Tianjin, China; [3]Tianjin Fifth Central Hospital, Tianjin, China*
Email: wangfengmeitj@126.com

Background and aims: Metabolic dysfunction-associated steatotic liver disease (MASLD) is a common chronic liver condition marked by excess fat accumulation. The cysteine-aspartic acid protease (Caspase)-8 is essential for modulating cell apoptosis and immune responses, but its function in macrophages during Metabolic Dysfunction-Associated Steatohepatitis (MASH) remains unknown.
Method: Casp8 expression was analyzed in patients with MASH and mouse models. We induced MASH in myeloid-specific Casp8 knockout ($Casp8^{M\text{-}KO}$) and floxed control ($Casp8^{fl/fl}$) mice by feeding them a high-fat/high-cholesterol diet. Through comprehensive experiments utilizing in vivo and in vitro, we investigated the mechanistic role of caspase-8 in liver macrophages during MASH pathogenesis. We also analyzed public transcriptomic datasets of MASH model mice.
Results: Caspase-8 deficiency in hepatic macrophages facilitated MASH progression by triggering an axis comprising the cellular FLICE-like inhibitory protein, ETS domain transcription factor 4, and prosaposin, which promoted macrophage M1 polarization and subsequently activated hepatocyte Rac1/CDC42/JNK signaling via G protein-coupled receptor 37-like 1. This molecular cascade was found to ultimately drive hepatic lipid accumulation and inflammation.
Conclusion: Our findings reveal a previously unrecognized role for macrophage caspase-8 in regulating lipid metabolism and inflammation during MASH progression, and identify its key regulatory mechanism as a potential therapeutic target in metabolic liver disorders.

WED-228
Prevalence of advanced liver fibrosis among first- second- and third-degree relatives of patients with MASLD-related advanced fibrosis
Ismael de Jesus Yepes Barreto[1], Nicole Chamorro[1], Guillermo Donado[1], Maria Saavedra[2], Samuel Perez[3], Yohana Poveda[4], Diana Marcela Escobar[5], Juan Carlos Restrepo[6]. *[1]Universidad de Cartagena, Asociacion Colombiana de Hepatologia, Cartagena de Indias, Colombia; [2]Clínica Ces, Medellín, Colombia; [3]Universidad de antioquia, Medellín, Colombia; [4]Imbanaco, Cali, Colombia; [5]Fundacion Valle Del Lili, Cali, Colombia; [6]Hospital Pablo Tobón Uribe, Medellín, Colombia*
Email: ismayep@yahoo.com

Background and aims: First-degree relatives of patients with MASLD-related cirrhosis are recommended to undergo liver fibrosis screening based on high prevalence rates reported in Europe and the United States. Genetic susceptibility and shared metabolic risk factors support a hereditary component in MASLD progression. However, it remains unclear whether this increased risk extends beyond first-degree relatives or applies to Latin American populations. This study aimed to determine the prevalence of advanced liver fibrosis among first- second- and third-degree relatives of patients with MASLD-related advanced fibrosis.
Method: Patients with confirmed MASLD-related advanced fibrosis were identified, and their relatives were invited to participate. First-degree relatives included parents, siblings, and children; second-degree relatives included grandparents and grandchildren; and third-degree relatives included uncles, aunts, nephews, and nieces. All participants underwent transient elastography (FibroScan®) and clinical evaluation, including anthropometric measurements, alcohol intake assessment, and metabolic comorbidities. Significant fibrosis was defined as liver stiffness ≥8.0 kPa. Only descriptive statistics were performed.
Results: A total of 166 relatives were included (65.7% female, mean age 45.0 ± 15.2 years). Overall, advanced fibrosis was detected in 9.1% of participants. Prevalence was highest among first-degree relatives (9.7%), but remained substantial in second-degree (5.6%) and third-degree relatives (6.7%). Mean body mass index was elevated across all groups, with similar values in first- (28.8 ± 6.1 kg/m^2), second- (26.9 ± 5.5 kg/m^2), and third-degree relatives (28.5 ± 5.0 kg/m^2). Alcohol consumption was generally low (29.9 ± 67.7 g/week) and showed no clear gradient by degree of kinship. Metabolic comorbidities were present but did not differ markedly across groups.
Conclusion: In this Latin American cohort, advanced liver fibrosis was frequent not only among first-degree relatives of patients with MASLD-related advanced fibrosis, but also among second- and third-degree relatives. The prevalence observed in these groups is markedly higher than the ~1.3% reported in first-degree relatives of individuals without steatosis or advanced fibrosis. These findings suggest that familial risk extends beyond first-degree kinship and support considering broader family-based screening strategies in MASLD, particularly in high-risk populations.

WED-229
Referral burden and second-tier testing in two-step algorithms for detecting significant hepatic fibrosis among Asian community-based type 2 diabetes mellitus
Eileen Yoon[1], Hyo Young Lee[1], Sang Bong Ahn[2], Joo Hyun Oh[3], Mimi Kim[4], Bo-Kyeong Kang[4], Chul-min Lee[4], Jihyun An[1], Ha Il Kim[1], Eun Chul Jang[5], Hye-Lin Kim[6], Jeong-Yeon Cho[7], Dae Won Jun[1]. *[1]Department of Internal Medicine, Hanyang University College of Medicine,, Seoul, Korea, Rep. of South; [2]Department of Internal Medicine, Nowon Eulji Medical Center, Eulji University, Seoul, Korea, Rep. of South; [3]Department of Internal Medicine, CHA University College of Medicine, Seongnam, Korea, Rep. of South; [4]Department of Radiology, Hanyang University College of Medicine, Seoul, Korea, Rep. of South; [5]Department of Occupational and Environmental Medicine, College of Medicine, Soonchunhyang University, Chunan, Korea, Rep. of South; [6]College of Pharmacy, Sahmyook University, Seoul, Korea, Rep. of South; [7]Department of Pharmacotherapy, University of Utah College of Pharmacy, Salt Lake, United States*
Email: noshin@hanyang.ac.kr

Background and aims: Current guidelines recommend a FIB-4 based two-step screening algorithm for hepatic fibrosis in type 2 diabetes mellitus (T2DM). We evaluated the social burden (need 2nd tier testing (%), referral rate, missing rate, and false-positive rate of 1st tier test) of two-step algorithm for significant hepatic fibrosis in community-based T2DM cohorts.
Method: We analyzed data from three Asian community-based health check-up cohorts comprising 3,152 individuals with T2DM assessed using vibration-controlled transient elastography or magnetic resonance elastography.
Results: The prevalence of significant hepatic fibrosis (≥F2) among individuals with T2DM ranged from 4.3% to 18.3%, and advanced fibrosis (≥F3) from 0.9% to 7.4%. Using the two-step algorithm based on age-adjusted FIB-4, 22.3–29.0% required 2nd tier testing, and 11.2–12.7% required hepatology referral. However, the FIB-4 model showed low sensitivity (54.9–58.1%), with a high negative rate of 2nd tier testing in the intermediate-risk group (72.6–100%). Lowering the FIB-4 threshold increased 2nd tier testing and referrals without improving sensitivity. In contrast, strategies based on NFS and MAF-5 tended to overclassify risk, resulting in higher rates of 2nd tier testing and referrals, whereas the LiverRisk score tended to underclassify risk, showing low sensitivity.
Conclusion: In Asian community-based cohorts, the FIB-4-based two-step algorithm demonstrated acceptable 2nd tier testing and referral rates but low sensitivity and a high negative rate of 2nd tier testing in individuals with T2DM for detecting significant hepatic fibrosis.

WED-230
Validation of noninvasive scores for identifying significant fibrosis and at-risk metabolic dysfunction-associated steatohepatitis in obese bariatric surgery patients

Jing Zhang[1], Xiaodie Wei[1], Zhang Nengwei[2], Meng Fanqiang[3]. *[1]Beijing You'an Hospital Affiliated to Capital Medical University, Beijing, China; [2]Department of Surgery, Capital Medical University Affiliated Beijing Shijitan Hospital, Beijing, China; [3]Department of General Surgery, China-Japan Friendship Hospital, Beijing, China*
Email: weixiaodie@aliyun.com

Background and aims: Significant fibrosis and at risk metabolic dysfunction-associated steatohepatitis (MASH) elevate risks of adverse liver and extrahepatic outcomes. This study aimed to validate the ability of noninvasive scores (NITs) based on routine clinical indicators to identify significant fibrosis and at-risk MASH in obese bariatric surgery patients.
Method: This study included 360 participants from two independent bariatric surgery cohorts, and liver biopsy and routine clinical data were collected. The efficacy of FIB4, NFS, APRI, LRS, FNI (combining aspartate aminotransferase, high-density cholesterol, and glycated hemoglobin), and FMO (including aspartate aminotransferase, alanine aminotransferase, triglycerides, and high-density lipoprotein cholesterol) in diagnosing significant fibrosis and at-risk MASH was compared.
Results: Among the 360 participants, 152 (38.9%) were diagnosed with significant fibrosis and 124 (31.7%) were diagnosed with at-risk MASH. The diagnostic efficacy of NITs for significant fibrosis was as follows: the AUC (95% CI) for FIB4, NFS, APRI, LRS, FNI, and FMO were 0.590 (0.533–0.648), 0.517 (0.458–0.576), 0.675 (0.620–0.730), 0.658 (0.602–0.714), 0.715 (0.662–0.767), and 0.696 (0.642–0.749), respectively. The FNI model demonstrated optimal rule-out[cutoff 0.10, sensitivity 87.42%, negative predictive value (NPV) 80.81%] performance, while FMO demonstrated optimal rule-in[cutoff 0.22, specificity 83.61%, positive predictive value (PPV) 60.20%] performance. For at-risk MASH patients, the AUCs for FIB4, NFS, APRI, LRS, FNI, and FMO were 0.591 (0.531–0.651), 0.512 (0.452–0.573), 0.715 (0.661–0.770), 0.678 (0.620–0.735), 0.748 (0.696–0.799), and 0.744 (0.692–0.796), respectively. FNI also demonstrated the best exclusion performance (cutoff value 0.10, NPV 89.90%), while FMO showed the best inclusion performance (cutoff value 0.22, PPV 57.14%).
Conclusion: Both FNI and FMO are accurate and cost-effective non-invasive scores that can effectively identify the risk of significant and at-risk MASH in patients with bariatric surgery.

WED-231
Two-tier screening approach for liver fibrosis stratification in outpatients with type 2diabetes mellitus: a multicenter cross-sectional study

Alessandro Mantovani[1,2], Rosa Lombardi[3,4], Andrea Dalbeni[5], Riccardo Morandin[6], Maria Giovanna Lando[6], Veronica Fiorio[6], Nicoletta Rolli[6], Matteo Forti[6], Dario Messetti[6], Mirko Zoncapè[7], Ilaria Milani[8], Maria Eugenia Parrotta[9], Danila Capoccia[8], Valeria Guglielmi[9], Frida Leonetti[8], Paolo Sbraccia[9], Anna Ludovica Fracanzani[3,4], Giovanni Targher[1,2]. *[1]Metabolic Diseases Research Unit, IRCCS Sacro Cuore-Don Calabria Hospital, Negrar di Valpolicella, Verona, Italy; [2]Department of Medicine, University of Verona, Verona, Italy; [3]Fondazione IRCCS Ca' Granda Ospedale Maggiore Policlinico di Milano, Milano, Italy; [4]Department of Pathophysiology and Transplantation, University of Milan, Milano, Italy; [5]Section of General Medicine C and Liver Unit, University and Azienda Ospedaliera Universitaria Integrata of Verona, Verona, Italy; [6]Section of Endocrinology, Diabetes and Metabolism, Department of Medicine, University and Azienda Ospedaliera Universitaria Integrata of Verona, Verona, Italy; [7]Clinica Medica 3, Azienda Ospedale Università di Padova, Padova, Italy; [8]Department of Medico-Surgical Sciences and Biotechnologies, Faculty of Pharmacy and Medicine, University of Rome La Sapienza, Roma, Italy; [9]Department of Systems Medicine, University of Rome Tor Vergata, Obesity Medical Center, University Hospital Policlinico Tor Vergata, Roma, Italy*
Email: alessandro.mantovani@univr.it

Background and aims: To examine the prevalence and severity of metabolic dysfunction-associated steatotic liver disease (MASLD) in outpatients with type 2 diabetes mellitus (T2DM), and to assess the effectiveness of the EASLEASD-EASO algorithm for liver fibrosis screening.
Method: We retrospectively enrolled 1203 Italian older outpatients with T2DM who underwent vibrationcontrolled transient elastography (VCTE) with liver stiffness measurement (LSM) and controlled attenuation parameter (CAP) assessment. MASLD was defined as CAP ≥248 dB/m. Significant liver fibrosis was defined as LSM ≥8 kPa, compensated advanced chronic liver disease (cACLD) as LSM ≥10 kPa, and clinically significant portal hypertension (CSPH) as LSM ≥25 kPa or LSM ≥20 kPa and platelet count <150 000/mm3. FIB-4 index was calculated in all participants.
Results: The prevalence rates of MASLD, significant liver fibrosis, cACLD, and CSPH were 71.3%, 21.1%, 11.7% and 1.7%, respectively. A 2-tier screening strategy for liver fibrosis using the FIB-4 index and VCTE showed that among patients with a normal FIB-4 index, 629 (83.3%) had LSM <8 kPa and 126 (16.7%) had LSM≥8 kPa. Sensitivity, specificity, NPV, and PPV of the FIB-4 index for detecting LSM≥8 kPa were 50.4%, 66.3%, 83.3% and 28.6%, respectively. Increased body weight (adjusted-OR 3.34, 95%CI 1.75–6.39) and elevated ALT levels (adjusted-OR 1.54, 95%CI 1.01–2.36) were the strongest predictors of significant liver fibrosis.
Conclusion: MASLD and significant liver fibrosis are common in older patients with T2DM. Fibrosis risk stratification using FIB-4, followed by VCTE, is a good strategy in real-world settings. However, relying solely on FIB-4 may fail to identify some patients with advanced disease, particularly those with increased body weight and elevated serum aminotransferase levels.

MASLD – Experimental and pathophysiology

ZDHHC17-mediated of palmoylation-modified D2HGDH nuclear translocating drives progression of metabolic associated steatohepatitis via HDAC1-H3K27ac pathways

Xi-Xuan Wang[1], Shu-Ling Chen[1], Rui-Qi Li[1], Jun Guo[1], Zihao Liang[1], Dandan Yin[1], Cai-Yun Zhang[1], Wei Chen[1], Changhua Yi[1], Qingfang Xiong[1], Jiangao Fan[2], Dawei Yang[1], Yongfeng Yang[1].
[1]Department of Hepatology, The Second Hospital of Nanjing, Medical School, Southeast University, Nanjing, China; [2]Department of Gastroenterology, Xin Hua Hospital, School of Medicine, Shanghai Jiao Tong University, Shanghai, China
Email: yyf1997@163.com

Background and aims: Aberrant nuclear translocation of metabolic enzymes is an emerging driver of epigenetic dysregulation in disease, yet its specific mechanisms and therapeutic relevance in metabolic dysfunction-associated steatohepatitis (MASH) remain poorly understood. This study aims to elucidate the role and targeting of the nuclear translocation of D-2-hydroxyglutarate dehydrogenase (D2HGDH) in MASH.
Method: Utilizing clinical samples, MASH mouse models, and cellular models, we conducted comprehensive analyses through metabolomics, proteomics combined with palmitoyl-proteomics, immunohistochemistry/immunofluorescence, subcellular fractionation, protein-protein interaction assays, epigenomic multi-omics (ATAC-seq, CUT&TAG), and virtual screening.
Results: During MASH progression, hepatocyte D2HGDH undergoes nuclear translocation, a phenomenon specific to fatty liver disease. Mechanistically, high-fat-induced oxidative stress promotes the palmitoyltransferase ZDHHC17 to catalyze palmitoylation of D2HGDH at cysteine 198. This modification facilitates D2HGDH nuclear import via binding of its C-terminal PY-nuclear localization signal (NLS) to the nuclear transport protein Transportin-1 (TNPO1), by affecting its mitochondrial targeting sequence and protein polarity. Within the nucleus, D2HGDH directly binds to and inhibits histone deacetylase 1 (HDAC1), leading to decreased histone H3 lysine 27 trimethylation (H3K27me3) and increased H3K27 acetylation (H3K27ac). This epigenetically reprograms chromatin accessibility genome-wide, specifically activating the transcription of lipogenesis-related genes, thereby driving hepatocyte lipid accumulation. Targeting ZDHHC17, either via genetic knockout or the small-molecule inhibitor TBK1-IN-1 identified through virtual screening, blocked D2HGDH palmitoylation and nuclear translocation, and effectively alleviated MASH both in vitro and in vivo.
Conclusion: This study unveils a novel signaling axis, driven by ZDHHC17-mediated palmitoylation of D2HGDH, that links cellular metabolism to nuclear epigenetic regulation and is critical for MASH development. Targeting the ZDHHC17-D2HGDH interaction presents a potential therapeutic strategy for MASH.

Hepatic IFRD1 suppresses metabolic dysfunction-associated steatohepatitis via GLUD1/α-KG axis

Mengya Geng[1], Hairui Li[2], Sihui Luo[1], Suowen Xu[1], Jianping Weng[3].
[1]Department of Endocrinology and Metabolism, The First Affiliated Hospital of USTC, Division of Life Sciences and Medicine, University of Science and Technology of China, Hefei, China; [2]department of Hepatobiliary Surgery, The First Affiliated Hospital of USTC, Division of Life Sciences and Medicine, University of Science and Technology of China, Hefei, China; [3]Division of Life Sciences and Medicine, University of Science and Technology of China, Anhui Medical University, Hefei, China
Email: gengmengya@mail.ustc.edu.cn

Background and aims: The key molecular targets and underlying mechanisms involved in regulating metabolic remodeling in metabolic dysfunction–associated steatotic liver disease (MASLD) remain unclear. Interferon-related developmental regulator 1 (IFRD1) is traditionally linked to embryogenesis, yet its role in MASLD has not been investigated. This study aims to clarify the role of IFRD1 in MASLD and its potential mechanisms.
Method: We collected liver and serum samples from MASLD patients and controls, as well as from Ifrd1 knockout mice (*Ifrd1*$^{-/-}$), Ifrd1 conditional knockout (CKO) mice, and liver-targeted Ifrd1 overexpression mice following treatment with various dietary regimens. These samples were subjected to Western blotting, Reverse Transcription Quantitative Real-Time Polymerase Chain Reaction (RT-qPCR), immunostaining, pathological staining, and biochemical assays. Mice were subjected to metabolic cage assays, and primary hepatocytes were isolated. Potential downstream mechanisms were investigated via RNA sequencing, CUT&Tag, subcellular fractionation, immunoprecipitation-mass spectrometry (IP-MS) analysis, and a variety of molecular biology experiments.
Results: IFRD1 expression significantly negatively correlates with metabolic-associated steatohepatitis (MASH) progression in human liver samples. In multiple mouse models, *Ifrd1*$^{-/-}$ mice exhibited a "lean fatty liver" phenotype due to enhanced systemic energy metabolism, hepatocyte-specific IFRD1 expression suppressed MASH progression, a function that was abrogated upon inhibition of GLUD1 enzymatic activity. Mechanistically, IFRD1 promotes GLUD1's mitochondrial localization via direct interaction, stabilizing the enzyme's activity to enhance α-ketoglutarate (α-KG) production. α-KG reduces H3K36me3 occupancy at lipogenic genes, thereby inhibiting DNL and ameliorating MASH. α-KG supplementation reverses MASH exacerbation in *Ifrd1*-CKO mice.
Conclusion: This study establishes the IFRD1-GLUD1-α-KG axis as a key metabolic-epigenetic regulatory pathway and supports the development of future MASH therapeutic strategies based on drugs that stabilize IFRD1 expression or promote α-KG production.

Mitochondrial cholesterol transport by stard1 links hepatocyte stress to macrophage inflammasome activation in MASLD

Hala Jaara[1], Mariana Acevedo[1], Laura Fàbrega[1], Susana Núñez[1], Vicent Ribas[1], M. Carmen Garcia-Ruiz[1,2], José Fernandez-Checa[1,2], Sandra Torres Núñez[1]. *[1]Department of Molecular and Cellular Biomedicine, Institute of Biomedical Research of Barcelona (IIBB), CSIC, Barcelona, Spain, CIBEREHD, Madrid, Spain, Instituto de Investigaciones Biomédicas August Pi i Sunyer (IDIBAPS), Liver Unit, Hospital Clinic I Provincial de Barcelona, Barcelona, Spain, Barcelona, Spain; [2]Department of Medicine, Keck School of Division of Gastrointestinal and Liver disease, University of Southern California, Los Angeles, CA, United States, Los Angeles, United States*
Email: sandra.torres@iibb.csic.es

Background and aims: Despite advances in understanding metabolic dysfunction–associated steatotic liver disease (MASLD), effective pharmacological therapies remain limited. Mitochondrial cholesterol accumulation promotes reactive oxygen species (ROS) generation, leading to mitochondrial dysfunction, inflammation, and hepatocellular death, thereby driving disease progression toward hepatocellular carcinoma (HCC). The ROS-sensitive NLRP3 inflammasome, predominantly active in macrophages, links mitochondrial damage to inflammatory liver disease. Steroidogenic acute regulatory

protein 1 (STARD1), which transports cholesterol into mitochondria, is upregulated in MASLD and implicated in HCC. We hypothesized that STARD1-driven mitochondrial ROS activates the NLRP3 inflammasome through hepatocyte–macrophage crosstalk.
Method: Mice with hepatocyte-specific (StARD1$^{\Delta Hep}$) or macrophage-specific (StARD1$^{\Delta Mac}$) deletion of StARD1 were fed control diets, a high-cholesterol/sodium cholate diet (HCSC) for 2 days, or a choline-deficient amino acid-defined high-fat diet (CDA-HFD) for 3 weeks. Liver injury, inflammation, oxidative stress, and inflammasome markers were assessed. Hepatocytes and macrophages were isolated to evaluate cell-specific responses. Primary hepatocytes from StARD1$^{f/f}$ and StARD1$^{\Delta Hep}$ mice were treated with soluble cholesterol under ACAT inhibition to assess mitochondrial cholesterol trafficking, ROS production, and inflammasome gene expression.
Results: Hepatocyte-specific deletion of StARD1 reduced mitochondrial ROS and decreased expression of Nlrp3, Asc, Casp1, and IL-1β, protecting against liver inflammation in both HCSC and CDA-HFD models. Cholesterol-loaded StARD1$^{f/f}$ hepatocytes exhibited mitochondrial cholesterol accumulation, increased ROS, and inflammasome gene induction, whereas StARD1$^{\Delta Hep}$ hepatocytes were protected. Macrophages from StARD1$^{\Delta Hep}$ mice showed reduced Stard1 and macrophage activation markers, indicating hepatocyte-dependent regulation of macrophages. Similarly, macrophage-specific deletion of StARD1 attenuated macrophage activation and resulted in reduced hepatic inflammation and liver injury in both dietary models. These findings suggest a trigger and amplification model of mitochondrial cholesterol loading in hepatocytes and macrophages, respectively.
Conclusion: STARD1 is a key upstream regulator of mitochondrial cholesterol–ROS–NLRP3 inflammasome activation and mediates pathogenic hepatocyte–macrophage crosstalk in MASLD, highlighting STARD1 as a potential therapeutic target.

CBS/H_2S-Dependent S-Sulfhydration of PREB regulates ApoB-mediated VLDL secretion and hepatic lipid homeostasis

Mingchang Pang[1], Huayu Yang[1], Yilei Mao[1], Yongfa Huang[2]. [1]*Peking Union Medical College Hospital, Chinese Academy of Medical Sciences & Peking Union Medical College, Beijing, China;* [2]*Department of Liver Surgery, Peking Union Medical College (PUMC) Hospital, PUMC and Chinese Academy of Medical Sciences, Beijing, China, Beijing, China*
Email: mingchangpang@yeah.net

Background and aims: Aberrant hepatic lipid accumulation affects approximately one-third of adults worldwide, and is associated with an increased risk of steatohepatitis and cirrhosis. H_2S-mediated S-sulfhydration is an emerging post-translational modification that regulates redox homeostasis and other critical biology processes. This study aims to investigate whether and how protein S-sulfhydration in hepatocytes regulates lipid metabolism.
Method: Global and liver-specific knockout of the gene encoding cystathionine-β-synthase (CBS) were generated in C57BL/6J mice to model H_2S deficiency. S-sulfhydration profiles were characterized using sulfhydryl-modified proteomics, and hepatic lipid metabolism was assessed through integrated transcriptomic, proteomic, and lipidomic analyses, biochemical testing, and histological examination. Molecular biology was delineated using DNA pull-down assays, luciferase reporter assays, chromatin immunoprecipitation sequencing, and gain/loss-of-function experiments.
Results: Extensive remodeling of the hepatic S-sulfhydrated proteome perturbed lipid transport and cholesterol metabolism in *Cbs*-deficient mice. Phenotypically, *Cbs*-deficient mice developed marked hepatic lipid accumulation featuring increased triglyceride and cholesterol ester, as well as decreased serum triglyceride levels. Integrated multi-omics analyses unveiled an underlying lipid export defect attributed to downregulation of apolipoprotein B (ApoB), the key mediator of very-low-density-lipoprotein (VLDL) assembly and secretion. Mechanistically, reduced H_2S availability diminished S-sulfhydration of the transcription factor prolactin regulatory element-binding (PREB), attenuating its positive regulation of *Apob* transcription. Pharmacological restoration of H_2S enhanced PREB-dependent ApoB expression in hepatocytes, supporting a critical role for the CBS/H_2S–PREB–ApoB axis in regulating hepatic lipid export.
Conclusion: These findings identified protein S-sulfhydration as a critical regulator of hepatic lipid export, and revealed a CBS/H_2S–PREB–ApoB axis governing VLDL assembly and secretion. Disruption of this pathway could result in marked hepatic lipid accumulation, providing potential translational and therapeutic insight into dyslipidemia and fatty liver disease.

Spatially resolved multi-omics unveil arginine metabolism promotes the transition from MASH to HCC

Yuan Liang[1], Rui Zhang[2], Ling Lu[3]. [1]*School of Biological Science & Medical Engineering, Southeast University, Nanjing, China;* [2]*Xuzhou Medical University, Xuzhou, China;* [3]*Affiliated Hospital of Xuzhou Medical University, Xuzhou, China*
Email: liang_yuan@seu.edu.cn

Background and aims: Metabolic dysfunction-associated steatotic liver disease (MASLD) is a significant cause of liver disease worldwide, ranging from simple steatosis to metabolic dysfunction-associated steatohepatitis (MASH) and hepatocellular carcinoma (HCC). The mechanisms underlying the dynamic reorganization of the inflammatory-cancer transition within the spatial context remain elusive.
Method: We induced MASH-to-HCC via diethylnitrosamine (DEN) combined with a high-fat, high-sucrose, high-cholesterol (HFHC) diet for the experimental group and curated an integrated atlas incorporating spatially resolved transcriptomics (Visium, n = 12) and metabolomics (air-flow-assisted desorption electrospray ionization–mass spectrometry imaging, AFADESI-MSI, n = 12), including three normal livers, four MASH livers, and five MASH-HCC livers, to comprehensively integrate multiple molecular layers.
Results: By deciphering regionally shared transcriptional domains across disease stages, we identified five spatially distinct meta-domains in the MASH-to-HCC transition. We inferred that the arginine biosynthesis-enriched domain is critical for the MASH-to-HCC transformation. We observed that Asl^{+} hepatocytes were specifically enriched in the arginine biosynthesis-enriched domain, overlapping with hypoxia activation in MASH. Hypoxia-induced reprogramming of arginine biosynthesis in Asl^{+} hepatocytes promotes MASH progression via the Hif1a-Arg1/Asl axis. We observed cellular and metabolic heterogeneity in the PV/CV region of MASH. However, Asl^{+} hepatocytes were located in the tumor margin region, accompanied by arginine biosynthesis activity. Moreover, MASH-HCC-specific Arginine-binding transcription regulator RACK1 regulates FABP5-mediated fatty acid metabolism through mTOR signaling to promote the MASH-HCC progression.
Conclusion: In conclusion, we integrated single-cell RNA-Seq and spatial multi-omics to elucidate the cellular and metabolic heterogeneity underlying MASH-to-HCC progression. Our findings establish Asl^{+} hepatocytes as key mediators of the MASH-to-HCC transition via hypoxia-induced arginine biosynthesis and reveal how the MASH-HCC-specific Arginine-binding transcription regulator RACK1 regulates FABP5-mediated fatty acid metabolism to promote HCC progression. Collectively, we reveal significant transcriptional and metabolic heterogeneity and highlight underlying cellular dynamics and molecular mechanisms of MASH-to-HCC transformation.

Email: carmen.garcia@iibb.csic.es

Background and aims: Metabolic dysfunction–associated fatty liver disease (MAFLD) is associated with extrahepatic complications, particularly cardiovascular disease (CVD), yet the mechanistic liver–heart connection remains unclear. Cholesterol trafficking to mitochondria via STARD1 promotes MAFLD progression and hepatocellular carcinoma. Mitochondrial cholesterol is converted by CYP27A1 into 27-hydroxycholesterol (27-OHC), the most abundant circulating oxysterol, which is elevated in MAFLD patients and induces atherosclerosis in mice. This study investigated the role of hepatic STARD1 in MAFLD progression and cardiac remodeling, focusing on 27-OHC as a mediator of the liver–heart axis.

Method: Male hepatocyte-specific StARD1 knockout ($StARD1^{\Delta Hep}$) and control ($StARD1^{f/f}$) mice were fed a standard diet or a high-fat, high-cholesterol (HFHC) diet (60% fat, 0.5% cholesterol) for up to 10 months. Liver injury, steatosis, and fibrosis were assessed histologically. Cardiac remodeling was evaluated by fibrosis staining, magnetic resonance imaging (MRI), and lipidomic analyses of cholesterol esters (CE), triglycerides (TG), ceramides, and 27-OHC. Cardiac expression of LRP-1 and cathepsin D (CatD) was analyzed in mouse hearts and in human cardiac myocytes treated with 27-OHC. Circulating 27-OHC was measured in serum from MAFLD patients.

Results: HFHC-fed $StARD1^{\Delta Hep}$ mice showed reduced liver injury, hepatocyte ballooning, steatosis, and fibrosis compared with $StARD1^{f/f}$ controls, confirming STARD1's role in MAFLD progression. Hearts from HFHC-fed $StARD1^{\Delta Hep}$ mice exhibited reduced LRP-1 and CatD expression and preserved cardiac output by MRI. Cardiac CE and TG content increased with HFHC feeding but did not differ between genotypes. Hepatic 27-OHC was nearly undetectable in $StARD1^{\Delta Hep}$ mice, while cardiac 27-OHC was reduced by ~50%, indicating that a substantial fraction of cardiac 27-OHC originates from the liver in a STARD1-dependent manner. Ceramide profiles were unchanged between genotypes.In vitro, 27-OHC reduced viability, increased ROS, and induced LRP-1 and CatD in human cardiac myocytes. Serum from MAFLD patients showed elevated circulating 27-OHC, supporting translational relevance.

Conclusion: Hepatic STARD1 promotes MAFLD progression and generates 27-OHC, contributing to cardiac remodeling and dysfunction. Elevated circulating 27-OHC in MAFLD patients supports a mechanistic liver–heart axis and identifies STARD1–27-OHC as potential therapeutic targets to mitigate liver–heart complications.

Maternal metabolic dysfunction-associated steatotic liver disease rewires placental-fetal selenium crosstalk and mediates fetal liver insulin resistance

Simran Sharma[1], Ahona Roy[1], Anupama Kumari[1], Aarti Sharma[1], Rajni Yadav[1], Ashwini Vasudevan[1], Dinesh Mani Tripathi[1], Neha Agarwal[1], Shiv Kumar Sarin[1], Savneet Kaur[1]. [1]*Institute of Liver and Biliary Sciences, New Delhi, India*
Email: savykaur@gmail.com

Background and aims: Metabolic dysfunction-associated steatotic liver disease (MASLD) is emerging as a major health concern in women of reproductive age globally. Recent studies link maternal MASLD to adverse neonatal outcomes, yet its effects on placental vasculature, early fetal liver changes, and underlying mechanisms remain ambiguous. We hypothesised and studied crosstalk between MASLD placenta and fetal liver using multi-omic profiling.

Method: Maternal MASLD mouse models (C57BL/6J, n = 20) were developed using high-fat diet (HFD) and high-fat high-carbohydrate diet (HFHCD) compared to control diet-fed dams at embryonic day 10 (E10) and (E18). Placentas were characterised by immunohistochemistry (CD31, VE-cadherin, CD90, lipid and calcium staining), RT-PCR and metabolomics. Fetal livers (E18) were studied histologically and by transcriptomics. Fetal hepatoblasts were cultured to study effects of one of the significantly upregulated genes *in vitro*.

Results: HFHCD induced maternal insulin resistance (liver insulin level ~198 pg/ml, HOMA-IR of 5.5), hyperglycemia, hypertriglyceridemia (serum triglycerides ~350 mg%), elevated liver enzymes (AST ~140 IU/l, ALT ~120 IU/l) and hepatic lipogenesis (GLUT2 +3-fold, SREBP1 +4-fold, PPARg +2-fold) compared to HFD and controls. At E18, HFHCD placenta showed increased angiogenesis, lipid accumulation, calcification. Placental metabolomics identified enriched selenoamino acid metabolism (6-fold, $p < 0.05$) in HFHCD versus controls. HFHCD fetal livers showed lipid accumulation, hyperinsulinemia (liver insulin level ~170 pg/ml), upregulated lipid metabolism and inflammatory genes (SREBP1, CXCL1, NF-kappa B), downregulation of insulin receptor IRS2 ($p < 0.05$). Integrated placental metabolome and fetal liver transcriptome identified selenoamino acid metabolism as overlapping pathway (top-ranked in both datasets, $p < 0.05$), wherein selenocysteine (SeCys) was reduced in HFHCD placenta (↓~0.6-fold, $p < 0.05$), while selenoprotein P (SeP) was upregulated in HFHCD fetal liver (↑~3-fold, $p < 0.01$). Hepatoblast organoids treated with SeP (0.5–2 ug/ml, 48 h), showed dose-dependent reduction in insulin-stimulated pAkt ($p < 0.05$).

Conclusion: Maternal MASLD leads to placental vascular changes and SeCys depletion, restricting fetal Se supply. Fetal liver compensates this by upregulating SeP expression. Abnormally high levels impair SeP-mediated antioxidant defence, driving insulin resistance. This study reveals novel placental-fetal Se axis underlying MASLD-induced fetal liver metabolic programming.

Liver-specific somatic beta-klotho knockout dysregulates hepatic lipid metabolism and increases bile acid synthesis

Alexandra Aaldijk[1], Cristy Verzijl[1], Milaine Hovingh[1], Nicolette Huijkman[1], Marieke Smit[1], Niels Kloosterhuis[1], Niels Mulder[1], Rick Havinga[1], Albert Gerding[1], Trijnie Bos[1], Mirjam Koster[1], Mariska de Graaf[1], Justina Wolters[1], Bart van de Sluis[1], Dicky Struik[1], Johan Jonker[1]. [1]*University Medical Centre Groningen (UMCG), Groningen, Netherlands*
Email: alexandraaaldijk@outlook.com

Background and aims: Beta klotho (KLB), a coreceptor required for fibroblast growth factor (FGF)19 and 21 signaling, has been identified as a drug target for metabolic and liver-related diseases. Understanding of its function in vivo is mainly based on germline mouse knockout models exhibiting developmental abnormalities, potentially confounding the interpretation of KLB in adult physiology and FGF19/21 pharmacodynamics. In this study, we applied liver-specific somatic gene editing to establish the role of hepatic KLB in adult physiology and validate its therapeutic potential as a drug target in liver disease.
Method: Liver-specific Cas9-transgenic mice on a C57BL/6J background were retro-orbitally injected with adeno-associated virus particles containing guide RNAs targeting exon 1 of the mouse *Klb* gene to generate a liver-specific *Klb* knockout (Klb^{HepKO}). Control mice received a matched viral dose of empty vector. Mice were fed a chow diet for 4 weeks or a high-fat diet for 12 weeks post-virus injection, followed by extensive phenotypic characterization.
Results: Under chow- and HFD-fed conditions, liver-specific knockout of *Klb* resulted in increased bile acid synthesis as shown by 2.6-fold ($p = 0.008$) and 5.8-fold ($p = 0.004$) elevated *Cyp7a1* expression, respectively. Fecal bile acid excretion was increased 2.9-fold in chow-fed ($p = 0.008$) and 7.9-fold ($p = 0.000$) in HFD-fed Klb^{HepKO} mice, and bile acid composition was altered as shown by a more hydrophobic bile acid composition under chow ($p = 0.008$) and HFD ($p = 0.004$) conditions. Moreover, hepatic *Klb* knockout resulted in 41.4% lower plasma triglyceride levels ($p = 0.008$) and 37.0% higher hepatic triglyceride levels ($p = 0.016$) only under chow conditions. The fraction of VLDL was 42.7% reduced ($p = 0.008$) in Klb^{HepKO} mice, suggesting elevated hepatic triglycerides might result from impaired VLDL secretion. Upon a HFD, effects on hepatic triglyceride levels were less pronounced ($p = 0.052$), showing only a trend towards altered lipid metabolism.
Conclusion: Liver-specific Cas9-mediated gene editing reveals hepatic KLB as a key regulator of bile acid homeostasis and hepatic lipid metabolism under both chow and high-fat diet conditions. These findings highlight KLB-dependent pathways as promising targets to enhance FGF-based therapies for liver disease.

SAT-091

Farnesoid X receptor signalling orchestrates gut-liver axis feedback to modulate ceramide-sphingolipid metabolism in metabolic associated steatotic liver disease

Basma Abdelrahman[1], Rasha Tawfiq[1], Olfat Hammam[2], Yasmeen Attia[1]. [1]*Department of Pharmacology, Faculty of Pharmacy, The British University in Egypt, Cairo, Egypt;* [2]*Department of Pathology, Theodor Bilharz Research Institute, Giza, Egypt*
Email: yasmeen.attia@bue.edu.eg

Background and aims: Ceramide accumulation acts as a systemic metabolic stress signal that disrupts lipid homeostasis and accelerates inflammatory progression in metabolic-associated steatohepatitis (MASH). Beyond hepatocellular injury, sphingolipid imbalance reflects impaired gut-liver communication, implicating extrahepatic regulatory circuits in disease evolution. Farnesoid X receptor (FXR) signalling, via intestinal fibroblast growth factor 15 (FGF15), regulates bile acid synthesis and hepatic lipid metabolism. Whether disruption of this FXR/FGF15 axis drives ceramide-sphingolipid dysregulation in MASH remains unclear. We, therefore, examined whether pharmacological FXR activation with obeticholic acid (OCA) restores gut-liver signalling and sphingolipid homeostasis in experimental MASH.
Method: MASH was induced using a high-fat diet (HFD) in male C57BL/6 mice, which were assigned to standard chow, HFD, or HFD plus obeticholic acid (OCA; 5 mg/kg/day, oral) groups. OCA was administered after 8 weeks of HFD for 4 weeks. Hepatic FXR activity was assessed by quantifying small heterodimer partner-1 (SHP-1) gene by qRT-PCR. Gut-liver axis feedback and intestinal barrier integrity were evaluated by measuring hepatic CYP7A1 alongside intestinal fibroblast growth factor-15 (FGF15) and claudin-1 by ELISA. Hepatic sphingolipid metabolism was evaluated by measuring sphingosine-1-phosphate (S1P) and acid sphingomyelinase (ASMase) using ELISA and sterol regulatory element-binding protein-1c (SREBP-1c) gene expression by qRT-PCR.
Results: OCA treatment markedly alleviated histopathological features of MASH. FXR activation was confirmed by a 2.6-fold increase in SHP-1 expression ($p < 0.0001$) accompanied by restoration of bile acid negative feedback, evidenced by a 1.7-fold increase in FGF15 ($p = 0.0068$) and a 79% reduction in CYP7A1 protein levels ($p < 0.0001$) compared to HFD group. OCA also attenuated the compensatory 2.7-fold increase in claudin-1 observed in HFD-fed mice ($p < 0.0001$). Concomitantly, sphingolipid dysregulation was corrected with OCA, with reductions in S1P (63.5%) and ASMase (49.1%) levels (both $p < 0.0001$), alongside a 64.6% decrease in SREBP-1c expression ($p < 0.0001$), as compared to HFD, indicating restoration of hepatic lipid homeostasis.
Conclusion: The present study implicates hepatic FXR activation in restoring gut-liver axis feedback on bile acid synthesis, rebalancing ceramides/sphingolipids metabolism, thereby alleviating MASH.

Email: noshin@hanyang.ac.kr

Background and aims: In metabolic dysfunction-associated steatosis liver disease (MASLD), liver sinusoidal endothelial cells (LSECs) play a pivotal role in the onset and progression of metabolic MASLD. However, the dynamics and roles of LSEC subclusters during MASLD progression remain largely unknown. This study aimed to analyze the molecular alterations and functions of LSEC subclusters as MASLD progressed, using single-cell analysis.
Method: We analyzed single-cell RNA-seq (scRNA-seq) in 11 individuals to compare endothelial subclusters between MASLD patients and healthy controls, validated the findings with single-nucleus RNA-seq (snRNA-seq) in 14 individuals from an independent cohort, and further examined their association with histological severity and zonal distribution using spatial transcriptomics in 12 individuals.
Results: Endo 4 subcluster, identified as the MASLD-enriched LSEC subcluster, was significantly increased in patients with MASLD compared to healthy controls in both scRNA-seq and snRNA-seq cohorts. Gene expression analysis revealed that ANGPT2 was

upregulated in the MASLD-enriched LSEC subcluster compared to other LSEC cells. Furthermore, gene expressions related to extracellular matrix, TGF-β signaling, and HIF-1 signaling were increased in the MASLD-enriched LSEC subcluster. Spatial transcriptomics showed MASLD-enriched LSEC sub-clusters increased progressively with the severity of steatosis, ballooning, inflammation, and fibrosis. Notably, the MASLD-enriched LSEC subcluster showed a higher degree of colocalization with scar-associated stellate cells than other subclusters. It also demonstrated increased interaction with hepatic stellate cells, T cells, and highest interaction with $CD14^+$ $CD16^+$ circulating monocytes.
Conclusion: The MASLD-enriched LSEC subcluster, associated with disease severity, was characterized by activation of extracellular matrix remodeling, TGF-β and HIF-1 signaling, and showed enhanced interactions with hepatic T cells, stellate cells, and peripheral circulating monocytes.

SAT-093-YI
Knockout of miR-92a and LNA-miR-92a treatments are promising therapeutic options against MASLD progression and portal hypertension
Philipp Althaus[1], Sara Zarei[1], Stefanie Dimmeler[2], Jonel Trebicka[1,3], Sabine Klein[1]. *[1]University Hospital Muenster, Internal Medicine B, Muenster, Germany; [2]Goethe-University Frankfurt am Main, Institute for Cardiovascular Regeneration, Frankfurt am Main, Germany; [3]European Foundation for the Study of Chronic Liver Failure, Barcelona, Spain*
Email: ph.althaus@unitybox.de

Background and aims: The rising incidence of MASLD, coupled with the lack of effective treatments for the advanced, decompensated stage, underscore the urgent need for new, effective therapies.
Therefore, we investigated whether knockout of miR-92a or administration of LNA-miR-92a halts disease progression through anti-inflammatory effects and thereby reducing fibrotic remodeling.
Method: Liver tissues from cirrhotic compensated wild-type (wt) mice treated with LNA-92a and from cell specific Alb-Cre^+miR92$a^{fl/fl}$ knock-out mice were examined and compared with untreated wt-controls. Gene expression of hepatic profibrotic and inflammatory markers were analyzed and fibrosis was assessed histologically using Sirius-Red staining and immunohistochemistry for α-smooth muscle actin (αSMA). Hepatic collagen content was determined by hydroxyproline assay. Necroinflammatory activity was assessed by measuring serum levels of the transaminases aspartate aminotransferase (AST) and alanine aminotransferase (ALT). Portal hypertension was recorded by in-vivo portal pressure measurements.
Results: Compensated cirrhotic knockout and treated wt mice showed reduced expression of profibrotic genes (TGFβ, PDGF, col1a1) compared with their respective wt controls. Less activation of hepatic stellate cells was depicted by gene expression of αSMA which displayed a 2.6-fold decrease of LNA-92a–treated wt MASH. Hydroxyproline analysis confirmed a significant reduction of hepatic collagen expression (1.6-fold), in Alb-Cre^+miR92$a^{fl/fl}$ mice compared to respective wt mice. Consistent with this, Sirius Red staining revealed decreased collagen accumulation and αSMA immunostaining depicts diminished hepatic stellate cell activation, reflecting attenuated fibrosis. Additionally, measurements of mitochondrial dysfunction indicated lessened chemokine release and diminished inflammation (TNFα, IL-6, IL-1β, NRF2). Lower serum parameters AST (5.7-fold) and ALT (3.1-fold) indicate diminished necroinflammation and reduced hepatocellular injury compared to wt controls. In addition, decreased portal pressure confirms attenuated cirrhosis resulting from reduced stellate cell activity.
Conclusion: Inhibiting miR-92a constitutes a promising therapeutic avenue in the treatment of MASLD. (Dimmeler, Trebicka (2025). Pharmaceutical composition comprising MIR-92 antagonist for treating liver disease. (25195510.0).

SAT-094-YI
Semaglutide prevents cognitive dysfunction in experimental metabolic dysfunction-associated steatohepatitis through anti-inflammatory and neuroprotective effects
Kristoffer Kjærgaard Amby[1], Anne Catrine Mikkelsen[1], Cecilie Bay-Richter[2], Anne M Landau[2,3], Peter Lykke Eriksen[1], Betina Elfving[2], Majken Thomsen[2,3], Farzaneh Tamnanloo[4], Jeppe Remme Yeoman[1], Stephen Hamilton-Dutoit[5], Hendrik Vilstrup[1], Christopher F. Rose[4], Rajeshwar Prosad Mookerjee[6], Karen Louise Thomsen[1]. *[1]Department of Hepatology and Gastroenterology, Aarhus University Hospital, Aarhus, Denmark; [2]Translational Neuropsychiatry Unit, Aarhus University, Aarhus, Denmark; [3]Department of Nuclear Medicine and PET, Aarhus University Hospital, Aarhus, Denmark; [4]Hepato-Neuro Lab, CRCHUM, Université de Montréal, Montreal, Canada; [5]Department of Pathology, Aarhus University Hospital, Aarhus, Denmark; [6]Institute for Liver and Digestive Health, University College London, London, United Kingdom*
Email: krikje@clin.au.dk

Background and aims: Cognitive dysfunction is an increasingly recognized and debilitating manifestation of metabolic dysfunction-associated steatohepatitis (MASH). The GLP-1 receptor agonist Semaglutide is a promising treatment for MASH, which also exhibits neuroprotective effects in neurodegenerative disease models. We investigated the short- and long-term effects of Semaglutide treatment on cognitive dysfunction and its possible underlying mechanisms in experimental MASH.
Method: MASH was induced using a 16-week high-fat, high-cholesterol (HFHC) diet. Sixty-four Sprague-Dawley rats were randomized into four groups: 1) standard diet, 2) HFHC diet, 3) HFHC diet with long-term Semaglutide treatment (10 weeks; 60 µg/kg/day), or 4) HFHC diet with short-term Semaglutide treatment (10 days; 30 µg/kg/day;). We assessed neurobehaviour, histological MASH severity, hepatic and systemic inflammation, blood ammonia and urea cycle enzyme expression, as well as brain synaptic density and microglia activation by autoradiography.
Results: HFHC animals exhibited impaired memory in the Fear Conditioning Test (Cued test; $p = 0.01$) and depression-like behaviour during the Forced Swim Test (Immobility; $p = 0.03$), both prevented by long-term Semaglutide treatment. Long-term Semaglutide reduced liver fat content ($p = 0.03$) and systemic inflammation (CCL2, CCL3, CXCL1; $p < 0.05$), whilst histological MASH remained unchanged. Moreover, Semaglutide treatment restored urea cycle enzyme expression (CPS1; $p = 0.03$) and reduced the hyperammonaemia ($p = 0.04$) observed in HFHC animals. In the prefrontal cortex, HFHC animals showed diminished synaptic density which was ameliorated by Semaglutide ($p = 0.01$), whilst no difference in microglia activation was observed.
Conclusion: Treatment with Semaglutide for 10 weeks effectively prevented memory impairment and depression-like behaviour in experimental MASH, whereas 10 days of treatment had no effect. These improvements are suggested to be attributed to the attenuation of systemic inflammation and protection against loss of synaptic density, and not resolution of MASH. Moreover, Semaglutide ameliorated hyperammonaemia which may also contribute to cognitive dysfunction in MASH. Our findings hold potential implications for the therapeutic management of MASH-associated cognitive dysfunction and warrant further confirmation in Man.

SAT-095-YI
Dysregulation of the E2F2-PCSK9 axis promotes MASLD progression and related cardiovascular disease

Background and aims: Metabolic dysfunction-associated steatotic liver disease (MASLD) is a risk factor for cardiovascular disease (CVD). E2F2 deficiency protects against MASLD progression. Upregulation of PCSK9 promotes dyslipidemia, but its role in hepatosteatosis or MASLD progression remains unclear. We aimed to investigate: 1) whether E2F2 contributes to dyslipidemia in MASLD and if this effect is mediated through PCSK9 and 2) the role of PCSK9 in MASLD progression.
Method: MASLD and MASLD-related hepatocellular carcinoma (HCC) were induced in WT and *E2f2*$^{-/-}$ mice by feeding a high-fat diet (HFD), combined or not with the *Sleeping Beauty* (Myc;*sg-Pten* plasmids) technique to promote HCC. *Pcsk9* was overexpressed *in vivo* specifically in hepatocytes of *E2f2*$^{-/-}$, WT and ApoE*3-Leiden.CETP mice (resembles human atherosclerosis) by *AAV8*. *E2f2* was also overexpressed in WT mice hepatocytes. Hepatic and serum lipidomic profiles, apolipoprotein content, and lipoprotein subfractions (ACTA-FPLC) were analyzed. *In vivo* triglyceride (TG) secretion and TG-rich lipoprotein uptake were assessed.
Results: MASH patients with high hepatic E2F2 protein levels showed an elevated atherogenic index, in concordance, *in vivo* overexpression of hepatocyte *E2f2*, increased serum PCSK9 and cholesterol in WT mice, while *E2f2* deficiency reduced them. *In vivo* hepatocyte *Pcsk9* overexpression altered serum lipidome, increasing cholesterol and number of circulating VLDL/LDL particles, as ApoB levels showed promoting hepatosteatosis, with ApoE levels elevated in both serum and liver, suggesting that increased hepatic uptake of ApoE-containing lipoproteins may contribute to hepatosteatosis. This phenotype worsened in preclinical models of MASLD, with increased VLDL secretion, more pronounced dyslipidemia and marked increase in TG species. *Pcsk9* overexpression in ApoE*3-Leiden.CETP mice that exhibit dysfunctional ApoE showed decreased hepatic (V)LDL uptake with none hepatosteatosis and a marked dyslipidemic serum profile that increased atheroma plaque formation and severity. *Pcsk9* overexpression in *E2f2*-deficient mice fed a HFD prevented the protection against hepatosteatosis, dyslipidemia and HCC. Consistently, in TGGA-LIHC cohort *E2F2* and *PCSK9* were upregulated and positively correlated.
Conclusion: E2F2 upregulation in hepatocytes promotes MASLD progression and related CVD, at least in part, via regulation of PCSK9. Targeting E2F2 could be valuable to prevent MASLD progression and associated CVD.

SAT-099-YI

Transcriptomic analysis of paired biopsies of liver and adipose tissue before and after bariatric surgery reveals distinct signaling pathways associated with persistence of MASLD despite significant weight loss

Anouar Aznou[1], Daniël Baars[1], Mijra Koning[1], Mare Bruin[1], Sjoerd Bruin[2], Arnold van de Laar[2], Joanne Verheij[1], Michail Doukas[3], Joost PH Drenth[1], Abraham Stijn Meijnikman[1], Max Nieuwdorp[1].

Email: a.aznou@amsterdamumc.nl

Background and aims: The persistence of metabolic dysfunction-associated steatotic liver disease (MASLD) and steatohepatitis (MASH) after substantial weight loss remains poorly understood. We analyzed liver and visceral adipose tissue (VAT) transcriptomics data of patients with and without MASLD both at baseline and one year after bariatric surgery to identify key pathways linked to disease resolution and persistence.
Method: We included patients from the prospective BARIA cohort who underwent bariatric (Roux-en-Y gastric bypass; RYGB) and subsequent repeat surgery (mostly for gallstone disease) in the year thereafter. We collected liver and VAT biopsies and scored liver biopsies histologically using the SAF score. All tissues underwent bulk RNA-seq, with differential gene expression analyzed longitudinally and between MASLD responders and non-responders, followed by functional annotation and pathway enrichment. Differentially expressed genes (DEGs) and pathways between responders and non-responders were further examined in an independent cohort of 288 patients with and without MASLD.
Results: Paired biopsies were available for liver (n = 33) and VAT (n = 20). RGYB was associated with broad transcriptional changes across tissues (after a range 8–15 months) with 6383 (liver) and 11829 DEGs (VAT). At the time of resurgery, MASLD persisted in 7 out of 15 patients who met diagnostic criteria at baseline. Longitudinal analysis of paired liver biopsies revealed 2122 DEGs in non-responders and 614 in responders, with enriched mitochondrial respiration pathways in the latter. In contrast, paired VAT biopsies in responders showed a greater number of DEGs compared to non-responders (3292 versus 829), with relative suppression of immune-associated pathways. Comparison of the liver transcriptome at resurgery between MASLD non-responders and responders revealed 29 DEGs and multiple enriched signaling pathways in non-responders, including PI3K–Akt, Wnt and Hippo signaling. In 288 bariatric patients across the MASLD spectrum (no steatosis, n = 109; MASLD, n = 139; MASH, n = 40), validation of these genes and pathways showed the strongest upregulation in MASH.
Conclusion: While RYGB is associated with extensive transcriptional remodeling of liver and adipose tissue in the year after surgery, MASLD persists in a subset of patients. Patients without MASLD resolution retain a liver transcriptomic signature enriched for core cellular signaling pathways shared with MASLD patients who did not undergo surgery.

SAT-100

Enhancing effects of combining resmetirom and semaglutide in a modified AMLN diet-induced mouse model for metabolic dysfunction-associated steatohepatitis (MASH)

Tai-Yu Huang[1], Chien-Chang Shen[1], Jessica Ramadhin[2], Jian-Xin (Jimmy) Bao[1,3]. [1]*Pharmacology Discovery Services Taiwan, Ltd., New Taipei City, Taiwan;* [2]*Taconic Biosciences, Rensselaer, United States;* [3]*Eurofins Discovery Services North America, LLC, St. Charles, United States*
Email: jimmy.bao@discovery.eurofinsus.com

Background and aims: Both a thyroid hormone receptor (THR)-beta agonist, resmetirom and a glucagon-like peptide-1 (GLP-1) receptor agonist, semaglutide were recently approved for treating noncirrhotic metabolic dysfunction-associated steatohepatitis (MASH) with moderate to advanced liver fibrosis. However, not all patients respond to resmetirom with MASH resolution. We therefore evaluated, before the indication expansion of semaglutide, whether semaglutide in combination with resmetirom would improve the effects of resmetirom using a modified AMLN diet induced mouse MASH model.
Method: Male C57BL/6NTac mice from Taconic Biosciences were fed a modified AMLN diet for 28 weeks and then treated for 8 weeks with either resmetirom alone at 3 and 10 mg/kg given orally every day,

semaglutide alone at 30 nmol/kg given subcutaneously every 3 days, or semaglutide in combination with 3 mg/kg resmetirom. Biochemical parameters, glucose and insulin levels were measured at week 0, week 4 and week 8. At termination, liver total cholesterol was quantified, and liver histopathological analyses were performed using hematoxylin and eosin, picrosirius red, and Oil Red O staining.
Results: Modified AMLN diet feeding induced body weight gain, increased adiposity, and the metabolic, biochemical and histopathological changes characteristic of MASH, including liver injury, steatosis, inflammation and fibrosis. Resmetirom treatment dose-dependently reduced serum and liver total cholesterol (TC), total triglycerides (TG) and low-density lipoprotein as well as liver weight and liver fat accumulation, decreased liver steatosis, inflammation and ballooning in histopathological assessment, and also effectively prevented liver injury. Semaglutide mainly decreased initial food intake (week 4), reduced body and liver weight, lowered serum TC and TG, reduced fat mass and tended to ease liver fat burden. Neither resmetirom nor semaglutide appeared to affect the liver fibrosis levels. Interestingly, semaglutide in combination of lower dose of resmetirom improved it's effects and their effects were potentially synergistic; additional studies and analyses are needed to confirm this.
Conclusion: Combined treatment with semaglutide and resmetirom produced enhancing effects when compared to either treatment alone. These data warrant further investigation into combination therapies of THR-beta agonists and GLP-1 receptor agonists for the potential treatment of MASH or other metabolic disorders.

Email: mlmartinez@cicbiogune.es

Background and aims: There is a body of evidence linking hypomagnesemia to the onset of insulin resistance (IR) and type 2 diabetes (T2D). In this work, we aim to elucidate the mechanism by which the metal transporter cyclin M1 (CNNM1) is involved in glycemic control, making it a potential therapeutic target against IR.
Method: Hepatic expression of *CNNM1* was analyzed in patients with T2D and in preclinical models of nutritional distress. IR was assessed in an acute 60% high-fat diet model and the genetic *db*/*db* mouse model of T2D. A counter-regulatory model was established by intraperitoneal administration of glucagon, with mice being sacrificed 10 minutes post-injection. In all preclinical models, *Cnnm1* expression was silenced by tail vein injection of an adeno-associated virus (AAV), and outcomes were evaluated from the third week after AAV administration. *Fibroblast growth factor 21* (*Fgf21*) gene was simultaneously silenced by intravenous delivery of a siRNA via tail vein, and mice were sacrificed after an overnight fast.
Results: Among all the mammalian magnesium transporters, only *Cnnm1* was found to be downregulated in both T2D patients and preclinical models of IR. When *Cnnm1* was further silenced, we were able to increase insulin sensitivity in mice, while *Cnnm1* overexpression led to no metabolic changes. Insulin resistant mice administered AAV-si*Cnnm1* showed decreased liver triglyceride (TG) accumulation, together with increased serum ketone bodies. Interestingly, *Cnnm1* silencing in these mice drove to heightened FGF21 concentration in serum. Concomitant silencing of *Cnnm1* and *Fgf21* in acute insulin resistant mice reverted the effects of *Cnnm1* downregulation, no longer improving insulin sensitivity and restoring TG accumulation in liver and serum to control levels. In the glucagon model, the beneficial effect of *Cnnm1* silencing was associated with increased hepatic activity of the gluconeogenic enzyme phosphoenolpyruvate carboxykinase (PEPCK).
Conclusion: Overall, our results suggest that the magnesium transporter CNNM1 plays a key role in the response to nutritional distress, potentially acting as a metabolic sensor of glucose availability. Silencing of *Cnnm1* may represent a novel therapeutic strategy for T2D, improving systemic insulin sensitivity through enhanced FGF21 signaling.

SAT-102-YI

Prime editing models the MTARC1 A165T variant in human liver organoids, demonstrating reduced steatosis, inflammation, and fibrosis

Amel Ben Saad[1], Arden Weilheimer[1], Alan Mullen[1]. *[1]University of Massachusetts Chan Medical School, Worcester, United States*
Email: bensaadamale@gmail.com

Background and aims: Metabolic dysfunction-associated steatotic liver disease (MASLD) is the most prevalent cause of chronic liver disease. MASLD is a progressive and multifactorial disease marked initially by hepatic steatosis, which can progress to steatohepatitis, fibrosis, cirrhosis, and liver cancer. Genetic factors influence the development, progression, and complications in MASLD, and genome-wide association studies (GWAS) have identified single nucleotide polymorphisms (SNPs) associated with altered risk. Mitochondrial amidoxime reducing component 1 (*MTARC1*) *rs2642438* (p.A165T) variant has been identified as protective, but the role of *MTARC1* and the impact of this variant in hepatocytes remains poorly understood.
Method: Here, we applied prime editing to create the *rs2642438* variant in human pluripotent stem cells (hPSCs) before differentiation into human liver organoids (HLOs) to investigate the effect of the variant under conditions of steatotic and fibrotic injury.
Results: Compared to HLOs formed from hPSCs containing the *MTARC1* reference sequence, HLOs with the *rs2642438* variant show lower levels of MTARC1 protein and triglycerides and are protected from steatotic and fibrotic injury, as predicted by the phenotype observed in patients carrying the variant. The observed decrease in triglyceride level with the variant appears to be driven more by suppression of de novo lipogenesis rather than stimulation in ß-oxidation in the HLO model. While resmetirom, the thyroid hormone receptor-beta (THRB) agonist approved to treat patients with metabolic dysfunction-associated steatohepatitis (MASH) was effective in reducing triglyceride levels in the setting of steatotic injury in HLOs with the reference sequence, HLOs containing the variant did

not show further reduction in triglyceride levels with exposure to resmetirom, despite increased expression of *THRB*.
Conclusion: Together, this study establishes an approach to model disease-related SNPs in HLOs and provides further insights into the activity of the *MTARC1* variant, and suggests that profiling SNPs may be a path to identify patients more likely to respond to therapies for MASLD.

SAT-103
Epigenetic programming of metabolic liver disease by early-life nutritional overload
Claudia Bigas[1], Josefina Martin[1], Blanca Majem[1], Salvador Aznar-Benitah[1,2]. [1]*IRB Barcelona, Aging and Metabolism Programme, Barcelona, Spain;* [2]*ICREA Research Professor, Barcelona, Spain*
Email: claudia.bigas@irbbarcelona.org

Background and aims: Metabolic dysfunction-associated fatty liver disease (MASLD) is a growing global health issue, even among pediatric populations. Emerging evidence suggests that early-life exposures, including maternal nutrition, can program long-term susceptibility to metabolic diseases. This study aims to investigate the developmental origins of MASLD by examining how maternal intake of a palmitic acid-enriched high-fat, high-sugar diet (PA-HFD) influences the offspring's liver metabolism through epigenetic mechanisms.
Method: A mouse model was used in which dams were fed a PA-HFD during pregnancy and lactation. Liver tissue from offspring was analyzed for histone modifications, transcriptomic and proteomic changes, and metabolic phenotype. Adult offspring were re-exposed to a high-fat diet to assess the functional impact of early-life epigenetic priming. Findings were further validated using human-derived liver organoids in vitro.
Results: Maternal PA-HFD consumption induced stable epigenetic changes in the offspring's liver, particularly H3K4me3 deposition, leading to persistent transcriptional reprogramming of genes involved in fatty acid β-oxidation. This resulted in a fasting-like hepatic phenotype. Upon re-challenge with a HFD in adulthood, these epigenetically primed offspring developed exacerbated liver pathology, including steatosis, mitochondrial dysfunction, oxidative stress, toxic lipid accumulation, and impaired glucose tolerance. Validation in human liver organoids confirmed the relevance of these findings to human health.
Conclusion: Our findings demonstrate that maternal consumption of a palmitic acid-enriched diet during critical windows of development induces stable epigenetic modifications in the offspring's liver, which persist into adulthood and predispose to worsened metabolic outcomes upon dietary challenge. These insights highlight the importance of maternal nutrition as a modifiable factor in preventing chronic liver disease and suggest potential epigenetic targets for early intervention strategies.

SAT-104
Global analysis of protein post-translational modifications reveals novel regulatory mechanisms in steatotic liver disease
Virginia Aranda García[1], Eduardo Moltó Pérez[1], Cristina Pintado[1], Ruy Andrade Louzada[2], Ernesto Bernal-Mizrachi[2], Antonio Andrés Hueva[3], Nilda Gallardo Alpízar[3], Elena Bonzon-Kulichenko[1]. [1]*Biochemistry Section, Castilla-La Mancha Health Research Institute (IDISCAM), Faculty of Environmental Sciences and Biochemistry, University of Castilla-La Mancha, Toledo, Spain;* [2]*Department of Internal Medicine, Division of Endocrinology, Diabetes and Metabolism, Miller School of Medicine, University of Miami, Miami, United States;* [3]*Biochemistry Section, Castilla-La Mancha Health Research Institute (IDISCAM), Faculty of Chemical Sciences and Technologies, University of Castilla-La Mancha, Ciudad Real, Spain*
Email: Elena.Bonzon@uclm.es

Background and aims: Metabolic dysfunction-associated steatotic liver disease (MASLD), a chronic inflammatory condition, is associated with obesity and high-fat diets (HFDs). Its molecular mechanisms remain unclear, including the role of protein post-translational modifications (PTMs). While PTMs have traditionally been investigated using targeted, closed-search mass spectrometry methods, open-search mass spectrometry (OS-PTM) offers a novel, unbiased approach to comprehensively analyse PTMs, proteins, and associated pathways.
Method: Public raw MS data of HFD-induced MASLD development over time in mice total liver lysate and phosphoproteome was reanalyzed by OS-PTM. Mice were fed HFD for 3 (HFD3, n = 3, insulin resistance) or 12 (HFD12, n = 3, MASLD) weeks. The control group (n = 3) was fed a low-fat diet. An advanced quantitative approach was used to capture coordinated PTM alterations.
Results: We detected the same MASLD linked pathways observed by the original authors such as an increase in peroxisome, mitochondria and fatty acid beta oxidation, since early stages, and an increase in amino acid metabolism, especially BCAA in later stages, which validates our approach. However, by considering all the modified protein forms, new changing pathways were detected in early stages: a decrease in the glutathione homeostatic action; increase in Cytochrome P450; in the steroid hormone biosynthesis; alterations in extracellular matrix and in the lipid binding machinery. At later stages the ATP-synthase complex, steroid biosynthesis and the ATF6 responsive genes from unfolded protein response were upregulated. In addition, there were early PTM responses enriched in clusters of functionally related proteins, not detected by the original authors. Ser/Thr pyrophosphorylation of proteins from organelle organization and translation was drastically decreased. Protein N-terminal processing of ribosomal and DNA-binding protein complexes, and the labile protein-bound iron and Met dioxidation of mitochondrial oxidoreductases were decreased as well. Cys trioxidation of mitochondrial cytotoxic-responsive enzymes active-sites was up-regulated, together with mannose N-glycosylation of endoplasmic reticulum carboxylic ester hydrolases.
Conclusion: OS-PTM technology allows a reliable detection of new PTM-mediated alterations underlying MASLD from early stages, which opens the way for innovative treatments.

SAT-105
The glucagon/glucagon-like peptide-1 receptor dual agonist survodutide reduces liver fibrosis in a 4-week carbon tetra chloride lean mouse model
Francois Briand[1], Mohsin Hassan[2], Thomas Klein[2]. [1]*Physiogenex, Escalquens, France;* [2]*Boehringer Ingelheim, Biberach, Germany*
Email: f.briand@physiogenex.com

Background and aims: In a phase 2 clinical trial, the glucagon/GLP-1 receptor dual agonist survodutide has demonstrated significant improvement in metabolic dysfunction associated steatohepatitis with 64.5% of patients with F2/F3 fibrosis at baseline showing an improvement in fibrosis by at least one stage. Here we tested whether survodutide would demonstrate anti-fibrotic effects in a 4-week carbon tetrachloride (CCl_4) injected lean mouse model of liver fibrosis.
Method: Lean, 8-week-old, C57BL6/J male mice were injected intraperitoneally with CCl_4 twice a week for a total of 4 weeks to induce liver fibrosis. Treatment started after 2 weeks of CCl_4 injection. In a first study, mice were treated subcutaneously, once daily with vehicle, a long-acting gastric inhibitory peptide (LaGIP) analogue at 100 nmol/kg, semaglutide 7.5 nmol/kg, or survodutide 7.5 nmol/kg, during the remaining 2-week CCl_4 injection period. In a second study, mice were treated with vehicle and a higher dose of survodutide at 10 nmol/kg. In each study and at the end of the 2-week treatment period, blood and liver were collected for biochemistry and histology analysis.

Results: In the first study, both the LaGIP analogue and semaglutide showed no effect on liver parameters, including liver fibrosis, indicating that GIP and GLP-1 receptors agonism had no impact. In contrast, survodutide 7.5 nmol/kg demonstrated anti-fibrotic effects, as shown by a significant reduction in liver %Sirius Red labelling ($p < 0.05$ vs. vehicle) and a non-significant reduction in fibrosis score. In the second study, the higher dose of survodutide (10 nmol/kg s.c. QD) reduced plasma alanine amino transferase levels by 33%, although not significantly. Compared with vehicle, survodutide at 10 nmol/kg again demonstrated anti-fibrotic effects with significant reduction in both liver % alpha-smooth muscle actin and % Sirius Red staining. The antifibrotic activity was further confirmed by a significant reduction in the hepatic expression of pro-fibrotic genes *Acta2* (alpha-SMA), *Col1a1* and *Timp1* in mice treated with survodutide. Importantly, expression of cytochrome P450 2e1, the key enzyme metabolizing CCl_4 into reactive trichloromethyl radicals driving liver injury and fibrosis was not reduced by survodutide.
Conclusion: In a 4-week CCl_4 lean mouse model, survodutide demonstrated significant anti-fibrotic activity. These preclinical data highlight the potential benefits of the glucagon/GLP-1 receptor agonist survodutide for the treatment of MASH and liver fibrosis in humans.

SAT-106

Surfaceome mapping of human hepatocytes uncovers proteome dynamics in steatotic hepatocytes

María Fernández Delgado[1], Leire Leire Uraga Gracianteparaluceta[1], Maria Unceta Suárez[1,2], María Luz Martínez-Chantar[3], Javier de las Heras Montero[1,4,5], Teresa C Delgado[1,3,6]. *[1]IIS Biobizkaia, Baracaldo, Spain; [2]Biochemistry Laboratory, Metabolism Area, Cruces University Hospital, Baracaldo, Spain; [3]Liver Disease Lab, Center for Cooperative Research in Biosciences (CIC bioGUNE), Derio, Spain; [4]Division of Paediatric Metabolism, CIBERER, MetabERN, Cruces University Hospital, Baracaldo, Spain; [5]Department of Paediatrics, University of the Basque Country (UPV/EHU), Leioa, Spain; [6]IKERBASQUE, Basque Foundation for Science, Bilbao, Spain*
Email: teresadejesus.cardosodelgado@bio-bizkaia.eus

Background and aims: Membrane proteins play critical roles in sensing extracellular stimuli and initiating intracellular signaling. The surfaceome (the set of cell membrane proteins exposed to the extracellular environment) is highly dynamic and likely to change in response to variations in intracellular lipid content and cellular stress, key features of MASLD. Thus, our primary aim is to characterize the surfaceome signature of human steatotic hepatocytes.
Method: HepG2, a human hepatoblastoma-derived cell line, and THLE2, an immortalized human hepatocyte cell line, were used. Cells were treated with 300 nM oleic acid (OA) or palmitic acid (PA) to induce steatosis. After 24 hours, cell surface proteins were biotinylated in adherent cells using EZ-Link Sulfo-NHS-LC-LC-Biotin (Thermo Scientific) and then isolated by pull-down assay. Control conditions included cells treated with BSA and non-biotinylated extracts. Pull-down eluted proteins were digested with trypsin/LysC and identified/quantified by Tandem Liquid Chromatography Mass Spectrometry (LC-MS/MS) using a Vanquish Neo HPLC system and Orbitrap Exploris 480 mass spectrometer. Data-independent acquisition was employed, with raw data analyzed using DIA-NN (v.1.8.1), and subsequent analysis was performed using the R package Prostar (v.1.34.6) and Perseus (v.2.0.10.0).
Results: In HepG2 cells, OA-induced steatosis led to the downregulation of 211 cell surface-specific proteins, whereas incubation with PA decreased the expression of 92 cell surface proteins compared to controls. STRING analysis revealed that most of these proteins were associated with the plasma membrane GO category. Otherwise, OA stimulation led to the enrichment of 65 cell surface proteins, while PA upregulated 58 proteins. STRING analysis indicated that enriched proteins are typically localized in ribosomal subunits and mitochondria under normal conditions. In the THLE2 cell line, OA-induced steatosis downregulated 288 proteins, while PA treatment downregulated 298 proteins. STRING analysis confirmed these proteins were primarily associated with the plasma membrane GO category. In contrast, OA treatment enriched 65 proteins, and PA incubation increased 29 proteins, predominantly ribosomal.
Conclusion: Steatotic human hepatocytes exhibit loss of cell membrane proteins and an enrichment of ribosomal proteins suggesting an extra-ribosomal role for these proteins in steatotic hepatocytes. Identifying steatotic hepatocyte surface proteins may provide new therapeutic targets for MASLD.

SAT-107-YI

Protease driven phenotypical changes in lipid associated macrophages attenuates metabolic dysfunction associated steatohepatitis progression

Júlia Cacho-Pujol[1,2,3], Paloma Ruiz-Blazquez[1,2,3,4], Maria Fernandez-Fernandez[1,2,3,4], Alejandro del Castillo-Cruz[1,2,3], Lucía Calderón-Robles[1], Anna Moles[1,2,3,4]. *[1]Institute of Biomedical Research of Barcelona (IIBB-CSIC), Barcelona, Spain; [2]August Pi i Sunyer Biomedical Research Institute (IDIBAPS), Barcelona, Spain; [3]Universitat de Barcelona (UB), Barcelona, Spain; [4]Spanish Networked Biomedical Research Center for Liver and Digestive Diseases (CiberEHD), Madrid, Spain*
Email: julia.cp.lab@gmail.com

Background and aims: Metabolic dysfunction associated steatohepatitis or MASH is currently the most common cause of liver dysfunction worldwide. Since inflammation is a key biological driver of MASH, there is no doubt that macrophages are essential effectors of this process. However, its role remains controversial with contradictory functions being attributed to them. Recent reports have suggested proteases, such as cathepsins, are essential for macrophage phenotypical shift during liver fibrosis however, its role in macrophages during MASH is currently unknown. Thus, this study aimed to investigate the role of macrophage associated cathepsin D (CtsD) during MASH.
Method: Regular diet (RD) or Western Diet-high sugar solution (WD) + CCl_4 was administered to $CtsD^{F/F}$ or CtsD-myeloid cell KO ($CtsD^{\Delta Myel}$) mice for 6-months to induce MASH. Liver damage (ALT), fibrosis (SR and HP), proliferation (BrdU) and lipid accumulation (ORO) was evaluated at the endpoint. Lipid metabolism and macrophage phenotypic gene profile expression was assessed by RTqPCR in $CtsD^{F/F}$ or $CtsD^{\Delta Myel}$ 6-month WD+CCl_4 liver tissue and liver macrophages isolated from $CtsD^{F/F}$ or $CtsD^{\Delta Myel}$ treated with choline-deficient and high-fat diet (CDAHFD) for 1-month.
Results: CtsD deletion in macrophages significantly reduced lipid accumulation in MASH livers without changes in liver damage, fibrosis or proliferation. Analysis of liver macrophages isolated from 1-month CDAHFD fed $CtsD^{F/F}$ or $CtsD^{\Delta Myel}$ mice demonstrated a significant decrease in the expression of markers related with lipid associated macrophages (LAMs), such as Arg1, FOLR2, TREM2, CD204, LXRa in $CtsD^{\Delta Myel}$ liver macrophages. In agreement, a significant reduction in the expression of TREM2 was also observed in $CtsD^{\Delta Myel}$ WD+CCl_4 livers, while the level of the total number of macrophages (F4/80) remained similar. Finally, macrophage phenotypical changes were accompanied by alterations in the expression of genes related with the lipid metabolism (CD36, LXRa, NPC2) in $CtsD^{\Delta Myel}$ WD+CCl_4 livers, indicating that protease-driven phenotypical changes in lipid associated macrophages might contribute to the reduction in lipid accumulation observed in these mice.

Conclusion: CtsD deletion in macrophages modulates lipid associated macrophage phenotype contributing to a reduction in hepatic lipid accumulation and the attenuation of MASH progression.

SAT-108

Hepatocyte succinate dehydrogenase/complex II promotes metabolic dysfunction–associated steatotic liver disease progression and represents a therapeutic target

David Carneros[1], Lucio Figueredo-Matto[1], María Ángeles Rodríguez-Hernández[1], Matilde Bustos[1]. *[1]Area of Liver, Digestive and Inflammatory Diseases, Institute of Biomedicine of Seville (IBiS), Virgen del Rocio University Hospital (HUVR), Spanish National Research Council (CSIC), University of Seville (US), Seville, Spain*
Email: mbustos-ibis@us.es

Background and aims: Metabolic dysfunction-associated liver disease (MASLD) encompasses a spectrum of pathologies ranging from simple steatosis to steatohepatitis with fibrosis and inflammation. Steatosis is characterized by excessive hepatic lipid accumulation, which is closely associated with mitochondrial dysfunction and may promote disease progression. The tricarboxylic acid (TCA) cycle and oxidative phosphorylation are key mitochondrial metabolic pathways. Succinate dehydrogenase (SDH) plays a dual role in the TCA cycle and the electron transport chain. Previous work from our laboratory showed that MASLD is associated with reduced levels of the SDH subunit D (SDHD). The aim of this study was to analyze the impact of SDH levels on liver disease progression.
Method: Hepatocellular carcinoma (HCC) and control tissues (adjacent non-tumor or normal liver) from two independent patient cohorts were used for gene expression analyses. A hepatocyte-specific SDH knockout (LSDH) mouse model was generated using the Cre-LoxP system. In the first experimental approach, male C57BL/6J mice were fed a methionine–choline-deficient (MCD) diet or a control diet for 4 or 6 weeks. Two weeks after diet initiation, mice received intravenous injections of adeno-associated virus encoding SDHD (AAV_SDHD) or control virus (AAV_Renilla). In a second approach, wild-type ($SDHD^{+/+}$) and heterozygous ($SDHD^{\pm}$) mice were fed an MCD diet for 6 or 8 weeks.
Results: The MCD diet reduced hepatic SDH activity and increased serum succinate levels, accompanied by decreased hepatic expression of SDH subunits, inflammation, and fibrosis. AAV_SDHD therapy restored SDH enzymatic activity impaired by the MCD diet and reduced hepatic steatosis and inflammation. Moreover, $SDHD^{\pm}$ mice fed an MCD diet displayed significantly increased steatosis after 8 weeks.
Conclusion: These results implicate SDH as a key regulator in MASLD progression and identify this enzyme as a potential therapeutic target for the disease.

SAT-109

PNPLA3 p.I148M variant affects lipid droplets number and size in patient-derived liver organoids

Elia Casirati[1], Alessandro Cherubini[1], Laura Cerami[1], Fabrizia Carli[2], Amalia Gastaldelli[2], Daniele Prati[3], Daniele Dondossola[4], Luca Valenti[1,5]. *[1]Fondazione IRCCS Ca' Granda Ospedale Maggiore Policlinico; Transfusion Medicine and Hematology, Precision Medicine Lab, Milano, Italy; [2]National Research Council (CNR), Institute of Clinical Physiology (IFC), Pisa, Pisa, Italy; [3]Fondazione IRCCS Ca' Granda Ospedale Maggiore Policlinico; Transfusion Medicine and Hematology, Milano, Italy; [4]Fondazione IRCCS Ca' Granda Ospedale Maggiore Policlinico, Hbp Surgery and Liver Transplantation Unit, Milano, Italy; [5]Università Degli Studi di Milano; Department of Pathophysiology and Transplantation, Milano, Italy*
Email: elia.casirati@policlinico.mi.it

Background and aims: PNPLA3 rs738409 C > G p.I148M variant is the main genetic determinant of metabolic associated steatotic liver disease (MASLD). To this day, this association still lacks a molecular characterization, due to the lack of comprehensive human models. To overcome this gap in knowledge, we generated patient-derived human liver organoids (HLOs) and studied lipid accumulation across different PNPLA3 genotypes.
Method: After HLO exposure to 300 µM Palmitic and Oleic fatty acids, Lipid droplets (LDs) average size and number (normalized for nuclei) were quantified by NileRed staining and compared between *PNPLA3* HLOs (n = 3 for each genotype). Similarly, lipidomics and transcriptomics analysis were conducted to dissect PNPLA3-driven alterations in lipid composition and transcriptional response.
Results: After NileRed data fitting in GLMs, number of mutated PNPLA3 alleles linearly correlates with LDs total area (β Estimate = 139.68, SE = 18.00, $p < 0.0001$) and number (β Estimate = 23.55, SE = 4.71, $p < 0.0001$), while LDs average size was only increased in homozygous HLOs (β Estimate = 0.227, SE = 0.075, $p = 0.0047$). Lipidomics highlight a lipid milieux reminiscent of MASH in HLOs mutated for *PNPLA3*, with Long-chained Unsaturated Fatty acids, Ceramides and Sphingomyelins linearly correlating with the number of rs738409 alleles. In keeping, Bulk RNA-Seq indicated proneness to inflammation, fibrosis, uncontrolled proliferation and, importantly, compromised metabolic control. Furthermore, ScRNA-Seq allowed to pinpoint a subset of cells enriched in in homozygous HLOs: GO analysis showed increased Oxidative phosphorylation, ROS production, adipogenesis, and activation of cancer-related pathways. Finally, PNPLA3-driven steatosis in HLOs can be rescued by both PNPLA3 siRNA silencing and Resmetirom treatment.
Conclusion: Regardless of FA treatment, homozygous HLOs showed increased LDs size when compared to eterozygous and wild-type ones. Conversely, LDs number showed direct correlation with the number of mutated alleles, suggesting that the p.I148M substitution promotes the formation of new LDs, which was exacerbated by exposure to FAs. *PNPLA3*-dependent development of steatosis in HLOs is accompanied by changes in lipid composition and transcriptome painting a pro-inflammatory and pro-fibrotic picture, which can be reversed by *PNPLA3* silencing or Resmetirom administration.

SAT-110-YI

Exploring the complexity of MASLD: sex-dependent genetic effect on body composition

Annalisa Cespiati[1,2], Rosa Lombardi[1,2], Piero Tarantini[2,3], Felice Cinque[1,2], Marica Meroni[1], Daniel Smith[1,2], Erika Fatta[1], Edoardo Pulixi[1], Daniela Bignamini[1], Paola Dongiovanni[1], Anna Ludovica Fracanzani[1,2]. *[1]SC Medicina ad Indirizzo Metabolico, Fondazione IRCCS Cà Granda Ospedale Maggiore Policlinico, Milan, Italy; [2]Department of Pathophysiology and Transplantation, University of Milan, Milan, Italy; [3]SC Medicina Interna ad Indirizzo Cardiologico, ospedale di Busto Arsizio, ASST Valle Olona, Busto Arsizio, Italy*
Email: annalisa.cespiati@unimi.it

Background and aims: Genetic variants in PNPLA3, TM6SF2, MBOAT7, GCKR, and HSD17B13 influence liver-related outcomes in metabolic dysfunction-associated steatotic liver disease (MASLD), while alterations in muscle mass and adipose tissue contribute to metabolic dysfunction. However, the impact of MASLD-related genetic variants on body composition remains poorly defined. Aim: to evaluate the association between common MASLD-associated genetic variants and body composition parameters.
Method: We enrolled 505 MASLD patients (mean age 50 ± 12 years, 65% male) from the Metabolic Liver Disease outpatient clinic at Policlinico Hospital, Milan. Body composition was assessed by bioimpedance analysis. Skeletal and trunk muscle mass indices (SMI and TMMI), adipose and trunk adipose tissue indices (ATI and TATI, a marker of dysfunctional adiposity) were calculated as mass/height2 (kg/m2). Genotyping for PNPLA3, TM6SF2, MBOAT7, GCKR, and HSD17B13 was performed.
Results: Compared with CC, PNPLA3 GG showed lower SMI (9.5 vs 10.1 kg/m^2, $p = 0.01$) and TMMI (3.0 vs 3.4 kg/m^2, $p = 0.01$), with a trend toward higher ATI (10.5 vs 9.5 kg/m^2, $p = 0.08$). In sex-stratified analysis, women carrying the PNPLA3 GG showed higher

TATI (4.9 vs 4.0 kg/m^2, p = 0.02). MBOAT7 GG showed lower SMI (9.4 vs 10.1 kg/m^2, p = 0.01) and TMMI (3.0 vs 3.4 kg/m^2, p = 0.03) compared with CC, without differences in adipose tissue. No associations were observed for TM6SF2, GCKR, HSD17B13. At multivariate models adjusted for age, fibrosis stage, and metabolic comorbidities, PNPLA3 GG remained associated with lower SMI (b = –0.3 kg/m^2, 95%CI –0.5 to –0.1, p = 0.01) and TMMI (b = –0.2 kg/m2, 95%CI –0.3 to –0.02, p = 0.02). These associations were attenuated after adjustment for sex, consistent with sex-related effect modification. In women, PNPLA3 GG remained independently associated with higher TATI after multivariable adjustment (b = 0.4 kg/m^2, bstd 0.25, 95%CI 0.01 to 0.8, p = 0.04). The association between MBOAT7 GG and lower SMI became significant only after adjustment for sex (b = –0.2 kg/m^2, bstd –0.27, 95%CI –0.3 to –0.02, p = 0.02).
Conclusion: Among MASLD-associated variants, MBOAT7 is linked to reduced skeletal muscle mass, while PNPLA3 shows a sex-specific association with dysfunctional adiposity in women. Sex-dependent modulation of genetic effects on body composition reflects the sexually dimorphic nature of MASLD and support the role of genetic background in muscle-adipose tissue remodeling. Integrating genetic and body composition assessment may improve phenotypic risk stratification in MASLD.

SAT-111

Therapeutic targeting of fibrosis-associated microRNAs attenuates steatohepatitis-related liver fibrosis

Young Chang[1], Soung Won Jeong[1], Jae Young Jang[1]. [1]*Soonchunhyang University Seoul Hospital, Seoul, Korea, Rep. of South*
Email: chyoung86@gmail.com

Background and aims: MicroRNAs (miRNAs) have emerged as important biomarkers and potential therapeutic targets in liver fibrosis. This study aimed to identify fibrosis-associated miRNAs and to evaluate the antifibrotic efficacy and underlying mechanisms of miRNA antagonists in steatohepatitis-associated liver fibrosis.
Method: Patients with steatotic liver disease (n = 20) were selected from a biopsy-proven cohort. Blood miRNAs were profiled using next-generation sequencing (NGS) to identify miRNAs associated with fibrosis stage. In a steatohepatitis mouse model, animals were treated with specific miRNA antagonists for 12 weeks. Liver fibrosis was assessed by histologic staining and measurement of fibrosis-related markers. In vitro, hepatocytes and hepatic stellate cells were co-cultured under steatohepatitis conditions and treated with miRNA antagonists. To explore mechanisms, liver tissue NGS and single-cell RNA sequencing (scRNA-seq) were performed.
Results: NGS identified miR-660-5p and miR-125a-5p as significantly associated with liver fibrosis stage. In cell and animal models, antagonism of either miRNA reduced fibrosis markers at the mRNA and protein levels and attenuated histologic fibrosis. Liver tissue NGS demonstrated down-regulation of FGF9 and up-regulation of FGF21 in antagonist-treated groups, implicating growth factor–related pathways in the antifibrotic effects. These findings were validated in an independent treatment model, in which both single-antagonist and combination therapies reproduced antifibrotic effects, with combination therapy showing a more potent reduction in fibrosis severity and related markers. scRNA-seq analysis showed that while most hepatic cell types overlapped across treatment conditions, hepatocytes exhibited treatment-dependent transcriptional shifts, with the combination group forming a more distinctly separated subpopulation. Within hepatocytes, shared changes involved growth factor signaling and glycogen metabolism, whereas combination therapy showed broader modulation of lipid metabolism, inflammatory, and fibrosis-related pathways.
Conclusion: miR-660-5p and miR-125a-5p antagonists significantly attenuate liver fibrosis in steatohepatitis models. Their antifibrotic effects are associated with regulation of the FGF9–FGF21 axis and marked transcriptional reprogramming of hepatocytes.

SAT-115

Tenofovir disoproxil fumarate inhibits cholesterol absorption by downregulating the expression of duodenum NPC1L1 to reduce serum cholesterol

Jing Tang[1], Yan Han[1], Zhiwei Chen[1], Peng Hu[1]. [1]*Department of infectious diseases, The second affiliated hospital of Chongqing Medical University., Chongqing, China*
Email: hp_cq@163.com

Background and aims: Tenofovir disoproxil fumarate (TDF), as a first-line antiviral agent for the treatment of hepatitis B virus (HBV) or human immunodeficiency virus (HIV) infections, has shown non-antiviral effects in lipid metabolism. Previous clinical studies have observed that TDF usage can reduce the serum total cholesterol (TC) level in patients with HBV or HIV infections; however, the underlying mechanisms remain incompletely elucidated.
Method: C57BL/6 mice were treated with TDF at a dosage of 45.5 mg/kg/day for four months to mimic the long-term usage of TDF in humans. The lipid profile was examined in serum, liver, and intestinal tissues. RNA sequencing (RNA-Seq) analysis was conducted on the liver and duodenum tissues to investigate the mechanism.
Results: After four months of gavage with TDF, the serum TC levels in the TDF group were significantly lower than those in the control group. The food intake, water intake, or respiratory exchange ratio of mice is similar between the two groups, suggesting that TDF does not influence the basal metabolism of mice. Furthermore, TDF also reduced the TC content in liver tissue. However, RNA-Seq showed that TDF had no significant impact on the cholesterol metabolism-related pathways in the liver. RT-PCR also demonstrated that TDF had no effect on the expression of key genes related to cholesterol metabolism (e.g. HMGCR, SREBP1c, INSIG1, and PPAR alpha) in the liver. This indicates that TDF may not regulate serum TC levels through the regulation of liver cholesterol metabolism. Considering that intestinal absorption of cholesterol is another main source of serum TC, we next detected lipid changes in the intestine. Interestingly, we found that TDF significantly reduced the TC content in the duodenum, but not in the jejunum and ileum. Hematein Eosin staining revealed that the shape and quantity of intestinal villi were similar between the two groups, indicating that TDF does not directly damage the absorption barrier of intestinal cells. In terms of mechanism, we found that NPC1L1, a key gene regulating cholesterol absorption, was markedly down-regulated in the TDF group. In vitro studies demonstrated that overexpression of NPC1L1 could rescue the inhibition of cholesterol absorption by TDF.
Conclusion: Our study demonstrated that TDF can reduce serum cholesterol via duodenum NPC1L1 downregulation, indicating that TDF may be a better selection for patients with HBV or HIV infection concurrent with hypercholesteremia.

SAT-116

MicroRNA-146a in extracellular vesicles from obese adipocytes trigger hepatic inflammation

Qiuyang Chen[1], Taisiia Shevchenko[1], Anja Heymans[1], Tamara Vanhaecke[1], Robim M Rodrigues[1]. [1]*Department of In Vitro Toxicology and Dermato-Cosmetology (IVTD), Faculty of Medicine and Pharmacy, Vrije Universiteit Brussel (VUB), Brussels, Belgium, Beussels, Belgium*
Email: qiuyang.chen@vub.be

Background and aims: Patients are diagnosed with metabolic dysfunction-associated steatotic liver disease (MASLD) if they have hepatic steatosis in the presence of at least one cardiometabolic risk factor, such as obesity. The onset and progression of MASLD toward its more severe form, metabolic dysfunction–associated steatohepatitis (MASH), are clearly linked to obesity. However, the mechanisms underlying the crosstalk between adipose tissue (AT) and the liver are not fully elucidated. This project investigates how extracellular vesicles (EVs) released from adipocytes might play a role in the development of MASH.

Method: Based on an *in vitro* setup using human adipose stromal cells (hATSc)-derived adipocytes exposed to obesogenic factors (hATSc-Adipo^{obe}) or vehicle control, we obtained EVs specific to obese and lean conditions.
Results: EVs secreted from hATSc-Adipo^{obe} induced an inflammatory response in HepG2 cells, contrarily to EVs secreted from control hATSc-Adipo. Isolation of EV-RNAs followed by miRNA sequencing showed a significant enrichment of hsa-miR-146a-5p in the obese condition. Using target gene prediction and RT-qPCR, we further identified *PRKAA2*, a gene coding for a subunit of AMP-activated protein kinase that controls a variety of metabolic processes, as a target gene of hsa-miR-146a-5p. Transfection of hsa-miR-146a-5p mimics into HepG2 cells led to the downregulation of *PRKAA2* and an increase in cellular inflammatory response, marked by an upregulation in the expression of *IL1B*, *TNFA*, *CXCL5* and *CCL2*. Moreover, knock down of *PRKAA2* in HepG2 cells also resulted in an increased inflammatory response. To validate the obtained *in vitro* data, we isolated EVs from serum of patients diagnosed with different MASLD severities and found that hsa-miR-146a-5p was upregulated in the MASH group (n = 3) compared to simple steatosis group (n = 8). This was demonstrated by receiver operating characteristic (ROC) analysis that showed strong discriminatory performance with an area under the curve (AUC) of 0.917.
Conclusion: In summary, using an *in vitro* setup mimicking the AT-liver crosstalk during obesity, we identified EV-bound hsa-miR-146a-5p, as well as the downregulation of its target gene *PRKAA2*, as contributors to hepatic inflammation. Both hsa-miR-146a-5p and *PRKAA2* could therefore represent novel potential targets to treat obese MASH.

SAT-117-YI
Ultrastructural assessment of liver sinusoidal endothelial cell capillarisation in metabolic-dysfunction associated steatotic liver disease and its modulation by lanifibranor
Shivani Chotkoe[1], Guillaume Wettstein[2], Joris De Man[1], Sofie Thys[3], Isabel Pintelon[3], Yang Lu[1], Nateneal Beyene[1], Jean-Louis Junien[2], Denise van der Graaff[4], Benedicte De Winter[1], Winnok De Vos[3], Luisa Vonghia[4], Wilhelmus J Kwanten[4], Sven Francque[4]. *[1]University of Antwerp, Laboratory of Experimental Medicine and Paediatrics, Wilrijk, Belgium; [2]Inventiva Pharma, Daix, France; [3]University of Antwerp, Laboratory of Cell Biology and Histology, Antwerp Centre for Advanced Microscopy, Wilrijk, Belgium; [4]Unversity Hospital Antwerp, Edegem, Belgium*
Email: shivani.chotkoe@uantwerpen.be

Background and aims: In metabolic dysfunction-associated steatotic liver disease (MASLD), intrahepatic vascular resistance (IHVR) increases in early stages, driven by liver sinusoidal endothelial cell (LSEC) dysfunction and their loss of fenestrae (capillarisation). This phenomenon contributes to disease progression. The current study explored sinusoidal remodelling across the MASLD spectrum in human and rodent livers and assessed the effects of lanifibranor on LSEC fenestrae at histological and ultrastructural levels in a rat model.
Method: Human liver biopsy samples (n = 13) across the full MASLD spectrum were evaluated by transmission electron microscopy (TEM). Male Wistar Han rats (n = 6 per group) were fed a methionine-choline-deficient diet (MCDD) or standard chow diet (CD) for 4 weeks and received simultaneously placebo or lanifibranor (100 mg/kg/day) via oral gavage QD. Rat livers were evaluated by CD34 immunostaining, TEM, and scanning electron microscopy (SEM) with quantitative analysis of fenestrae. Evolution of capillarisation over time was also explored by CD34 in a second model using C57BL/6 mice (n = 6 per group) fed either CD or a high-fat high-fructose diet (HFHFD) at 24, 36 and 44 weeks.
Results: On biopsies, non-MASLD liver displayed normal fenestrated sinusoids. Early MASL (F1–2) retained fenestrae but developed basement membrane fragments and perisinusoidal fibrosis. Steatohepatitis (F2–3) showed LSEC thickening and loss of fenestrae, whereas complete capillarisation was observed in livers with cirrhosis. Placebo-treated MCDD-fed rats compared to CD-fed rats showed increased CD34 staining (38.8 ± 2.5 vs. 20.9 ± 2.8, $p < 0.001$), and ultrastructurally, increased fenestrae diameters, reduced fenestrae frequency (7.2 ± 0.4 vs. 10.8 ± 0.3, $p < 0.0001$) and decreased LSEC porosity (5.7 ± 0.4 vs. 7.5 ± 0.2, $p < 0.01$). In MCDD-steatosis, lanifibranor decreased CD34 staining (21.4 ± 5.7 vs. 38.8 ± 2.5, $p < 0.05$) and restored fenestrae frequency (9.3 ± 0.3 vs. 7.2 ± 0.4, $p < 0.01$) and LSEC porosity (7.2 ± 0.3 vs. 5.7 ± 0.4, $p < 0.01$) to levels comparable with controls. In HFHFD-fed mice, CD34 staining increased with diet duration, reaching significant elevations at 36 and 44 weeks.
Conclusion: Across species, LSEC capillarisation develops early in MASLD, albeit heterogeneously, and progresses with disease severity. Lanifibranor restores LSEC (ultra)structure in early MASLD, highlighting its therapeutic potential to restore vascular alterations and beneficially influence disease progression.

SAT-118
Activation of SIRT5 drives mitochondrial dysfunction, impaired hepatic differentiation and steatotic injury in human liver organoids
Maura Cimino[1], Rosaria Tinnirello[1], Riccardo Perriera[1], Giovanni Zito[1], Salvatore Gruttadauria[1], Massimo Pinzani[1], Federico Salomone[2], Vitale Miceli[1]. *[1]IRCCS ISMETT, Palermo, Italy; [2]Ospedale di Acireale, Acireale, Italy*
Email: vmiceli@ismett.edu

Background and aims: Metabolic dysfunction-associated steatotic liver disease (MASLD) is driven by alterations in mitochondrial function and lipid homeostasis. Sirtuin 5 (SIRT5), a mitochondrial lysine deacylase, has emerged as a potential regulator of hepatic bioenergetics and redox balance, yet its functional role in human liver tissue remains incompletely defined. Here, we investigated the impact of SIRT5 modulation on proliferation, differentiation, mitochondrial function, and lipid metabolism using human liver organoids (HliOs), aiming to define its contribution to MASLD-related mechanisms.
Method: HliOs were maintained under undifferentiated or hepatocyte differentiation conditions and treated with a selective SIRT5 activator or inhibitor at different concentrations. HliO viability were assessed by bright-field imaging and luminescence-based assays. Mitochondrial function was evaluated by measuring mitochondrial membrane potential, while mitochondrial oxidative stress was assessed by quantifying mitochondrial superoxide production. Hepatic differentiation was determined by the expression of key hepatocyte markers (ALB, CYP3A4, HNF4alpha). A lipid overload–based model of steatosis was established using free fatty acids, and lipid accumulation was quantified by Nile Red staining.
Results: Activation of SIRT5 significantly impaired HliO proliferation in a concentration-dependent manner and increased mitochondrial superoxide production, accompanied by mitochondrial membrane depolarization. During hepatic differentiation, SIRT5 activation markedly reduced the expression of key hepatocyte markers, indicating impaired hepatocellular maturation. In a steatosis model, SIRT5 activation exacerbated lipid droplet accumulation, mitochondrial oxidative stress, and loss of cell viability. Conversely, SIRT5 inhibition attenuated mitochondrial ROS generation, preserved mitochondrial membrane potential, reduced lipid accumulation, and partially rescued cell viability under steatotic conditions.
Conclusion: In conclusion, SIRT5 emerges as a critical regulator of mitochondrial homeostasis and metabolic resilience in HliOs.

Excessive SIRT5 activation promotes mitochondrial oxidative stress, impairs hepatic differentiation, and aggravates steatotic injury, whereas SIRT5 inhibition confers protection against lipotoxic stress. These findings support a pathogenic role for SIRT5 in MASLD progression and identify SIRT5 inhibition as a potential therapeutic strategy to mitigate mitochondrial dysfunction and disease severity.

SAT-119

NLT-101 targets the nuclear envelope and protects hepatocytes against lamin B1 alterations associated with lipotoxic metabolic stress

Stefan Hoenow[1], Thomas Ryan[2], Arundhati Dongre[2], Daniel Bakowski[2], Michael Cooreman[3,4], Christopher Shepard[3]. *[1]Apollo Health Ventures, Berlin, Germany; [2]Sygnature Discovery, Nottingham, United Kingdom; [3]Apollo Alpha, St Petersburg, United States; [4]Virginia Commonwealth University, Richmond, United States*
Email: michaelpcooreman@msn.com

Background and aims: Hepatic steatosis affects nuclear envelope (NE) integrity; NE filament lamin B1 is associated with lipotoxicity through regulation of lipid metabolism genes. Endogenous 17alpha estradiol (17aE2) improves insulin resistance and lipid metabolism without reproductive effects of 17beta E2 (17bE2), through preferential affinity to estrogen receptor alpha (ERa) over ER beta (ERb). NLT-101, a novel small-molecule selective ERa partial agonist (ShERPA) improves steatohepatitis and fibrosis in the GAN-diet induced obese murine MASH model. We investigated the effect of NLT-101 on lamin B1 and NE structure in a model of fatty acid (FA) lipotoxicity.
Method: Primary cultured hepatocytes (PHH) were incubated for up to 72 hours with 100–800 uM of palmitate, a saturated FA that induces cellular lipotoxicity, and 100–400 mM of oleate, an unsaturated FA that protects from lipotoxicity. Lamin B1, A and its splice variant C were measured by automated Western Blot (WB) and immune fluorescence (IF). The effect of FAs on lamin levels was further studied with ERa ligands 17aE2 (1–10 mM), 17bE2 (10 mM) and NLT-101 (10 mM) during incubation. Nuclear area (NA) was measured with DAPI staining at 12 hours of palmitate incubation. Results of duplicate experiments are expressed as mean values. Viable cells as percentage of BSA control were assessed with the CellTiter-Glo luminicent Cell Viability Assay.
Results: Palmitate reduced protein levels of lamin B1 on WB in a dose- and time-dependent manner to 50% after 48 hours of incubation at 400 mM; a more pronounced lamin B1 decrease to 25% was observed with IF after 12 hours at 800 mM palmitate. Oleate did not significantly alter lamin B1 levels. Both FAs had no effect on lamin A, but reduced its splice variant lamin C by 50% at 48 hours. Both 17aE2 and NLT-101 rescued palmitate-induced lamin B1 decrease to the same degree, while 17bE2 had no such effect. Rescue occurred after the decrease and was more pronounced at 12 than at 6 hours, suggestive of a transcriptional effect. Palmitate dose-dependently reduced NA, with partial rescue by 17aE2. Palmitate, but not oleate, significantly reduced cell viability after 48 hours, with higher rescue by 10 mM NLT-101 compared to 10 mM 17aE2.
Conclusion: 17aE2 and NLT-101 prevented palmitate induced reductions of lamin B1 and cell viability in PHH. These data warrant further exploration of NE integrity and lamin biology in the disease biology of MASLD/MASH and the therapeutic potential of selective ERa agonists.

SAT-120

Diet and sex dictate CD1d-mediated immune alterations in MASLD and HCC

Carlos Cuño-Gómiz[1], Anna Tutusaus[2], Flavia Savino[1], Patricia Rider[2], Diba Zare[1], María Reig[3], Albert Morales[2], Montserrat Marí[2]. *[1]IIBB-CSIC/IDIBAPS, Barcelona, Spain; [2]IIBB-CSIC/IDIBAPS, CIBEREHD, BCLC, Barcelona, Spain; [3]IDIBAPS, CIBEREHD, BCLC, Hospital Clinic, Barcelona University (UB), Barcelona, Spain*
Email: monmari@clinic.cat

Background and aims: Metabolic dysfunction-associated steatotic liver disease (MASLD) is becoming a major driver of hepatocellular carcinoma (HCC), particularly in men and postmenopausal women. Estrogens provide metabolic and immune protection, reducing liver cancer risk. The liver hosts abundant natural killer T (NKT) cells, implicated in both tumor suppression and promotion. CD1d-knockout (KO) mice, lacking NKT cells, are widely used to study these roles, yet CD1d also exerts NKT-independent functions in different immune cell types. How sex influences CD1d activity and NKT cells remains unclear. This work explores sex-specific consequences of CD1d loss in MASLD and related HCC.
Method: Male and female Balb/c and CD1d-KO mice were fed either a high-fat choline-deficient (HFCD) or Gubra Amylin NASH (GAN) diet, with or without diethylnitrosamine (DEN) to induce HCC. Control mice were fed a Chow diet. Serum alpha-fetoprotein (AFP) was monitored throughout the study, and liver leukocytes were analyzed by spectral flow cytometry at the endpoint. Serum transaminases (ALT and AST) were determined. Total liver RNA was isolated to evaluate gene expression by RT-qPCR.
Results: HFCD induced severe MASH with fibrosis, high ALT and AFP, and DEN+HFCD caused HCC in all groups except Balb/c females. CD1d-KO mice, especially males, displayed aggravated disease with greater tumor load and liver injury. In contrast, GAN diet produced steatosis without inflammation, and DEN+GAN led to HCC only in males. Remarkably, CD1d-KO males exhibited milder GAN-related pathology than Balb/c males. Male mice displayed higher infiltration of injury-promoting myeloid populations. Females showed stronger NK activity, whereas males had more FOXP3+ regulatory T cells. CD1d-KO mice demonstrated broad immune shifts beyond NKT loss, including depletion of RORγT+ (IL-17A) T cells and enrichment of TBET+ CD8+ (IFNγ) T cells, while Th2-derived IL-4 persisted. Total $CD4^+$ T cells were also reduced, associated to a loss of MHC II expression by Kupffer cells, confirming NKT-independent modulation.
Conclusion: Diet and genetic background critically shape MASLD progression and HCC risk, with pronounced sex differences. CD1d deficiency rewires hepatic immunity in a context-dependent manner, yielding protective or detrimental effects based on sex and diet. Notably, female mice exhibit compensatory immune mechanisms that mitigate CD1d loss.

The chronic environmental exposure to Bisphenol A influences trained immunity-related pathways and induces immunometabolic innate cells reprogramming, promoting the metabolic dysfunction associated steatotic liver disease (MASLD) progression

Marcello Dallio[1], Mario Romeo[1], Fiammetta Di Nardo[1], Alessia Silvestrin[1], Giusy Senese[1], Annachiara Coppola[1], Carmine Napolitano[1], Paolo Vaia[1], Simone Olivieri[1], Alessandro Federico[1]. *[1]Hepatogastroenterology Division, Department of Precision Medicine, University of Campania Luigi Vanvitelli; Piazza Miraglia 2, 80138, Naples (Italy), Naples, Italy*
Email: marcello.dallio@unicampania.it

Background and aims: Metabolic dysfunction-associated steatotic liver disease (MASLD) is a growing global health concern, often progressing to steatohepatitis (MASH) and advanced fibrosis (AF). Beyond insulin resistance, recent evidence implicates damage-associated molecular patterns (DAMPs) and gut-derived pathogen-associated molecular patterns (PAMPs), such as lipopolysaccharide (LPS), in driving MASLD progression via innate immune activation, inflammation, and reactive oxygen species (ROS) generation. The concept of trained immunity (TI)—a memory-like response in innate immune cells—has emerged as a key mechanism, involving metabolic reprogramming and heightened inflammatory output. Bisphenol A (BPA), a widespread endocrine disruptor, has been identified as a TI trigger capable of inducing immunometabolic remodeling in monocytes. This study investigates the role of chronic BPA exposure in MASLD progression through TI-mediated innate immune activation.
Method: Ten healthy controls and twenty MASLD patients (10 MASLD-SS, 10 MASLD-SH) undergoing liver biopsy were enrolled. At baseline (T0) and after a 3-month BPA-free diet (T1), BPA serum levels were quantified (LC-MS/MS), and cytokines (IL-1β, IL-6, TNF-α) were assessed (ELISA). Monocytes were isolated and subjected to a TI-BPA protocol (BPA priming, LPS rechallenge), followed by cytokine profiling and metabolic assessment (Seahorse XFb, ROS assay).
Results: At T0, BPA levels progressively increased from controls to MASLD-SS and MASLD-SH, with significantly elevated cytokines in MASLD-SH vs MASLD-SS (all $p < 0.0001$). TI-BPA-stimulated MASLD-SH monocytes produced higher IL-1β, IL-6, and TNF-α than other groups (all $p < 0.001$). Seahorse analysis revealed increased glycolysis and reduced mitochondrial respiration in MASLD-SH vs MASLD-SS (ECAR/OCR, all $p < 0.0001$). The BPA-free diet significantly reduced BPA levels (T1 vs T0, $p = 0.0002$), especially in MASLD-SH. At T1, "enhanced trained response" prevalence was higher in MASLD-SH vs MASLD-SS (82% vs 31%, $p < 0.0001$), with no metabolic differences between groups.
Conclusion: BPA promotes trained immunity and immunometabolic reprogramming in MASLD, exacerbating inflammation and disease progression. These findings underscore the impact of environmental exposures and support TI-targeted interventions in MASLD management.

SAT-122
Hepatic estrogen receptor alpha shapes sex differences in MASLD development and progression

Sara Della Torre[1], Arianna Dolce[1], Clara Meda[1]. [1]*Università degli Studi di Milano, Milano, Italy*
Email: sara.dellatorre@unimi.it

Background and aims: Metabolic dysfunction–associated steatotic liver disease (MASLD) encompasses a spectrum ranging from simple steatosis to steatohepatitis (MASH), fibrosis, cirrhosis and hepatocellular carcinoma. Despite its growing public health burden, effective therapeutic options remain limited, likely reflecting an incomplete understanding of the biological drivers underlying disease heterogeneity and progression. MASLD development is influenced by multiple factors, including obesity, genetic and epigenetic determinants, lifestyle, diet and hormonal status. Notably, compared with men and post-menopausal women, premenopausal women display a lower incidence of MASLD, suggesting a protective role of estrogens. However, despite the clear sexual dimorphism of MASLD, the contribution of hepatic estrogen signaling to sex-specific susceptibility and disease progression remains poorly explored. In the liver, estrogens predominantly signal through estrogen receptor alpha (ERα), which is downregulated in MASH compared with MASLD patients, implicating hepatic ERα in limiting disease progression. We hypothesize that hepatic ERα acts as a sensor of hormonal and nutritional cues, driving sex-specific regulation of liver metabolism and inflammation and thereby influencing MASLD development and progression.
Method: To identify sex-specific molecular drivers of MASLD, we analyzed liver transcriptomic and metabolomic profiles together with inflammatory and fibrogenic markers in mouse models at early and advanced disease stages. The role of hepatic ERα was assessed by comparing liver-specific ERα knockout (LERKO) and control (CTRL) mice fed a high-fat, high-cholesterol (HFHC) diet.
Results: LERKO mice exhibited marked alterations in hepatic gene expression, indicating that hepatic ERα is required for optimal metabolic adaptation to dietary lipid overload. HFHC feeding induced profound transcriptomic remodeling, with the earliest and most pronounced changes observed in LERKO males after 12 weeks, consistent with increased susceptibility to metabolic and inflammatory dysregulation.
Conclusion: Hepatic ERα is a critical regulator of sex-specific metabolic adaptations during HFHC-induced MASLD. Impaired hepatic ERα signaling may increase vulnerability to disease development and progression. Targeting hepatic ERα pathways may represent a novel strategy to prevent or mitigate MASLD progression.

Multi-organ crosstalk via Exosomal TCA cycle enzymes underlies metabolic benefits of exercise and daytime time-restricted feeding in murine MASH resolution

Xi-Xuan Wang[1], Xiaoying Dong[1], Rui-Qi Li[1], Tianhao Mao[2], Jun Guo[3], Yang Wang[3], Zihao Liang[3], Cai-Yun Zhang[2], Hao Ren[1], Wei Chen[3], Changhua Yi[3], Qingfang Xiong[1], Dandan Yin[3], Shu-Ling Chen[3], Dawei Yang[3], Yongfeng Yang[1]. [1]*Department of Hepatology, The Second Hospital of Nanjing, Medical School, Southeast University, Nanjing, China;* [2]*Nanjing Key Laboratory of Hepatology, The Second Hospital of Nanjing, Nanjing, China;* [3]*The Second Hospital of Nanjing, Affiliated to Nanjing University of Chinese Medicine, Nanjing, China*
Email: yyf1997@163.com

Background and aims: Emerging evidence highlights the interplay between peripheral organs and hepatic metabolism in metabolic dysfunction-associated steatohepatitis (MASH), yet systemic mechanisms linking behavioral interventions to tissue repair remain unclear.
Method: We established a murine MASH model via 24-week GAN diet followed by 8-week normal chow realimentation, with four intervention groups: sedentary ad libitum (SED-AL), exercise (EX), daytime time-restricted feeding (TRF), and EX+TRF. Body weight, insulin resistance, pathological staining of different organs, ultrastructure under electron microscope of different organs, and multi-omics of different organs were detected.
Results: While both TRF and EX+TRF demonstrated superior weight loss, all active interventions ameliorated insulin resistance and hepatic steatosis. Strikingly, EX induced skeletal muscle damage and reduced adipocyte lipid droplet size, whereas TRF preferentially restored adipose morphology without myofiber injury. Ultrastructurally, EX uniquely rescued hepatic mitochondrial cristae disruption in MASH. Multi-omics integration revealed profound TCA cycle rewiring across liver, muscle, and adipose tissues, with phospho-/acetyl-/lactyl-proteomics implicating post-translational regulation of metabolic enzymes. Mechanistically, exercise triggered skeletal muscle secretion of citrate synthase (CS), IDH3, and OGDH via exosomes, which restored hepatic mitochondrial energetics and attenuated lipid peroxidation. Conversely, TRF stimulated adipose-derived exosomes enriched with phosphorylated/acylated TCA modifiers, synergistically enhancing hepatic metabolic flexibility.

Conclusion: Our findings establish a novel paradigm of inter-organ communication through exosomal enzyme traf ficking, positioning combined chrono-exercise therapy as a systems-level strategy for MASH resolution.

SAT-125-YI

The role of Pyroptosis in metabolic dysfunction-associated steatotic liver disease

Lauredana dos Santos Ferreira Grani[1], Ahmed Ghallab[2], Jan G. Hengstler[2], Petr Broz[3], Mihael Vucur[1], Vangelis Kondylis[1], Tom Luedde[1,4]. [1]*University Hospital Düsseldorf, Department of Gastroenterology Hepatology and Infectious Diseases, Medical Faculty at Heinrich-Heine-University Düsseldorf, Düsseldorf, Germany;* [2]*Leibniz Research Centre for Working Environment and Human Factors (IfADo), Technical University Dortmund, Dortmund, Germany, Dortmund, Germany;* [3]*Department of Immunobiology, University of Lausanne, Lausanne, Switzerland, Lausanne, Switzerland;* [4]*Center for Integrated Oncology Aachen Bonn Cologne Duesseldorf (CIO ABCD), Düsseldorf, Germany*
Email: lauredana.ferreira@med.uni-duesseldorf.de

Background and aims: Metabolic dysfunction-associated steatotic liver disease (MASLD) is the most common cause of chronic liver disease. Liver injury is linked to inflammation and fibrosis, promoting the development of cirrhosis and hepatocellular carcinoma (HCC). The mechanisms driving the transition between disease stages remain unclear, but previous studies have implicated pyroptosis, an inflammatory form of regulated necrosis, in promoting progression to advanced steatohepatitis. We aimed to clarify the role of pyroptosis in promoting inflammation, fibrosis and HCC development in two murine models of metabolic dysfunction-associated steatohepatitis (MASH) and metabolic dysfunction and alcohol-associated liver disease (MetAld).
Method: Gasdermin (GSDM) transgenic mouse lines, including *Gsdmd*$^{-/-}$, *Gsdme*$^{-/-}$, *Gsdmd*$^{-/-}$/*Gsdme*$^{-/-}$ and *Gsdmd*$^{D88A/D88A}$, were fed a western diet (WD, 40% fat, 22% fructose, 10% sucrose, 2% cholesterol) or WD supplemented with 10% ethanol (WD+EtOH) for either 24 weeks, to assess levels of liver injury, inflammation and fibrosis, or 60 weeks to analyze HCC development. A glucose tolerance test was performed 4 weeks prior to experimental endpoint. Liver functions were assessed in serum samples, while liver tissue samples were analyzed by immunoblotting, qRT-PCR and immunohistochemistry.
Results: Expression of genes linked to pyroptosis, such as *Casp-1, Casp-11* and *Il1b,* were upregulated in livers of mice after both diets. Immunoblot analysis also showed induction of GSDMD cleavage, but not GSDME, a marker of pyroptosis execution. Ongoing analyses in mice fed for 24 weeks with WD and WD+EtOH revealed similar body weight gain, liver-to-body weight ratios and glucose tolerance across all mouse lines and wild-type controls. Unlike *Gsdme*$^{-/-}$ and *Gsdmd*$^{-/-}$/*Gsdme*$^{-/-}$ mice that showed not effect, *Gsdmd*$^{-/-}$ mice exhibited significantly lower liver injury after 24 weeks of WD feeding, accompanied by reduced hepatic inflammation. Upon WD+EtOH feeding, this protective effect appeared less striking.
Notably, mice expressing GSDMD mutant, which confers resistance to GSDMD inactivation by apoptotic caspases, showed a trend for lower ALT and AST levels compared to controls in WD feeding, but displayed significantly elevated liver damage after WD+EtOH.
Conclusion: GSDMD-dependent pyroptosis can influence hepatocellular injury and hepatitis in a context-dependent manner. Ongoing analyses will further define its contribution in MASLD-to-HCC transition and its potential as a therapeutic target.

SAT-126

Unveiling the protein cargo of high-density lipoprotein particles in metabolic dysfunction-associated steatohepatitis: a biomarker study

Aleksandra Dudzik[1,2], Stan Driessen[3], Yuhan Du[4], Rachel Byrne[1,2], Koen van Son[3,5], Anne Linde Mak[3], Anne-Marieke van Dijk[3], Julia Witjes[3], Veera Houttu[3], Diona Zwirs[3], Han Levels[3], Michail Doukas[6], Max Nieuwdorp[3], Stephen Pennington[2], A.G. (Onno) Holleboom[3,7], Fiona McGillicuddy[1,2]. Email: aleksandra.dudzik@ucdconnect.ie

Background and aims: Metabolic dysfunction associated steatohepatitis (MASH) is a major driver of liver cirrhosis/failure worldwide, and it is strongly associated with cardiovascular disease. Non-invasive biomarkers to identify and stage steatohepatitis are currently lacking. High-density lipoprotein (HDL-) particles (P), which are predominantly liver-derived, represent an important conduit between the liver and the vasculature and carry a large cargo of proteins systemically. In the setting of obesity, HDL-P are enriched with hepatic-derived pro-inflammatory and depleted of anti-inflammatory proteins. HDL proteome can mirror changes in the liver proteome in preclinical studies. In the current study we hypothesized that the HDL proteome can be utilised as a novel non-invasive biomarker for MASH.
Method: HDL was separated from serum using fast protein liquid chromatography (FPLC) in a set of patients with histologically validated MASLD ($n = 24$) and MASH ($n = 28$) derived from the Amsterdam UMC ANCHOR study cohort. Small (S-) and large (L-) HDL-containing FPLC fractions were further purified with lipid removal agent and processed for proteomic analysis on timsTOF Pro mass spectrometer (Bruker).
Results: S-HDL-P were enriched with Vitronectin, Aldolase B, Beta-2-glycoprotein 1, Complement Factor B and depleted of Complement component C6, Serum amyloid P-component, Coagulation factor V in MASH relative to MASLD. Angiotensinogen, Kininogen-1 were enriched and Apolipoprotein B, Complement C4-B, were depleted on L-HDL-P in MASH relative to MASLD. On S-HDL-P, Sex hormone binding globulin significantly correlated with fibrosis ($r = 0.42$) but not NAFLD activity score (NAS) ($r = 0.01$); while Complement Factor I correlated with NAS ($r = 0.37$), but not fibrosis ($r = 0.21$); vitamin D binding protein correlated with both NAS ($r = 0.32$) and fibrosis ($r = 0.36$). On L-HDL-P, Alpha-1-antitrypsin, Serum amyloid A-1, Complement component C7 correlated with fibrosis ($r = 0.31$; $r = 0.29$; $r = 0.52$) but not NAS ($r = 0.12$; $r = 0.08$; $r = 0.25$). Inter-alpha-trypsin inhibitor heavy chain H1 and H3 correlated with NAS ($r = -0.29$; $r = -0.34$) but not fibrosis ($r = -0.12$, $r = -0.01$).
Conclusion: Our findings highlight specific changes in the proteomic composition of HDL-P in advanced MASLD, providing insights into underlying pathophysiology. The HDL proteome may serve as a novel non-invasive biomarker to identify high-risk patients with MASH. Larger-scale validation studies are critical to confirm the clinical utility of this approach.

SAT-127

Glucose-dependent insulinotropic polypeptide signaling in adipose tissue macrophages protects against obesity-induced metabolic dysfunction-associated steatotic liver disease by promoting adaptive adipogenesis

Irina Efimova[1,2,3], Shani Ben Shlomo-Zidovetzki[1], Anat Neumann[1,2], Noam Erez[1], Sigal Fishman[1,3], Chen Varol[1,2]. [1]*Research center for digestive tract and liver diseases, Tel-Aviv Sourasky medical center, Tel-Aviv, Israel;* [2]*Department of clinical microbiology and immunology, Gray faculty of health and medical science, Tel-Aviv university, Tel-Aviv, Israel;* [3]*Department of gastroenterology and liver diseases, Tel-Aviv Sourasky medical center, Tel-Aviv, Israel*
Email: efimovais@gmail.com

Background and aims: Glucose-dependent insulinotropic peptide (GIP) regulates glucose homeostasis and energy expenditure, thereby contributing to body weight maintenance. Dual glucagon-like peptide 1 (GLP1) and GIP receptor agonists, such as tirzepatide, have demonstrated significant clinical efficacy in the treatment of metabolic dysfunction-associated steatotic liver disease (MASLD). However, the cellular and molecular mechanisms mediating these beneficial effects remain incompletely defined. We previously demonstrated that immune cell intrinsic GIP signaling restrains obesity and metabolic dysfunction. The present study investigates whether GIP signaling in adipose tissue macrophages (ATMs) regulates white adipose tissue expansion and hepatic lipid accumulation during obesity.
Method: We generated Gipr tdTomato/+ reporter mice to enable fluorescent tracking of GIPR expressing cells. To assess GIP receptor (GIPR) function in immune cells, we employed a bone marrow (BM) chimerism approach: lethally irradiated wild-type (WT) recipients were reconstituted with BM from WT (control) or Gipr-/- donors. After 8 weeks of reconstitution, mice were maintained on high fat diet (HFD) for 5 weeks and analyzed for metabolic and immunophenotypic parameters.
Results: Immune cell specific GIPR deficiency impaired epididymal white adipose tissue lipid storage capacity, resulting in pronounced hepatic steatosis even after short term HFD exposure, as confirmed by increased hepatic triglyceride levels and enhanced lipid droplet biogenesis. Analysis of Gipr tdTomato reporter mice identified ATMs as a major GIPR expressing immune population. Next, mice targeted deletion of GIPR in immune cells exhibited increased adipocyte hypertrophy, reduced expression of adipocyte differentiation markers, and diminished abundance of committed adipocyte progenitors in white adipose tissue. Transcriptomic profiling of ATMs revealed markedly impaired expression of adipogenesis associated genes, including Apoe, Bmp2, and C5a receptor genes, all of which have been implicated in adipogenesis.
Conclusion: GIP signaling in ATMs promotes healthy white adipose tissue expansion during chronic energy excess by supporting adaptive adipogenesis. Disruption of this pathway impairs adipose tissue lipid storage capacity and promotes ectopic lipid deposition in the liver, thereby exacerbating MASLD pathogenesis.

Email: olgaeste@ucm.es

Background and aims: In the present study we investigated the role of gut-liver crosstalk for the hepatocellular carcinoma (HCC) development in steatotic liver disease (SLD) induced by the compound effect of alcohol and metabolic risk factors.
Method: C57Bl6Wt male mice were fed with DUAL diet that was composed of a high-fat, high cholesterol (HFHC) Western diet (WD) and 10% alcohol in sweetened drinking water for 52 weeks and compared to mice fed with standard control diet (CTRL). Liver and gut phenotypes were evaluated via histochemistry, gene expression and serum metabolomic analysis. FITC-dextran (20 kDa) was used to study intestinal permeability. The hepatic and fecal microbiota profile was evaluated by 16S rRNA gene sequencing.
Results: Within 52 weeks of DUAL diet, livers became extraordinary enlarged with visible tumor nodules on the liver surface. Moreover, animals developed significant increase of plasma AST, ALT, LDH and serum cholesterol. Liver histology revealed histological evidence of steatosis, associated with a significant increase in cell death (TUNEL) accompanied by increased immune cell infiltration (CD45, CD3, B220, F4/80, CD11b) and higher IL23 expression. Collagen accumulation (Sirius red, αSMA, Collagen I) and an increase in cell proliferation (Ki67) was also detected in the area of tumor nodules. At the intestinal level, DUAL mice showed a significant colon shortening. Hence, a significant increase in of FITC dextran in the serum confirmed intestinal barrier dysfunction. Corresponding increase in the expression of Tlr2, Tlr3, and Tlr4 in the liver was validated by qPCR analysis. Analysis of 16S in stool and liver samples showed clear dysbiosis, with a loss of beneficial bacteria (especially Muribaculaceae and Lachnospiraceae) and an increase in pro-inflammatory microorganisms (Bacteroides and Desulfovibrionaceae). The serum metabolomic profile showed extensive alterations in the levels of lipids, fatty (myristelaidic acid and polyunsaturated acids), amino and bile acids, revealing a significant impact of the DUAL diet on various metabolic pathways.
Conclusion: Our results highlight the close relationship between intestinal and hepatic dysbiosis, altered metabolites, and tumor progression from steatohepatitis to HCC in the MetALD DUAL preclinical model, which constitutes a physiologically relevant experimental tool for evaluating new therapeutic strategies.
CIBER EHD25PI02 MICRO-BOOST.

Genome-wide shRNA screen identifies Eif4ebp1 as a novel therapeutic target in metabolic dysfunction-associated steatotic liver disease (MASLD)

Ayat Fayez[1], Amanpreet Kaur[2], Shainan Hora[1], Rong Gao[3], Torsten Wuestefeld[1,3]. [1]*Genome Institute Of Singapore, Singapore, Singapore;* [2]*Amity University, Punjab, India;* [3]*Lee Kong Chian School Of Medicine Nanyang Technological University, Singapore, Singapore*
Email: ibrahimaf@a-star.edu.sg

Background and aims: Metabolic dysfunction-associated steatotic liver disease (MASLD) is a leading cause of chronic liver injury with limited therapeutic options. We performed a genome-wide shRNA screen to identify novel targets that modulate MASLD progression.
Method: A doxycycline-inducible shRNA library was delivered to C57BL/6 mice via hydrodynamic tail vein injection. Mice were fed a Western diet (WD) for 24 weeks, with doxycycline administered during the final 16 weeks to induce shRNA expression. Deep

sequencing identified enriched shRNAs conferring hepatoprotective effects. Candidates were validated *in vitro* and *in vivo* using hepatocyte-specific knockdown models in both chronic (WD) and acute liver injury settings.
Results: The screen identified Eif4ebp1, a translation repressor that blocks eIF4E-mediated cap-dependent translation, as a top candidate. Eif4ebp1 knockdown enhanced hepatocyte regenerative capacity *in vitro* and reduced fibrosis by up to two grades in WD-fed mice. In human MASLD transcriptomic datasets, EIF4EBP1 expression correlated positively with disease severity. Furthermore, EIF4EBP1 was upregulated in human hepatocytes treated with oleic and palmitic acids.
Conclusion: Eif4ebp1 plays a pathogenic role in MASLD progression, and its targeting represents a promising therapeutic strategy to attenuate fibrosis and enhance liver regeneration.

SAT-133

Reprogramming lipid-driven immunometabolic dysfunction in metabolic dysfunction-associated steatohepatitis through PLT012 targeting CD36

Janusz Von Renesse[1], Laura Fernandez-Rodriguez[1], Yi-Ru Yu[1], Mina Tsakovska[2,3], Jie Ting Low[2,3], Karina Lobo Hajdu[2,3], Zhen Meng[1], Yun-Han Lin[1], Ping-Chih Ho[2,3]. *[1]Pilatus Biosciences, Epalinges, Switzerland; [2]Department of Fundamental Oncology, University of Lausanne, Epalinges, Switzerland; [3]Ludwig Institute of Cancer Research Lausanne Branch, Epalinges, Switzerland*
Email: ping-chih.ho@unil.ch

Background and aims: Metabolic dysfunction-associated steatohepatitis (MASH) is driven by sustained hepatic lipid overload, which triggers lipotoxicity, inflammation, and fibrosis. Evidence shows that maladaptive lipid sensing and uptake across multiple hepatic cell types are key drivers of this pathogenesis. Crucially, CD36, a fatty acid transporter, is markedly upregulated in hepatocytes and in liver-resident immune and stromal cells in steatotic and MASH livers. CD36-driven lipid uptake promotes lipid accumulation, inflammation, and fibrosis, reshaping the hepatic microenvironment. Consequently, targeting CD36 with the humanized IgG4 antibody PLT012 offers a compelling therapeutic option.
Method: PLT012 was developed by phage display, affinity maturation, and developability optimization. Its efficacy was evaluated in complementary mouse MASH models, including the Western diet-induced and the choline-deficient, amino-acid-defined high-fat diet representing obese and non-obese disease. Disease hallmarks were assessed by histology, flow cytometry, gene expression, and biochemical analyses. PLT012 safety and pharmacokinetics were evaluated in cynomolgus monkeys.
Results: PLT012 showed cross-reactivity across murine, non-human primate (NHP), and human CD36. Cryo-electron microscopy–based structural analysis confirmed that PLT012 binds the CD36 lipid-binding domain, supporting a targeted action on lipid transport relevant to MASH. Across preclinical MASH models, PLT012 effectively reduced key disease hallmarks. The treatment lowered hepatic steatosis and adipose tissue mass, decreased the expression of crucial de novo lipogenesis genes (Acaca, Fasn, Mlxipl), and lowered serum levels of alanine aminotransferase and aspartate aminotransferase, suggesting reduced liver damage. It also diminished hepatic inflammation (TNF-alpha, IL-1beta, and Ccl2 expression) and reduced immune cell infiltration. Additionally, PLT012 remodeled the macrophage population, decreasing lipid-associated, inflammatory, and pro-fibrotic macrophages. Correspondingly, fibrosis was reduced, as evidenced by reduced collagen deposition in Picrosirius staining and lower expression of fibrotic genes (Col1a1, Col3a1). Beyond mouse studies, PLT012 exhibited excellent tolerability in NHP studies, with no adverse effects.
Conclusion: Taken together, these results show that blocking CD36 with PLT012 reshapes the hepatic microenvironment toward a more balanced, homeostatic state, highlighting its therapeutic potential across steatotic liver diseases.

Email: jifortea@gmail.com

Background and aims: Electron microscopy (EM) has provided key insights into hepatocellular alterations in MASLD, but most studies relied on percutaneous biopsies and primarily focused on selected features such as megamitochondria or autophagic vesicles. We aimed to evaluate the feasibility of ultrastructural analysis in transjugular biopsies and to provide a comprehensive description of hepatocellular changes in patients with MASLD.
Method: Patients with MASLD, well characterized by hepatic venous pressure gradient (HVPG) and stratified by fibrosis stage, portal hypertension, and MASH status, were prospectively enrolled. 18G transjugular liver biopsies were processed for EM. Hepatocellular alterations were systematically assessed, including mitochondrial, endoplasmic reticulum (ER), autophagic, cytoskeletal, and nuclear changes.
Results: Eighteen patients were included; 8 (44.4%) had advanced fibrosis (F3–F4), 12 (66.7%) fulfilled diagnostic criteria for MASH, and 7 (38.9%) had portal hypertension (HVPG ≥6 mmHg). Transjugular specimens consistently yielded tissue suitable for high-quality ultrastructural assessment. The most frequent alterations were mitochondrial swelling, ER cisterns dilation, and accumulation of autophagic vesicles, reflecting cellular stress responses linked to hepatocellular injury, inflammation, and fibrogenesis. Cytoskeletal adaptations, specifically reinforcement of the cortical actin cytoskeleton and hypertrophy of adherens junctions, were also observed. These changes were observed across the fibrosis, portal pressure, and MASH subgroups.
Conclusion: Transjugular liver biopsies are suitable for EM studies in MASLD. The observed hepatocellular alterations appear to reflect core cellular stress responses and were noted consistently throughout the cohort. These findings provide a framework for integrating ultrastructural data into mechanistic and translational research in MASLD.

A non-human primate liver organoid model recapitulates fibrotic and inflammatory features of metabolic dysfunction-associated steatotic liver disease

Bowen Gao[1], Li Wang[2], Wayel Jassem[3], Yun Ma[1]. [1]*King's College London, London, United Kingdom;* [2]*Suzhou Jiyan Biopharmaceutical Technology, Suzhou, China;* [3]*King's College London, King's College Hospital, London, United Kingdom*
Email: bowen.3.gao@kcl.ac.uk

Background and aims: The translation of findings from rodent Metabolic Dysfunction Associated Steatotic Liver Disease (MASLD) to human clinical contexts is often hindered by interspecies variability, while human-based research is frequently obstructed by ethical mandates and scarce tissue availability. Monkey-derived liver organoids (LOs) provide a genetic profile more analogous to humans than rodents. This study seeks to develop and validate a monkey organoid model to facilitate MASLD research.
Method: LOs derived from monkey liver tissue were exposed to 250 μM palmitic acid and oleic acid for 24 hours after 5 days differentiation. Lipid accumulation was evaluated by Oil Red O staining and total cholesterol (TC) quantification. LOs with or without exposure to free fatty acids (FFAs) were harvested for DIA based LC-MS/MS proteomics profiling. Statistical significance was defined as p.adjust < 0.05 (Benjamini-Hochberg FDR correction) for enrichment analysis and $p < 0.05$ for individual proteins.
Results: Oil Red O staining and TC detection confirmed lipid accumulation and secretion in the LOs ($p < 0.05$). Proteomic profiling identified 8643 proteins with 634 upregulated and 200 downregulated in the steatotic group. GO enrichment analysis revealed an upregulation of wound healing (enrichment ratio, ER = 5.55, p.adjust = 0.0013), suggesting liver damage induced by oxidative stress from lipid toxicity, and followed by an attempt at repair and regeneration. Pathways related to collagen trimer complex formation were upregulated (ER = 23.15, p.adjust = 0.0363), indicating a remodeling of extracellular matrix (ECM) and increased risk for fibrosis, which is consistent with significantly increased expression of fibrosis markers such as COL1A1 (fold change = 5.17, $p = 1.36 \times 10^{-27}$) and COL1A2 (fold change = 8.13, $p = 2.69 \times 10^{-44}$). Conversely, DNA replication initiation was downregulated (ER = 45.05, p.adjust = 0.0301), which represents a suppression in cell proliferation and DNA repair. Noteworthy, the upregulation of TGF-beta (fold change = 16.37, $p = 6.26 \times 10^{-167}$) indicates an activation of inflammation.
Conclusion: FFAs-treated monkey LOs showed significant features of cell damage, inflammation, metabolic disorders and ECM remodeling. These findings suggest that monkey LOs are a promising and reliable model for MASLD and have the potential to recapitulate liver fibrosis. This model will be used to evaluate anti-steatosis compounds for preclinical testing.

Oral administration of low molecular weight heparin polysaccharide alleviated metabolic dysfunction-associated steatotic liver disease by modulating the gut microbiota and metabolites in mice

Dekai Zheng[1], Xuelian Gao[1], Changhao Cheng[1], Xun Wang[1], Zhixin Fang[1], Ting Zhang[1], Kangsen Yang[1], Yuchuan Chen[1], Routing Wang[1], Zhixian Lan[1], Yanhua Tang[2], Jian Sun[1]. [1]*Department of Infectious Diseases, Nanfang Hospital, Southern Medical University, Guangzhou, China; State Key Laboratory of Multi-organ Injury Prevention and Treatment; Key Laboratory of Infectious Diseases Research in South China, Ministry of Education; Guangdong Provincial Key Laboratory for Prevention and Control of Major Liver Diseases; Guangdong Provincial Clinical Research Center for Viral Hepatitis; Guangdong Institute of Hepatology; Guangdong Provincial Research Center for Liver Fibrosis Engineering and Technology, Guangzhou, China;* [2]*Pulmonary and Critical Care Medicine, The First Affiliated Hospital, Hengyang Medical School, University of South China, Hengyang, China*
Email: sunjian@smu.edu.cn

Background and aims: Metabolic dysfunction-associated steatotic liver disease (MASLD) is the most prevalent chronic liver disease globally, yet therapeutic options remain limited. Oral low molecular weight heparin polysaccharide (LMWH) has demonstrated anti-inflammatory properties in colitis, but its potential efficacy in MASLD is unknown. We aimed to investigate the therapeutic effects of oral LMWH on MASLD and elucidate the underlying gut-liver axis mechanisms.
Method: We investigated the protective effects of oral LMWH in both high-fat diet (HFD) and high-fat high-cholesterol (HFHC) diet-induced mouse models through biochemical analyses (ALT, AST, TC, TG), histopathological evaluation (H&E, Oil Red O), and quantification of hepatic lipid accumulation (liver TC and TG levels). Antibiotic depletion and fecal microbiota transplantation (FMT) models assessed microbiota involvement. 16S rRNA sequencing integrated with metabolomics profiling were conducted to explore the underlying mechanisms. The ameliorating effect of 7-Ketolithocholic acid (7-K-LCA) was verified in vitro and in vivo. Activity-based protein profiling (ABPP) was used to identify the direct molecular targets of 7-K-LCA.
Results: Oral LMWH attenuated MASLD progression, reducing liver injury and hepatic steatosis in mice. Antibiotic depletion and FMT experiments confirmed the microbiota-dependent protective role of LMWH. Integrated 16S rRNA sequencing and metabolomics analyses revealed that LMWH selectively enriched *Akkermansia muciniphila* (*A. muciniphila*) and its derived metabolite, 7-K-LCA in vivo. Notably, LMWH promoted the growth of *A. muciniphila* in a dose-dependent manner in vitro. Supplementation with either *A. muciniphila* or 7-K-LCA replicated the beneficial effects of LMWH on MASLD. Mechanistically, 7-K-LCA was found to directly bind to and target Perilipin 3 (PLIN3), thereby inhibiting lipid droplet formation in hepatocytes and reducing intrahepatic lipid accumulation. Molecular docking demonstrated that 7-K-LCA bound to PLIN3 through hydrogen bonds and hydrophobic interactions.
Conclusion: Oral LMWH alleviated MASLD by enriching *A. muciniphila* and its metabolite 7-K-LCA, which targeted PLIN3 to reduce hepatic lipid deposition. These findings uncover a novel gut-liver axis through which oral LMWH remodels the gut microbiome to combat MASLD. This work highlights the therapeutic potential of targeting the gut microbiota with LMWH or its downstream metabolites as a promising strategy for managing MASLD.

SAT-137

Extracellular ATP (eATP) and related pathways in the progression of metabolic dysfunction–associated steatotic liver disease (MASLD)

Vanessa García-Fernández[1,2], Antonio Gil-Gómez[1,2,3], Rocío Munoz-Hernández[1,2,3], Sheila Gato-Zambrano[1,2], Ángela Rojas Álvarez-Ossorio[1,2], Isabel Fernández-Lizaranzu[1,2,4], M. Email: vgarcia-ibis@us.es

Background and aims: Extracellular ATP (eATP) is a damage-associated molecular pattern (DAMP) that promotes inflammation, leading to immune cell recruitment and cytokine release.

Ectonucleoside Triphosphate Diphosphohydrolase 1 (ENTPD1) metabolizes eATP, reducing circulating ATP levels and limiting inflammatory signaling. The purinergic receptor P2X7 (P2RX7) is activated by eATP and, in turn, stimulates the NLR family pyrin domain containing 3 (NLRP3)/interleukin-1beta pathway, amplifying liver inflammation. The aim of this study was to determine the role of eATP and the NLRP3 pathway in the progression of MASLD.

Method: A study was performed in twenty male C57BL/6J mice fed a High Fat High Carbohydrate and Cholesterol (HFHCC) diet (n = 10) or chow diet (n = 10). *Entpd1, P2rx7, Panx1 and Nlrp3* genes and Entpd1 and P2rx7 protein levels were assessed by PCR and IHC. Moreover, one hundred seventy biopsy-proven MASLD patients were classified according to SAF and NAS Score as simple steatosis (SS) (n = 74) or Metabolic dysfunction-associated steatohepatitis (MASH) (n = 96). Serum ENTPD1 levels were measured by ELISA.

Results: *Entpd1* was increased in HFHCC-fed mice (fold change 1 ± 0.83 vs 1.97 ± 0.75; p = 0.0005). *P2rx7* (fold change 1 ± 0.62 vs 2.24 ± 0.58; p < 0.0001) and *Nlrp3* (fold change 1 ± 0.41 vs 2.28 ± 0.71; p < 0.0001) were also upregulated. *Panx1* expression was decreased (fold change 1 ± 0.53 vs 0.32 ± 0.14; 0 = 0.0012). In the control group, Entpd1 protein expression localized around the central vein, with minimal signal in the portal vein area, while in HFHCC-fed mice, Entpd1 shifted towards the portal vein, showing increased portal expression and reduced central vein expression. P2rx7 positive cells/area were higher in HFHCC-fed mice (272.4 ± 79.8 *vs.* 391.8 ± 121.8; p = 0.0035). Patients with MASH (1588 ± 1750 pg/ml) had higher ENTPD1 levels than those with SS (1136 ± 808 pg/ml, p = 0.03). ENTPD1 levels increased with inflammatory activity [none (n = 23), 1477 ± 1131 pg/ml; mild (n = 99), 1113 ± 890 pg/ml; moderate (n = 48), 1925 ± 2163pg/ml; p = 0.005], with a significant difference between the mild and moderate inflammation group (p = 0.015). ENTPD1 levels were not significantly associated with ballooning or fibrosis.

Conclusion: In conclusion, upregulation of *Entpd1*, *P2rx7* and *Nlrp3* gene expression, together with increased Entpd1 and P2rx7 protein levels supports the role of eATP-related pathways in MASLD progression. Serum ENTPD1 levels reflects inflammatory activity, linking eATP-related pathways to inflammation-driven progression of MASLD.

SAT-138

Synergy of SOAT2-inhibitor PRD001 with resmetirom in reducing MASH and fibrosis in obese Ldlr-/-.Leiden mice

Eveline Gart[1], Kanji Hosoda[2], Martine C. Morrison[1], Anita M. van den Hoek[1], Hans M.G. Princen[1], Hiroshi Tomoda[2]. *[1]TNO, Leiden, Netherlands; [2]PRD Therapeutics, Inc., Tokyo, Japan*
Email: eveline.gart@tno.nl

Background and aims: Metabolic-dysfunction associated steatohepatitis (MASH) is characterized by hepatic lipid accumulation and inflammation. Sterol *O*-acyltransferase 2 (SOAT2), formerly known as ACAT2, plays a key role in intestinal cholesterol absorption and hepatic secretion. Pharmacological inhibition of SOAT2 reduces cholesterol uptake, thereby limiting hepatic lipid accumulation and secretion. Combining a SOAT2-inhibitor with resmetirom, a thyroid hormone receptor-β (THR-β) agonist that promotes lipid oxidation, could provide complementary reductions in fat and plasma lipids. This study aimed to assess the effects of PRD001, a SOAT2-inhibitor, combined with resmetirom on MASH and liver fibrosis.

Method: 20-week high-fat diet (HFD) without cholesterol supplementation fed Ldlr-/-.Leiden mice received vehicle, resmetirom (3 mg/kg), or resmetirom + PRD001 (30 mg/kg) for 12 weeks.

Results: Resmetirom and the combination treatment reduced body weight and fat mass, while increasing lean body mass as % of body weight. Fecal neutral sterol excretion, mainly driven by cholesterol excretion, was significantly increased with resmetirom and tended to be further enhanced when combined with PRD001. Resmetirom decreased plasma lipids and apoB with a significant further decrease for both when combined with PRD001. Lipoprotein profiles confirmed that this additional decrease was primarily due to a further decrease in VLDL- and LDL-cholesterol. Hepatic triglycerides and cholesterol esters were significantly decreased as well with resmetirom and combination with PRD001 led to a significant further decrease in hepatic cholesterol ester content. Hepatic macrovesicular steatosis, microvesicular steatosis, inflammation and fibrosis were all significantly reduced upon resmetirom treatment with a further decease in macro- and microvesicular steatosis when combined with PRD001. Hepatic gene expression confirmed involvement of (lipid) metabolism, inflammation pathways and mitochondrial pathways with more significant genes when resmetirom was combined with PRD001.

Conclusion: Using an advanced translational MASH model, we demonstrate resmetirom improved MASH and hepatic fibrosis. Adding PRD001 provided additional benefits on cholesterol excretion, plasma lipids, lipoproteins and steatosis highlighting the complementary mechanisms of PRD001 and resmetirom. Given the CVD risk in MASH patients, the observed lowering of atherogenic lipoproteins underscore substantial clinical advantages for the combination treatment.

SAT-139

The liver RNF43-Wnt/β-catenin pathway remotely regulates the intestinal inflammation repair pattern through bile acid reprogramming

Ying Geng[1], Jian Jiao[1]. *[1]China-Japan Union Hospital, Jilin University, Changchun, China*
Email: gengying23@mails.jlu.edu.cn

Background and aims: Previous studies have suggested that levels of DCA, TCA, LCA and GDCA are elevated in MASLD (metabolic dysfunction-associated steatotic liver disease). DCA and TCA have anti-apoptotic effects and induce proliferation of colon epithelial cells. The role of RNF43 as a negative regulator of the Wnt pathway in the mechanism of MASLD-related changes in the bile acid spectrum and abnormal proliferation of intestinal epithelial cells is unclear. This study aims to address these issues.

Method: An animal model of MASLD combined with intestinal epithelial cell injury and abnormal proliferation was established. Liver-specific knockdown of RNF43 using AAV-shRNA was used, and the levels of bile acids in the serum and faeces of each group of mice were detected using LC-MS/MS. Immunohistochemical methods were also used to detect the expression levels of bile acid metabolism pathways.

Results: In the model group, mice exhibited elevated DAI (Disease activity index) scores, increased intestinal inflammatory cell infiltration, heightened Ki-67 expression, and decreased TGR5 expression. These symptoms were alleviated in the RNF43 knockdown group. The fecal levels of LCA and GDCA in the model group were higher than those in the control group (p < 0.05). Compared to the model group, mice in the RNF43 knockdown group showed higher levels of serum TUDCA and TCA, lower levels of faecal DCA and LCA, and higher levels of GCA-3S, GDCA-3S and TDCA-3S (p < 0.05). Mechanistically, CYP7A1 expression in the livers of the RNF43 knockdown group was higher than in the model group (p < 0.01), BSEP decreased and NTCP increased (p < 0.0001).

Conclusion: Knocking down RNF43 in mouse livers further activates the hepatic Wnt/β-catenin pathway, reprogramming bile acid metabolism, elevates serum TUDCA and TCA levels, and directly acts on TGR5 in intestinal epithelial cells to inhibit inflammation and apoptosis. Concurrently, levels of toxic bile acids (DCA, LCA) decrease, while levels of sulfated bile acids (which are more water-soluble and less toxic) increased. These combined effects mitigate damage to intestinal acinar epithelial cells, reduce Ki-67-positive intestinal epithelial cell proliferation, and improve the morphology of abnormal crypt foci in mice.

SAT-140-YI

Inhibition of hepatic bile salt uptake using Bulevirtide attenuates pre-existing diet-induced metabolic dysfunction-associated steatohepatitis in mice

Claire Groenen[1,2], Thuc-Anh Nguyen[1,2], Joost Lambooij[3], Rudi de Waart[1,2], Kam Ho-Mok[1,2], Isabelle Bolt[1,2], Esther Vogels[1,2], Dagmar Tolenaars[1,2], Suzanne Duijst[1,2], Bruno Guigas[3], Joanne Verheij[4,5], Coen Paulusma[1,2], Wietse In het Panhuis[1,2], Stan F.J. van de Graaf[1,2]. *[1]Tytgat Institute For Liver And Intestinal Research, Amsterdam University Medical Centers, Amsterdam, Netherlands; [2]Amsterdam Gastroenterology, Endocrinology Metabolism (AGEM), Amsterdam University Medical Centers, Amsterdam, Netherlands; [3]Leiden University Center for Infectious Diseases, Leiden University Medical Center, Leiden, Netherlands; [4]Department of Pathology, Amsterdam University Medical Centers, Amsterdam, Netherlands; [5]Department of Pathology, Antwerp University Hospital/ University of Antwerp, Antwerp, Belgium*
Email: k.f.vandegraaf@amsterdamumc.nl

Background and aims: Metabolic dysfunction-associated steatotic liver disease (MASLD) affects over 30% of the global population and is characterized by hepatic fat accumulation. MASLD can progress into steatohepatitis (MASH), which involves inflammation that can lead to fibrosis and eventually cirrhosis and liver failure. Inhibition of the Sodium-dependent Taurocholate Cotransporting Polypeptide (NTCP) represents a potential therapeutic strategy, as this increases circulating bile salts, thereby improving glucose and lipid metabolism and reducing inflammation. We investigated whether NTCP inhibition with Bulevirtide, a safe and approved drug for treatment of hepatitis B and D, could attenuate liver steatosis, inflammation, and fibrosis in a MASH mouse model.
Method: Hyperlipidemic C57BL/6J$^{oatp1a1/1a4/1b2/ldlr-/-}$ male and female mice were used to mimic human hepatic bile salt uptake dynamics. Mice were fed a high-fat/high-cholesterol diet (40% and 0.15% w/w) and 15% fructose water (HFHCF) for 22 weeks to induce MASH. Liver biopsies confirmed features of MASH at baseline week 16. Subsequently, mice received daily subcutaneous injections of Bulevirtide (2.5 mg/kg) or vehicle for 6 weeks while continuing the HFHCF diet.
Results: HFHCF diet significantly increased liver-to-body weight ratios, plasma triglyceride, insulin levels, and induced hepatic steatosis, lobular inflammation and F2 perisinusoidal and periportal fibrosis. Bulevirtide increased plasma bile salt levels 20-fold. Bulevirtide treatment significantly decreased liver-to-body weight ratios (−19%) and tended to reduce Oil Red O-positive area percentage (−19%), liver triglyceride (−15%) and cholesterol content (−19%). Bulevirtide significantly lowered plasma triglyceride levels (−84%) and reduced plasma insulin levels (−45%). Bulevirtide treatment lowered abundance of monocytes in plasma (−35%) and liver (−22%) and induced a shift towards a less inflammatory (Ly6C^{high}TREML4^{low}) and more regulatory (Ly6C^{low}TREML4^{high}) profile. Bulevirtide treatment tended to lower F2 perisinusoidal and portal/periportal fibrosis scores, and significantly reduced liver COL1A1 abundance (3.5-fold) compared to vehicle in males only.
Conclusion: Bulevirtide improved MASH, but also metabolic parameters in a mouse model with pre-existing MASH. These findings suggest that NTCP inhibition may be a promising treatment for MASH, addressing both hepatic pathology and metabolic dysfunction.

SAT-141

Succinate alleviates metabolic dysfunction-associated steatotic liver disease through the hepatocyte Sucnr1/PPAR-gamma/Plin2 axis

Lei Gu[1], Shizhe Li[1], Shuoen Zhang[2], Zhonghe Xian[2], Zi Zuo[3], Hua Wang[3], Xiaowei Liu[4]. *[1]Department of Gastroenterology, Xiangya Hospital, Central South University, Innovation and Entrepreneurship Laboratory for College Students, Anhui Medical University, Department of Oncology, The First Affiliated Hospital of Anhui Medical University, Changsha, China; [2]School of Pharmacy, Innovation and Entrepreneurship Laboratory for College Students, Anhui Medical University, Hefei, China; [3]Entrepreneurship Laboratory for College Students, Laboratory of Molecular Biology, Department of Biochemistry, Anhui Medical University, Department of Oncology, the First Affiliated Hospital of Anhui Medical University, Hefei, China; [4]Department of Gastroenterology, Xiangya Hospital, Central South University, Changsha, China*
Email: gulei_279@163.com

Background and aims: Metabolic dysfunction-associated steatotic liver disease (MASLD) is the most prevalent chronic liver disease worldwide, representing a leading cause of liver-related morbidity and mortality. Its pathogenesis, however, remains incompletely elucidated. Gut microbiota dysbiosis and their metabolites are recognized as key contributors to MASLD progression. Among these, succinate, a dual-origin metabolite from both the host and gut microbiota, regulates immune and metabolic homeostasis via its cognate receptor SUCNR1. However, its specific role in MASLD pathogenesis remains unclear.
Method: Metagenomic analysis was performed to characterize the gut microbiota composition in patients with MASLD. A Western diet (WD)-induced MASLD mouse model was employed to evaluate the effects of dietary succinate supplementation and assess hepatic SUCNR1 expression. Molecular mechanisms were further investigated using proteomic analysis of liver tissues and *in vitro* assays with primary hepatocytes isolated from wild-type (WT) and SUCNR1-knockout (SUCNR1$^{-/-}$) mice.
Results: We found a reduced abundance of key succinate-producing bacteria in patients with MASLD, which was inversely correlated with the severity of hepatic steatosis. In WD-induced MASLD mice, hepatic SUCNR1 expression was significantly downregulated. Dietary succinate supplementation not only restored SUCNR1 levels but also ameliorated hepatic steatosis and inflammation. Proteomic analysis identified that succinate suppressed the expression of hepatic PPARγ and its downstream target, the lipid droplet-associated protein perilipin 2 (Plin2). Consistently, *in vitro* studies using primary hepatocytes demonstrated that succinate, acting via SUCNR1, directly inhibited PPARγ expression, reduced Plin2 protein levels, and subsequently alleviated cellular steatosis.
Conclusion: We provide evidence that succinate mitigates MASLD progression by activating the hepatocyte SUCNR1/PPAR-gamma/Plin2 signaling cascade. Restoring this metabolic axis represents a novel therapeutic approach to resolve hepatic steatosis and inflammation.

Semaglutide improves metabolic and histological outcomes and reverses clinically relevant biomarker alterations in the GAN diet-induced obese and biopsy-confirmed mouse model of MASH

Henrik H. Hansen[1], Jacob Nøhr-Meldgaard[1], Kristian Bendtsen[2], Kristoffer Niss[2], Jenny Egecioglu Norlin[2], Sanne Skovgård Veidal[2], Susanne Pors[1], Mathilde Teilmann[1], Kristoffer Voldum-Clausen[1], Markus Robert Latta[2], Michael Feigh[1]. *[1]Gubra A/S, Hørsholm, Denmark; [2]Novo Nordisk, Måløv, Denmark*
Email: hbh@gubra.dk

Background and aims: The long-acting glucagon-like peptide-1 (GLP-1) receptor agonist semaglutide was recently approved as the first GLP-1–based therapy for people with MASH and moderate-to-severe fibrosis. Clinical studies show that semaglutide not only improves liver health but also reverses several biomarker alterations characteristic of the disease. In this study, we characterized metabolic, histological, and biomarker responses to semaglutide in the Gubra Amylin NASH (GAN) diet-induced obese, biopsy-confirmed mouse model of MASH, and compared these findings with clinical observations.

Method: Male C57BL/6 mice were fed GAN diet, high in fat, fructose and cholesterol for 38 weeks prior to study start. A liver pre-biopsy was collected 4 weeks before treatment start. Only GAN DIO-MASH mice with NAFLD Activity Score (NAS ≥ 5) and fibrosis stage F2-F3 were included and stratified into treatment groups. Semaglutide (30 nmol/kg) or vehicle was administered subcutaneously once daily for 12 weeks. Vehicle-dosed, chow-fed mice served as healthy controls. Endpoints included aptamer-based SomaScan plasma proteomics, blood/liver biochemistry, pre-to-post individual assessment of NAS and fibrosis stage, and quantitative histology.
Results: Semaglutide promoted a weight loss of approx. 21% and improved hepatomegaly, plasma transaminases, plasma and hepatic lipid markers, NAS, and quantitative histological measures of steatosis and inflammation. Semaglutide also reduced fibrogenesis by histomorphometric analysis. Notably, the GAN DIO-MASH mouse model recapitulated key human MASH-associated circulating protein changes, including semaglutide-responsive biomarkers related to metabolism, inflammation, and fibrosis.
Conclusion: The GAN DIO-MASH mouse model exhibits strong translational relevance across metabolic, histological, and molecular domains, offering a robust platform for advancing mechanistic understanding of semaglutide and supporting the development of next-generation MASH therapies.

SAT-147

Lack of MASP-3 ameliorates liver injury and fibrosis in diet-induced fatty liver via modulation of apoptosis and inflammatory pathway in mice

Manabu Hayashi[1], Chikako Saito[1], Rie Hikichi[1], Takeshi Machida[2], Yumi Ishida[2], Mika Takasumi[1], Tatsuro Sugaya[1], Mai Murakami[1], Tomoaki Mochimaru[1], Michio Onizawa[1], Kazumichi Abe[1], Hideharu Sekine[2], Hiromasa Ohira[1]. *[1]Department of Gastroenterology, Fukushima Medical University, Fukushima, Japan; [2]Department of Immunology, Fukushima Medical University, Fukushima, Japan*
Email: m884884@fmu.ac.jp

Background and aims: The incidence of metabolic dysfunction-associated steatotic liver disease (MASLD) is increasing worldwide. The complement system is an innate immune system maintaining biological homeostasis, but its overactivation is associated with disease progression. Excessive C3 deposition in the liver is observed in MASLD patients, and it has been suggested that the complement alternative pathway contributes to the development of fatty liver disease. Mannose-binding lectin-associated serine protease (MASP)-3 plays a pivotal role in both the alternative pathway of the complement system and its development. This study aimed to clarify the involvement of MASP-3 for diet-induced fatty liver and the underlying mechanisms.
Method: MASP-3–deficient mice, which lack the exons encoding MASP-3–specific serine protease domain, were generated using the CRISPR-Cas9 system. Wild-type (WT) or MASP-3–deficient mice were fed either chow control or a choline-deficient, L-amino acid-defined, high-fat diet (CDAHFD) for 3 weeks or 28 weeks. At the time of sacrifice, livers were harvested and analyzed by RNA sequencing (RNA-seq), proteome analysis, and Western blotting. Gene ontology analysis and gene set enrichment analysis (GSEA) were used to examine alterations in signaling pathways.
Results: MASP-3–deficient mice exhibited low serum liver transaminases, mild histological liver injury, lower fibrosis area and fat deposition after 3 weeks of CDAHFD compared with WT mice. Gene ontology analysis using RNA-seq revealed significant downregulation of gene sets related to the extracellular matrix pathway and extracellular structure organization pathway in MASP-3–deficient mice. Western blot analysis of alpha-smooth muscle actin showed reduced expression in MASP-3–deficient mice compared with WT mice. GSEA using RNA-seq and proteome analysis showed down-regulation of gene sets related to apoptosis and inflammatory pathways in MASP-3–deficient mice compared with WT mice. Liver fibrosis after 28 weeks of CDAHFD was significantly ameliorated in MASP-3–deficient mice compared with WT mice.
Conclusion: Lack of MASP-3 ameliorated liver injury and fibrosis via modulation of apoptosis and inflammatory pathways in a MASLD mouse model. Our results suggest that inhibition of MASP-3 is a potential therapeutic target for MASLD.

SAT-148

Fat stiffens! The influence of steatotic progression on liver tissue

Alexander Hayn[1], Philip Friedrich[2], Jörg Walter[2], Madlen Matz-Soja[1], Thomas Berg[1], Josef Käs[2], Florian van Bömmel[1]. *[1]Leipzig University Medical Center, Medical Department II, Division of Hepatology, Leipzig, Germany; [2]Leipzig University, Peter Debye Institute for Soft Matter Physics, Soft Matter Physics Division, Leipzig, Germany*
Email: alexander.hayn@medizin.uni-leipzig.de

Background and aims: Biophysical alterations of liver tissue play a central role in the progression of metabolic associated steatotic liver disease. Accumulated fat deposits and fibrosis increase tissue stiffness and impair viscoelasticity, thereby influencing mechanosensitive cellular processes. Yet, the dynamics of these changes during disease progression remain poorly characterized.
Method: Liver tissue from mice fed either a Western diet (WD) or a Standard diet (SD) for 13, 26, or 32 weeks was analyzed to capture biophysical changes associated with fat accumulation and fibrosis. Tissue stiffness and viscoelasticity were quantified using atomic force microscopy, and effects on nuclear deformation in mechanosensitive cells were assessed.
Results: Progressive steatosis was consistently linked to increased tissue stiffness and reduced viscoelasticity. At all stages, WD tissue displayed significantly altered mechanical properties compared to SD. After 13 weeks, the WD tissue stiffened by a factor of 1.5, after 26 weeks by a factor of 2.5, and after 32 weeks by a factor of 3.1, compared to the SD tissue. In addition, a significant heterogeneity in stiffness was demonstrated between 26 and 32 weeks. With disease progression, these differences became more pronounced and were accompanied by enhanced nuclear deformation.
Conclusion: Stiffness and viscoelasticity emerge as sensitive indicators of steatotic liver disease. Their translation into clinical practice could help detect harmful consequences of steatosis at an early stage. Complementary proteomic analyses are essential to link these biophysical changes to molecular mechanisms and biological outcomes.

SAT-149

AxiomerTM mediated RNA editing converts the pathogenic PNPLA3 I148M variant to a wildtype-like form to reduce hepatic steatosis in MASLD/MASH

Werner Helvensteijn[1], Petra de Bruijn[1], Lieke Herbschleb[1], Nadia Keijzer[1], Marguerite Toros[1], Naomi van Vlies[1], Tsinatkeab Hailu[1], Lakshmi Baskar[1], Renee Salz[1], Jordy Bezemer[1], Saskia Haast[1], Mark de Lange[1], Iris Schmidt[1], Arlette Ruuls[1], Francesco De Chiara[1], Seda Yilmaz-Elis[1], Gerard Platenburg[1]. *[1]ProQR Therapeutics, Leiden, Netherlands*
Email: gplatenburg@proqr.com

Background and aims: Metabolic dysfunction-associated steatotic liver disease (MASLD) is the most common chronic liver disease characterized by hepatic fat accumulation. Disease progression can lead to metabolic dysfunction-associated steatohepatitis (MASH), cirrhosis, and hepatocellular carcinoma, making MASH a leading cause for liver transplantation in the US and EU. Patatin-like phospholipase domain-containing protein 3 (PNPLA3), is a hepatocyte-expressed protein involved in hepatic lipid metabolism. The *PNPLA3* I148M (rs738409) variant is the strongest genetic risk factor for MASH progression and is present in about 40–50% of patients. Axiomer-RNA editing uses editing oligonucleotides (EONs) to recruit endogenous ADAR enzymes, introducing site-specific conversion of adenosine-to-inosine, read as guanosine by ribosomes. EONs were

designed to convert the pathogenic methionine codon (ATG) to a valine codon (GTG), resulting in expression of PNPLA3 148 V wild-type-like variant that functionally mimics native PNPLA3 148I. Unlike gene silencing approaches, RNA editing preserves PNPLA3 protein expression while correcting its pathogenic function, potentially offering superior therapeutic benefit. This study evaluated Axiomer-mediated correction of *PNPLA3* I148M and its impact on hepatic lipid accumulation in a humanized mouse model.
Method: A lead N-Acetylgalactosamine (GalNAc)-conjugated EON was evaluated in FRG mice engrafted with homozygous PNPLA3 I148M PHH. Mice were fed a Western diet 1 month prior to and during treatment. Animals (n = 6 per group) received subcutaneous EON dosing (20 mg/kg, 14 doses over 28 days). Liver tissue was analyzed for RNA editing, steatosis, and macrovesicular lipid droplets (MLD) burden. A clinical-stage PNPLA3 antisense oligonucleotide (ASO) was included as a comparator (0,7 mg/kg, 14 doses over 28 days).
Results: In PHH, the lead 3′ GalNac-conjugated EON induced a dose-dependent correction of *PNPLA3* I148M, achieving 50% RNA editing. In humanized FRG mice, EON treatment resulted in 22% hepatic RNA editing of *PNPLA3* I148M and a marked reduction in MLD, exceeding the effect observed with the clinical-stage PNPLA3 ASO.
Conclusion: Axiomer RNA editing effectively converts the pathogenic *PNPLA3* I148M allele toward a wildtype-like variant, restoring lipid regulatory function and markedly reducing MLD in humanized *in vivo* systems. These findings support further development of *PNPLA3*-targeting EONs as a therapeutic strategy for MASLD/MASH.

Email: felix.hempel@live.de

Background and aims: Transforming growth factor-beta-activated kinase 1 (TAK1) is an essential signalling hub regulating hepatic cell death, inflammation, and fibrogenesis via nuclear factor-kappaB and mitogen-activated protein kinases in metabolic dysfunction-associated steatotic liver disease (MASLD). Recently, specific TAK1 inhibitors had been developed and demonstrated efficacy in preclinical models of arthritis, systemic sclerosis, and lung fibrosis. However, we have previously reported severe hepatitis, focal necrosis, and premature death in mice with genetic deletion of TAK1 in liver parenchymal cells. We therefore sought to explore the safety and efficacy of pharmacological TAK1 inhibition in a murine model of MASLD.
Method: Six-week-old male C57BL/6J mice were fed a diet enriched in fat, refined carbohydrates, and cholesterol (Western Diet) for 20 weeks to recapitulate human MASLD. 30 days prior to necropsy, the TAK1 inhibitor HS-276 (25 mg/kg, n = 14) or vehicle (sterile saline, n = 14) were administered intraperitoneally once daily. Serum samples were collected before the start of HS-276 or vehicle and during necropsy two hours after the final injection.
Results: HS-276 treatment led to weight loss during the treatment period (p = 0.034 for interaction). At 30 days, body weight was 5.1% lower in the treatment group (95% confidence interval [CI] 2.0 to –12.3, p = 0.154). No clinical or behavioural changes were observed. HS-276 was detected at an average concentration of 22.5 pmol/mg in liver tissue (95% CI 18.1 to 26.9 pmol/mg) by liquid chromatography-mass spectrometry, confirming hepatic exposition towards the compound. Serum alanine aminotransferase (–42.1 U/l, 95% CI –4.8 to –79.5, p = 0.029) and glutamate dehydrogenase (-45.8 U/l, 95% CI –23.6 to –68.0, p < 0.001) levels decreased comparing HS-276- and vehicle-treated mice before and after treatment. Additionally, perigonadal (epididymal) white adipose tissue was less abundant in mice treated with HS-276 (-0.9 percentage points, 95% CI –0.3 to –1.5, p = 0.005). Weight and histologic appearance of the heart, kidneys, and spleen were unchanged by HS-276 treatment.
Conclusion: TAK1 inhibition by HS-276 was well tolerated in a murine model of MASLD, contrasting our previous findings from genetic models. Our data suggest an attenuation of liver injury and favourable metabolic effects, highlighting the potential of TAK1 inhibition for the treatment of MASLD.

SAT-151-YI
Intramuscular fat in steatotic liver disease is linked to muscle function impairment, insulin resistance and specific inflammatory pathways in the liver

Email: nicolas.lanthier@saintluc.uclouvain.be

Background and aims: A muscle-liver axis, described on the basis of muscle density, appears to operate in cases of metabolic steatohepatitis. Here, we want to investigate the muscle phenotype (surface and intramuscular fat) by magnetic resonance imaging (MRI) in relation to muscle function and liver disease.
Method: Patients with SLD with an increased liver stiffness on transient elastography (≥7.8 kPa) were prospectively recruited. They underwent liver/skeletal muscles MRI and liver biopsy on the same day. Controls underwent the same MRI protocol. Mean liver and muscles (abdominal and paravertebral muscles) fat were measured by proton density fat fraction (PDFF). Muscle mass was assessed at the third lumbar vertebrae using the skeletal muscle index (SMI). Intramyocellular (IMCL) and extramyocellular lipids (EMCL) of right soleus and tibialis anterior were quantified using proton magnetic resonance spectroscopy. Muscle strength was assessed by the Liver Frailty Index (LFI). Liver biopsies were used for both histology and bulk mRNA sequencing.
Results: Patients with SLD (n = 92, 54 MASLD, 38 ALD) and controls (n = 10) were comparable for age. Ballooning was identified in 50% and fibrosis was graded as ≥ 2 in 63% of the SLD cohort. Median liver PDFF (19% vs. 3%, p < 0.001), mean muscle PDFF (22% vs. 9%, p < 0.001) and mean SMI (54 cm^2/m^2 vs. 36 cm^2/m^2, p < 0.001) were higher in the SLD group compared to controls. Despite significant metabolic differences such as BMI or presence of type 2 diabetes, muscle PDFF, LFI and SMI were similar in MASLD and ALD groups. Participants with

SLD and high muscle PDFF (>30%) showed decreased muscle strength compared to participants with low PDFF (<30%) but comparable age and BMI in both sexes. No correlation was found however between EMCL, IMCL and the liver frailty index while insulin resistance specifically correlated to soleus EMCL in MASLD ($r = 0.72$, $p = 0.005$) but not in ALD. Finally, transcriptomic analysis reveals that muscle fat is associated with an upregulation of hepatic inflammatory pathways and a downregulation of bile acid synthesis and fatty acid degradation.
Conclusion: Muscle fat assessed by MRI is increased in the presence of SLD and is associated with decreased muscle strength. EMCL are linked to insulin resistance in MASLD. Mechanistically, this disruption of the muscle-liver axis is associated with hepatic transcriptional changes including upregulated inflammatory pathways and downregulated bile acid biosynthesis and fatty acid degradation.

SAT-152
Dissecting paraoxonase 1 genotype combinations modulating paraoxonase activity and risk of dysglycemia and liver fibrosis
Laura Herrera[1,2], Maria João Meneses[1,3], Rogerio Ribeiro[2], Joao-Filipe Raposo[1,2,4], José Manuel Boavida[2], Luís Gardete-Correia[2], Carlos Penha-Gonçalves[2,5], Maria-Paula Macedo[1,2]. [1]*iNOVA4Health, NOVA Medical School, Faculdade de Ciências Médicas, NMS, FCM, Universidade NOVA de Lisboa, Lisbon, Portugal;* [2]*APDP – Diabetes Portugal, Education and Research Center, Lisbon, Portugal;* [3]*ProRegeM PhD Program, NOVA Medical School, NMS, Universidade Nova de Lisboa, Lisbon, Portugal;* [4]*Portuguese Society of Diabetology, Lisbon, Portugal;* [5]*Global Health and Tropical Medicine, GHTM, LA-REAL, Instituto de Higiene e Medicina Tropical, IHMT, Universidade NOVA de Lisboa, Lisbon, Portugal*
Email: laura.herrera@apdp.pt

Background and aims: Metabolic disorders such as dyslipidemia, metabolic dysfunction–associated steatotic liver disease (MASLD), and diabetes are promoted by chronic pro-inflammatory and pro-oxidative states. Paraoxonase 1 (PON1), a liver-derived enzyme associated with high-density lipoproteins (HDL), plays an important antioxidant role by hydrolyzing oxidized lipids and protecting against oxidative stress–induced damage. Genetic variation in PON1, particularly in promoter and coding regions, modulates enzyme expression and activity, thereby influencing susceptibility to metabolic and cardiovascular diseases. This study investigated the genetic determinants of serum paraoxonase (PONase) activity and their relationship with dysmetabolic phenotypes.
Method: A genome-wide association study was conducted in 922 Portuguese individuals from the PREVADIAB2 cohort. Genetic variants and haplotypes related to PONase activity were analyzed, and associations with dysglycemia and liver fibrosis were evaluated in individuals aged over 55 years.
Results: We identified two key PON1 variants as determinants of PONase activity: rs2057681 (in strong linkage disequilibrium with the non-synonymous Q192R variant) and rs854572 (located in the promoter region). Analysis of rs854572–rs2057681 haplotypes revealed that specific combinations differentially modulate PONase activity and confer risk or protection for dysglycemia and liver fibrosis, depending on the rs2057681 genotype context. Notably, although PONase activity was strongly associated with PON1 variants, it did not directly correlate with dysmetabolic phenotypes, suggesting that genetic context and haplotype structure, rather than enzyme activity alone, shape disease susceptibility.
Conclusion: These findings highlight the complex genetic architecture of PON1 and its role in metabolic disease risk, supporting the use of PON1 genetic information to uncover predisposition to dysmetabolic conditions. Our results provide insights into the interplay between PON1 genetics, enzyme function, and dysmetabolism, with implications for risk stratification in metabolic liver disease.

SAT-153
Combined exposure to alcohol and the PNPLA3 I148M variant drives hepatocytes toward pro-inflammatory, oncogenic, and profibrotic states in a western diet model
Stephen Hoang[1], Mulugeta Seneshaw[1], Faridoddin Mirshahi[1], Hae-Ki Min[1], Arun J. Sanyal[1]. [1]*Virginia Commonwealth University, Richmond, United States*
Email: arun.sanyal@vcuhealth.org

Background and aims: The genetic variant PNPLA3 I148M and alcohol consumption are distinct risk factors for the progression of steatotic liver disease, yet the mechanisms by which they interact to accelerate pathology remain incompletely defined. This study aimed to resolve how the combination of a Western diet, alcohol, and the PNPLA3 I148M genotype reshapes hepatocyte identity, pathway activity, and intercellular signaling networks.
Method: We used single-nucleus RNA sequencing (snRNA-seq) to profile liver tissue from mice exposed to a Western diet and alcohol, comparing controls with those carrying the PNPLA3 I148M variant. Prior to sequencing, injury was verified via histology. We identified hepatocyte subpopulations and constructed cell fate trajectories to assess state transitions. Pathway activities were quantified using Gene Set Variation Analysis (GSVA), and intercellular communication was inferred using CellPhoneDB. Findings were validated through protein quantification of inflammatory, metabolic, and fibrogenic markers.
Results: The combined exposure to Western diet, alcohol, and PNPLA3 I148M drove a coordinated shift in hepatocyte composition, yielding the highest abundance of stress-responsive subpopulations, including interferon-stimulated and injury-response hepatocytes. Trajectory analysis indicated that the combined treatment drove hepatocytes from quiescent states into phenotypes characterized by upregulated glycolysis (adj. $p < 0.001$) and oxidative phosphorylation (adj. $p < 0.001$). This was accompanied by a reciprocal downregulation of core functions, such as bile acid metabolism (adj. $p < 0.001$). Joint exposure enhanced profibrotic signaling interactions (adj. $p < 0.05$), specifically collagen-integrin, PDGF, and TGF-β interactions. Protein analysis corroborated these findings, showing significant elevation of inflammatory markers IL-1β ($p < 0.01$) and NLRP3 ($p < 0.01$), apoptotic cleaved Caspase-3 ($p < 0.05$), and fibrogenic markers COL1A1 ($p < 0.01$) and α-SMA ($p < 0.01$) in the combined treatment group relative to controls.
Conclusion: The interaction between alcohol and PNPLA3 I148M synergistically rewires the hepatic transcriptomic landscape, driving hepatocytes away from metabolic homeostasis toward inflammatory and apoptotic programs. This joint exposure promotes an energetically demanding injury response consistent with oncogenic priming and creates a signaling niche that actively drives fibrogenesis.

SAT-154
Kupffer cell-specific deletion of Sirt6 ameliorates diet-induced metabolic liver disease via macrophage reprogramming
Cao Huanyi[1], Chen Junnian[1], Wu Wenjing[2], Guan Haixia[1]. [1]*Department of Endocrinology, Guangdong ProvincialPeople's Hospital, Guangdong Academy of Medical Sciences, Southern Medical University, Guangzhou, China;* [2]*Department of Nephrology, Hubei Provincial Hospital of Traditional Chinese Medicine, Affiliated Hospital of Hubei University of Chinese Medicine, Wuhan, China*
Email: caohuanyi@link.cuhk.edu.hk

Background and aims: Metabolic dysfunction-associated steatotic liver disease (MASLD) progression involves hepatic macrophage activation. Preliminary analysis of published single-nucleus RNA sequencing (snRNA-seq) data indicated decreased *Sirt6* expression in liver macrophages from MASLD patients and high-fat diet (HFD)-fed mice. We aimed to investigate the functional role of *Sirt6* specifically in Kupffer cells (KCs) during diet-induced steatohepatitis (MASH).
Method: SIRT6 downregulation was validated in multiple murine models (PA-treated primary KCs, MCD/HFD-fed mice, *db/db* mice) via

western blot and immunofluorescence. To assess its KC-specific role, we generated Clec4f-Cre-driven *Sirt6* knockout mice and fed them a MASH-inducing diet for 22 weeks. Metabolic phenotyping, serum biochemistry, and liver histology (HE, BODIPY, Sirius Red, Masson) were performed. The hepatic immune landscape was profiled using 10x Genomics snRNA-seq on four key experimental groups.
Results: SIRT6 protein expression was consistently downregulated in liver macrophages across all tested models (PA-treated KCs, MCD/HFD-fed mice, and aging *db/db* mice), confirming the initial snRNA-seq observation. Contrary to expectations, KC-specific *Sirt6* deletion in the experimental model protected against MASH. Sirt6$^{\Delta KC}$ mice showed reduced body weight, improved glucose/insulin tolerance, enhanced energy expenditure, lower serum ALT/AST/triglycerides, and significantly less hepatic steatosis and fibrosis. snRNA-seq revealed profound macrophage reprogramming: diet-fed KC-specific *Sirt6* deletion livers exhibited an increase in Cyp2a22+ macrophages, a decrease in Clec4f+ resident KCs, and a reduction in recruited Ccr2+ macrophages.
Conclusion: *Sirt6* deletion in Kupffer cells paradoxically ameliorates diet-induced MASH, improving systemic metabolism and attenuating liver injury and fibrosis. This protection is associated with a fundamental shift in the hepatic macrophage composition, suggesting SIRT6 in KCs is a critical regulator of macrophage heterogeneity and a potential therapeutic target in MASLD/MASH.

SAT-155
Quercetin activates TP53-mediated lipophagy to ameliorate metabolic dysfunction-associated steatotic liver disease
Cao Huanyi[1], Chen Junnian[1], Wu Wenjing[2], Heng Wan[3], Guan Haixia[1]. [1]*Department of Endocrinology, Guangdong ProvincialPeople's Hospital, Guangdong Academy of Medical Sciences, Southern Medical University, Guangzhou, China;* [2]*Department of Nephrology, Hubei Provincial Hospital of Traditional Chinese Medicine, Affiliated Hospital of Hubei University of Chinese Medicine, Wuhan, China;* [3]*Department of Endocrinology and Metabolism, Shunde Hospital, Southern Medical University (The First People's Hospital of Shunde), Foshan, China*
Email: caohuanyi@link.cuhk.edu.hk

Background and aims: Metabolic dysfunction-associated steatotic liver disease (MASLD) lacks effective therapies. Quercetin, a natural flavonoid, shows clinical promise; however, its direct molecular target and unifying mechanism remain unknown, which hinders its development. This study aimed to identify the upstream target of quercetin and delineate its downstream mechanistic pathway in MASLD.
Method: Quercetin was identified as the hub active component via systems pharmacology. *In vivo*, MASLD was induced in mice using high-fat diet (HFD) and methionine-choline-deficient (MCD) models with quercetin intervention. Phenotypic and histological analyses were conducted. Molecular docking, surface plasmon resonance (SPR), and isothermal titration calorimetry (ITC) were used to assess the quercetin-TP53 interaction. Downstream mechanisms were explored through RNA sequencing (RNA-Seq) and immunoblotting of liver tissues. Key findings were validated in primary mouse hepatocytes.
Results: Quercetin treatment significantly ameliorated hepatic steatosis, inflammation, and fibrosis in mice. This effect was associated with upregulated TP53 expression in vivo. SPR/ITC confirmed a direct, high-affinity interaction between quercetin and TP53 protein. RNA-Seq from quercetin-treated HFD and MCD primary hepatocytes consistently identified SCD1 as a core downregulated target, accompanied by suppressed protein expression. Furthermore, quercetin activated the AMPK pathway and enhanced lipophagy markers in both settings. Critically, in primary hepatocytes, quercetin directly reduced lipid accumulation in a manner dependent on TP53-SCD1-AMPK signaling.
Conclusion: Our data demonstrate that quercetin-activated TP53 transcriptionally represses *Scd1* and concurrently activates AMPK-mediated lipophagy, coordinately reducing lipid burden. This "TP53-SCD1-AMPK-lipophagy" axis, rigorously validated in vivo and in primary cells, provides a unified and physiologically relevant framework for quercetin's therapeutic effects against MASLD.

SAT-156
Endothelial glycogen synthase kinase 3β promotes dendritic cells maturations and drives liver inflammation and fibrosis in metabolic dysfunction-associated steatohepatitis
Akitoshi Sano[1], Qianqian Guo[1], Samar Ibrahim[1,2]. [1]*Mayo Clinic, Rochester, United States;* [2]*Mayo Clinic, Pediatrics, Rochester, United States*
Email: ibrahim.samar@mayo.edu

Background and aims: Metabolic dysfunction–associated steatohepatitis (MASH) is a progressive liver disease marked by lipotoxic injury and chronic inflammation. A key feature is lipotoxic endotheliopathy, where liver sinusoidal endothelial cells (LSECs) adopt a proinflammatory phenotype, upregulating adhesion molecules and chemokines that drive pathogenic myeloid cells recruitment. We previously identified glycogen synthase kinase 3 beta (GSK3β) as a central kinase signaling hub in LSECs during MASH. However, LSEC GSK3β functional role in MASH remained unclear and will be investigated in this study.
Method: Endothelial-specific Gsk3β knockout mice (Gsk3β$^{\triangle End}$) were generated and fed a choline-deficient high-fat diet (CDHFD). Parallel studies used high-fat, fructose, and cholesterol (FFC)-fed mice treated with the GSK3 inhibitor elraglusib. Human studies involved palmitate-treated LSECs co-cultured with dendritic cells (DCs). Analyses included transcriptomics (Nanostring), Ingenuity pathway analysis (IPA), immune profiling by flow cytometry and CyTOF, and functional assays for lipid peroxidation and mitochondrial respiration.
Results: Endothelial GSK3β deletion in murine MASH attenuated lipotoxic endotheliopathy, reducing ICAM-1 expression, hepatic inflammation, and hepatocellular injury. Immune profiling revealed decreased proinflammatory monocytes, monocyte-derived DCs, and conventional type 1 DCs in Gsk3β$^{\triangle End}$ mice. Similar immune alterations were observed in FFC-fed mice treated with elraglusib. Transcriptomics showed downregulation of proinflammatory pathways, notably CXCL10 signaling. In vitro, palmitate-induced CXCL10 expression in LSECs enhanced DC maturation (MHC II, CD80, and CD86 expression), which was blocked by GSK3 inhibition. Mechanistically, GSK3 inhibition protected LSECs under lipotoxic condition from oxidative stress and ferroptosis, restored mitochondrial respiration and biogenesis, reversed lipotoxic morphological changes of the mitochondria, and activated AMPK signaling, preserving endothelial metabolic fitness. Endothelial GSK3β deletion also reduced liver fibrosis and portal hypertension in murine MASH.
Conclusion: Endothelial GSK3β drives lipotoxic endotheliopathy in MASH by promoting mitochondrial dysfunction, CXCL10-mediated DC maturation, and proinflammatory signaling. Genetic or pharmacological inhibition of GSK3β mitigates hepatic inflammation, fibrosis, and vascular dysfunction. Hence, targeting endothelial GSK3β is as a promising therapeutic approach in human MASH.

D-amino acids enriched java plum extracellular vesicles improve glucose tolerance and hepatic lipid metabolism to attenuate metabolic dysfunction–associated steatotic liver disease
Vibhuti Jakhmola[1,2], Sukriti Baweja[1], Patnala Debishree Subudhi[1], Anupama Kumari[1], Shiv Kumar Sarin[1]. [1]*Institute of Liver and Biliary Sciences, New Delhi, India;* [2]*Institute of Liver and Biliary Sciences, Department of Molecular and Cellular Medicine, New Delhi, India*
Email: sukritibiochem@gmail.com

Background and aims: Metabolic dysfunction–associated steatotic liver disease (MASLD) is a metabolic disorder defined by steatosis, insulin resistance, and hepatic inflammation, with limited

therapeutic options. Plant-derived edible extracellular vesicles (EEVs) are emerging as novel nutraceutical therapies. We evaluated the therapeutic efficacies of functional food derived EVs from, ginger (GinEVs), turmeric (TurEVs), carrot (CarEVs), garlic (GarEVs), and java plum (JapEVs) in a diet-induced murine MASLD model.
Method: EVs were isolated by differential ultracentrifugation and characterized using nanoparticle tracking analysis. Male C57BL/6J mice fed on high carb high fat (58%) diet for 20-weeks, followed by oral EV treatment (50 nm–300 nm; −17 ± −2.4 mV; 4×10^4 particles/kg) for 3 weeks. Metabolic indices (body weight, ITT, OGTT), liver histology, biochemical markers, and genes regulating lipid metabolism, and inflammation were analyzed. Fecal metaproteomics, proteomics, and metabolomics were performed to assess microbial and metabolic alterations.
Results: EEV treatment reduced body weight ($p < 0.05$) and improved insulin/glucose tolerance (ITT/OGTT AUC; $p < 0.05$). CarEVs, GarEVs, and JapEVs lowered hepatic steatosis, serum ALT ($p < 0.002$), and AST ($p < 0.001$). These effects were associated with decreased intestinal TNF-α and IL-17α ($p < 0.02$) and increased adiponectin ($p < 0.003$). While GarEVs markedly reduced hepatic inflammation (TNF-α, IL-17α; $p < 0.001$), JapEVs showed significant effect on lipid metabolism, increasing hepatic leptin ($p < 0.05$) and decreasing resistin ($p < 0.04$). JapEV cargo metabolomics revealed enrichment of D-glucosamine, L-asparagine, and D-glutamine (all $p < 0.001$), metabolites known to modulate fatty acid metabolism. Fecal metabolomics (378 annotated compounds) and proteomics (1,369 proteins) resembled controls, with JapEVs forming a distinct cluster, most strongly upregulating histidine metabolism ($p = 0.03$). Metaproteomics showed Lactobacillaceae enrichment and Clostridiaceae depletion ($p = 0.001$), indicating favorable microbial colonization, correlating with improved barrier integrity and reduced inflammation, collectively ameliorating MASLD.
Conclusion: Edible EVs effectively mitigate HFD-induced MASLD by modulating lipid metabolism, inflammation, and gut barrier function. JapEVs enriched in D-amino acids acts through histidine-mediated adiponectin induction to restore gut–liver axis homeostasis and MASLD amelioration.

SAT-158-YI

Epigenetic maintenance by DNMT1 safeguards the liver from inflammatory and fibrotic injury in MASLD/MASH

Email: lina.jegodzinski@uksh.de

Background and aims: Metabolic dysfunction-associated steatotic liver disease (MASLD) represents a major global health burden, with progression to steatohepatitis and fibrosis determining clinical outcome. Hepatocellular lipid overload induces metabolic stress responses, including mitochondrial dysfunction and oxidative injury. While epigenetic mechanisms are known to shape inflammatory and metabolic gene programs in chronic liver disease, the functional relevance of DNA methylation maintenance in MASLD pathogenesis remains unclear.
Method: To investigate the role of DNA methylation in MASLD, mice with hepatocyte-specific deletion of *Dnmt1*(*Dnmt1*$^{flox/flox;Alb-Cre}$) and wild-type (WT) littermate controls were fed Western (WD) or control (CD) diets starting at 6–8 weeks of age for up to six months. Liver injury and inflammation were evaluated using serum biochemistry and histological analyses. Hepatic transcriptomic changes were analyzed by RNA sequencing, and metabolomic profiling was performed using NMR and LC-MS.
Results: Despite reduced body weight gain and attenuated hyperinsulinemia, *Dnmt1*-deficient mice developed pronounced hepatic pathology under WD conditions. While triglyceride accumulation was comparable between genotypes, loss of *Dnmt1* resulted in excessive intrahepatic cholesterol deposition after prolonged dietary challenge. Early elevations in serum alkaline phosphatase indicated biliary injury in *Dnmt1*-deficient mice. Histological analyses demonstrated increased hepatocellular senescence and marked infiltration of macrophages and $CD8^+$ T cells, culminating in advanced fibrosis exclusively in *Dnmt1*-deficient livers. Transcriptomic profiling indicated activation of oxidative stress and mitochondrial dysfunction pathways, supported by metabolomic evidence of increased glutamate and reduced glutathione in *Dnmt1*-deficient livers.
Conclusion: Hepatocyte-specific loss of DNMT1 promotes inflammatory remodeling and fibrosis during MASLD/MASH progression. These findings identify impaired epigenetic maintenance as a critical determinant of hepatic stress responses and disease severity, identifying DNMT1-dependent DNA methylation as a potential target for future therapeutic strategies in MASH.

SAT-159

Hepatocellular GALNT15 promotes the development of metabolic dysfunction-associated steatohepatitis

Zhonghao Jiang[1], Baolin Qian[1], Wenguang Fu[1]. *[1]The Affiliated Hospital of Southwest Medical University, LuZhou, China*
Email: jiang_zhonghao@163.com

Background and aims: Metabolic dysfunction-associated steatohepatitis (MASH) represents an advanced stage of metabolic dysfunction-associated steatotic liver disease (MASLD) with limited therapeutic options. This study aimed to identify novel therapeutic targets for MASH.
Method: Transcriptomic and molecular analyses were performed on MASH mouse models and wild-type (WT) controls to identify differentially expressed genes. The functional role of Polypeptide N-acetylgalactosaminyltransferase 15 (GALNT15) was evaluated using hepatocyte-specific overexpression mice, conditional knockout mice, and multiple MASH models.
Results: GALNT15, a key glycosylation enzyme, was significantly upregulated in livers of obese MASH patients and diet-induced MASH mice. Hepatocyte-specific GALNT15 deficiency markedly attenuated hepatic injury and inflammation. Mechanistically, GALNT15 promotes glycosylation of Golgi integral membrane protein 4 (GOLIM4), thereby inhibiting COPII vesicle-mediated transport of very low-density lipoprotein (VLDL) from the endoplasmic reticulum to the Golgi apparatus. This trafficking defect leads to triglyceride accumulation and accelerates MASH progression.
Conclusion: These findings establish GALNT15 as a key mediator in the progression from metabolic dysfunction-associated steatosis to MASH, highlighting its potential as a therapeutic target.

SAT-163

Inflammation-associated gene expression profiles distinguishing significant fibrosis in metabolic dysfunction-associated steatotic liver disease (MASLD): evidence from a Turkish patient cohort

Deniz Cansen Kahraman[1], Esra Nalbat[1,2], Dilara Turan Gökçe[3], Saba Kiremitçi[4], Ramazan Idilman[3]. [1]*Cancer Systems Biology Laboratory, Department of Health Informatics, Graduate School of Informatics, METU, Ankara, Türkiye;* [2]*Department of Surgery, Klinikum Rechts der Isar, Technical University of Munich, Munich, Germany;* [3]*Department of Gastroenterology, Faculty of Medicine, Ankara University, Ankara, Türkiye;* [4]*Department of Medical Pathology, Faculty of Medicine, Ankara University, Ankara, Türkiye*
Email: cansen@metu.edu.tr

Background and aims: In metabolic dysfunction–associated steatotic liver disease (MASLD), progression from minimal fibrosis (F0/F1) to significant fibrosis (≥F2) represents a key prognostic threshold guiding screening, surveillance, and therapeutic decisions. While inflammatory pathways contribute to fibrosis progression, the molecular features distinguishing these stages and their relationship to clinical characteristics remain incompletely defined across populations. This study aimed to identify inflammation-related gene expression differences associated with fibrosis stage in MASLD patients from Türkiye.
Method: Liver biopsy specimens preserved as formalin-fixed paraffin-embedded tissue (FFPE) were obtained from 36 MASLD patients and categorized as F0/F1 (n = 23) or ≥F2 (n = 13). The cohort had a mean age of 47 years, and 66% of patients were female. Inflammation-focused transcriptomic profiling was performed using the NanoString nCounter Human Inflammation Panel encompassing 249 genes. Differentially expressed genes (DEGs) were identified based on |log2 fold change| ≥ 0.5 and adjusted p-values. Functional enrichment analysis was conducted using Enrichr, and protein–protein interaction networks were evaluated with STRING.
Results: No significant differences were observed between fibrosis groups with respect to BMI or sex distribution. Although diabetes mellitus, hypertension, hyperlipidemia, and coronary artery disease were more prevalent among patients with ≥F2 fibrosis, none of these associations reached statistical significance. Transcriptomic comparison identified 23 inflammation-related DEGs between early and significant fibrosis stages. Patients with ≥F2 fibrosis exhibited increased expression of multiple chemokines and chemokine receptors involved in immune cell trafficking, including CCL2, CCL5, CCL19–21, CXCL1, CXCL6, CXCL8, CXCL9–10, and CXCR4. Upregulation of fibrogenic mediators (TGFB1–3) and key innate immune signaling components (TLR2, TLR8, TNF, STAT1) was also observed. Network analysis revealed a chemokine- and innate immune–centered interaction core driven by highly connected hub genes, with peripheral nodes implicating oxidative stress, complement, and lipid-mediated inflammatory pathways.
Conclusion: In this MASLD cohort, significant fibrosis is associated with distinct inflammatory transcriptional signatures independent of major clinical covariates, supporting the translational relevance of inflammation-related transcriptomic signatures for fibrosis risk stratification.

SAT-164

Imeglimin attenuates liver injury in a nondiabetic mouse model of MASH by restoring mitochondrial function

Kosuke Kaji[1], Norihisa Nishimura[1], Masafumi Oyama[1], Tatsuya Nakatani[1], Tadashi Namisaki[1], Hitoshi Yoshiji[1]. [1]*Department of Gastroenterology, Nara Medical University, Kashihara, Japan*
Email: kajik@naramed-u.ac.jp

Background and aims: Metabolic dysfunction–associated steatohepatitis (MASH) can progress to liver fibrosis even in the absence of diabetes. Mitochondrial dysfunction plays a central role in MASH pathogenesis by impairing fatty acid (FA) oxidation, increasing reactive oxygen species (ROS) production, and inducing hepatocyte apoptosis and fibrogenesis. Imeglimin, an antidiabetic agent, improves mitochondrial bioenergetics; however, its glucose-independent effects on MASH remain unclear. This study aimed to evaluate the effect of imeglimin on liver injury and fibrosis in a nondiabetic MASH model by improving mitochondrial dysfunction.
Method: Male C57BL/6J mice were fed a choline-deficient, L-amino acid-defined, high-fat diet (CDAHFD) for 8 weeks to induce nondiabetic MASH. Imeglimin (100 or 200 mg/kg, twice daily) or vehicle was administered orally. Liver injury, steatosis, inflammation, apoptosis, and fibrosis were assessed histologically and biochemically. Mitochondrial function was evaluated by measuring oxidative stress, mitochondrial biogenesis, and FA oxidation-related markers. In vitro, palmitic acid (PA)–stimulated human hepatocytes were used to examine the effects of imeglimin on lipid accumulation, inflammation, apoptosis, mitochondrial membrane potential, respiratory chain activity, and oxygen consumption.
Results: CDAHFD-fed mice developed steatohepatitis and liver fibrosis without hyperglycemia. Imeglimin significantly attenuated hepatic steatosis, inflammation, and ballooning. These effects were accompanied by restoration of FA oxidation-related gene expression and marked suppression of hepatic ROS accumulation. Imeglimin enhanced mitochondrial biogenesis, increased PGC-1α and TFAM expression, and reduced hepatocyte apoptosis and macrophage-mediated inflammatory responses. Consequently, hepatic fibrosis was significantly decreased. In vitro, imeglimin suppressed PA–induced lipid accumulation, inflammatory cytokine production, and apoptosis in hepatocytes. Importantly, imeglimin restored mitochondrial membrane potential, improved respiratory chain complex activity, increased oxygen consumption, and promoted mitochondrial biogenesis.
Conclusion: Imeglimin attenuates liver injury and fibrosis in a nondiabetic MASH model by restoring mitochondrial function, enhancing FA oxidation, and reducing oxidative stress–mediated hepatocyte damage. These glucose-independent hepatoprotective effects suggest that imeglimin may represent a promising therapeutic option targeting mitochondrial dysfunction in MASH.

Email: noshin@hanyang.ac.kr

Background and aims: Bile acid dysregulation is increasingly recognized as a mechanistic contributor to metabolic dysfunction–associated steatotic liver disease (MASLD) and metabolic dysfunction–associated steatohepatitis (MASH). However, prior studies have largely focused on circulating bile acids, leaving intrahepatic determinants—including biliary bile acids and hepatic transporter or synthetic pathway alterations—poorly characterized. This study aimed to delineate multi-compartment bile acid alterations across the histological spectrum of MASLD by integrating serum and biliary bile acid profiling with hepatic transcriptomics.
Method: Adult participants were recruited from three tertiary centers and stratified by fibrosis stage and clinical diagnostic category

(control, MASLD, MASH). Serum and biliary bile acids were quantified using validated LC–MS/MS methods. Liver histology was assessed and hepatic gene expression was evaluated using RNA sequencing. Group differences in biochemical markers, bile acid species, and transporter/synthetic pathway expression were analyzed using parametric or nonparametric tests as appropriate.
Results: Disease progression was associated with distinct and compartment-specific remodeling of bile acid pools. Serum cholic acid (CA), taurocholic acid (TCA), and the composite 12α-hydroxylated bile acid fraction increased significantly in Fibrosis 1 and Fibrosis 2–3, and were similarly elevated in MASLD and MASH compared with controls. In contrast, biliary primary, conjugated, and non-12α-hydroxylated bile acids decreased across fibrosis stages, indicating depletion of biliary bile acids and redistribution toward the systemic circulation. Hepatic transcriptomic profiling revealed downregulation of canonical uptake transporters OATP1B1/1B3 and upregulation of alternative uptake (OATP2A1/2B1/3A1/4A1/5A1) and efflux transporters (MRP2/3/4, ABCG5/8). Concurrent elevation of CYP7A1, CYP8B1, TGR5, FGFR4, and FIC1, along with reduced CYP7B1 expression, indicated synthetic-pathway bias toward 12α-hydroxylated bile acids and activation of bile acid–responsive signaling pathways.
Conclusion: Integrated serum–bile–transcriptome analyses demonstrate that progressive MASLD is characterized by impaired hepatobiliary transport, increased 12α-hydroxylated bile acid flux, and activation of bile acid–responsive signaling circuits.

SAT-166

Picroside II loaded nanostructured lipid carriers attenuates metabolic dysfunction-associated steatohepatitis via restoring mitochondrial biogenesis and autophagic reflux

Swati Katoch[1,2,3], Garima Sagar[2,3], Jessica Kretzmann[3], Cameron Evans[3], K Iyer[3], Vikram Patial[1,2], Nicole Smith[3].

Background and aims: Chronic exposure of the liver to multiple insults culminates in the development of metabolic dysfunction-associated steatohepatitis (MASH), a complicated metabolic syndrome characterized by hepatic steatosis, with inflammation typically progresses to cirrhosis and liver cancer. Despite extensive clinical evaluation, there remain challenges in MASH drug development, which are primarily due to unsatisfactory efficacy and limited specificity. Picrosides are bioactive compounds found primarily in the medicinal plant *Picrorhiza kurroa*, known for their anti-inflammatory, antioxidant, and hepatoprotective properties. Herein we develop a picroside II loaded nanostructured lipid carrier (NLC) functionalized with GalNAc and evaluate its biological effects using *in vitro* model of MASH.
Method: For hepatic targeting β-GalNAc-PEG3-Azide was conjugated with DSPE-PEG(2000)-DBCO *via* SPAAC click chemistry. After functionalization of NLCs with conjugate, a comprehensive characterization was done by using various techniques like DLS/Zeta, UV-Vis, EE%, FTIR, MS, and NMR. To test the biological effect of these NLCs *in vitro*, a combination of palmitate-oleate (PO) was used in the HepaRG cells to mimic the pathogenesis of MASH. Cellular uptake was assessed by rhodamine loaded NLCs. Reactive oxygen species levels and mitochondrial membrane potential were assessed by DCFDA and JC1 staining respectively. qPCR analysis was done for mitochondrial biogenesis and autophagy related biomarkers.
Results: NLCs prepared exhibited a size of 161.7 ± 9.32 nm with PDI 0.406 ± 0.026, and zeta potential of −4.51 ± 0.67 mV. The encapsulation efficiency was observed to be as 95.5 ± 0.96%. MTS assay revealed the hepatoprotective effect of picroside II loaded NLC on PO treated HepaRG cells. DCFDA and JC1 staining showed that NLCs significantly alleviated ROS levels and mitochondrial membrane potential as compared to the free picroside II. The qPCR results for autophagy and mitochondrial biogenesis markers showed protective effect of NLCs loaded with picroside II on PO treated HepaRG cells.
Conclusion: In conclusion, the picroside II loaded GalNAc coated NLCs effectively prevented MASH by restoring mitochondrial function and autophagic reflux in HepaRG cells.

SAT-167

Region-specific transcriptomic reprogramming and inter-compartmental signaling in metabolic dysfunction–associated steatohepatitis

Jisup Kim[1], Aron Park[2], Baeki Kang[3], Seungyoon Nam[4], Dae Ho Lee[5].
[1]Department of Pathology, Gil Medical Center, Gachon University College of Medicine, Incheon, Korea, Rep. of South; [2]Department of Health Sciences and Technology, Gachon Advanced Institute for Health Sciences and Technology (GAIHST), Gachon University, Incheon, Korea, Rep. of South; [3]Molecular and Integrative Biology (MIB) Lab, Sungkyunkwan University School of Medicine, Suwon, Korea, Rep. of South; [4]Department of Genome Medicine and Science, Gil Medical Center, Gachon University College of Medicine, Incheon, Korea, Rep. of South; [5]Department of Internal Medicine, Gil Medical Center, Gachon University College of Medicine, Incheon, Korea, Rep. of South
Email: jspath@gilhospital.com

Background and aims: Metabolic dysfunction–associated steatohepatitis (MASH) is driven by complex interactions among hepatocytes and non-parenchymal cells within the hepatic microenvironment. Spatial transcriptomics provides a powerful framework for region-specific molecular profiling across distinct cellular compartments in human liver tissue. Leveraging this approach, we aimed to characterize compartment-specific transcriptomic alterations in MASH livers and to explore potential inter-compartmental communication using spatially resolved gene expression data, complemented by protein expression analyses.
Method: Formalin-fixed, paraffin-embedded liver tissues from patients with MASH and non-MASH controls were analyzed using the GeoMx Digital Spatial Profiler. Regions of interest (ROIs) enriched for hepatocytes (albumin), immune cells (CD45), and stromal cells (vinculin) were selected for spatial transcriptomic profiling. Differential gene expression and pathway analyses were performed across ROI types. Potential interactions between ROIs were inferred using ligand–receptor analysis based on ROI-specific gene expression patterns. Selected genes were further examined by multiplex immunofluorescence to evaluate ROI-specific protein expression.
Results: Spatial transcriptomic profiling revealed marked molecular heterogeneity across ROIs in MASH compared with non-MASH livers. Genes involved in xenobiotic metabolism, including cytochrome P450 family members, were selectively downregulated in non-parenchymal ROIs, specifically vinculin-enriched regions, whereas inflammatory mediators such as S100A8 and S100A9 were preferentially upregulated within the same stromal compartments. Interleukin-32 was increased across multiple cellular compartments, including hepatocyte- immune- and stroma-enriched ROIs. Multiplex immunofluorescence analyses further supported these findings by demonstrating ROI-specific protein expression patterns. Ligand–receptor analysis suggested altered inter-compartmental communication between parenchymal and non-parenchymal ROIs in MASH, including increased pro-fibrotic CCL21–CCR7 signaling from vinculin- to albumin-enriched regions and enhanced pro-inflammatory VEGFA–KDR signaling from hepatocyte- to immune-enriched compartments.
Conclusion: Our study demonstrates that MASH is associated with pronounced region-specific transcriptomic reprogramming and altered potential inter-compartmental signaling across hepatocyte-immune- and stromal-enriched regions.

SAT-168

Gut-liver axis modulates the development of hepatic tumorigenesis via gut microbiome alteration and immunomodulation

Seongjoon Ko[1]. [1]*Seoul National University College of Medicine, Seoul, Korea, Rep. of South*
Email: jel1206@naver.com

Background and aims: Hepatocellular carcinoma (HCC) increasingly arises on a background of metabolic dysfunction. How intestinal inflammation shapes hepatic immunity to promote tumorigenesis remains unclear. We investigated whether chronic colitis accelerates HCC in a diet-induced model and delineated microbiome–immune links along the gut–liver axis.
Method: Male C57BL/6 mice were fed a choline-deficient, L-amino acid–defined high-fat diet (CDAHFD) for 19, 24, or 31 weeks and randomized to CDAHFD alone (control) or CDAHFD plus cyclic 2% dextran sulfate sodium (DSS). Colon and liver pathology, serum biochemistry, hepatic immune cell phenotypes, and fecal microbial analysis with functional predictions were performed.
Results: DSS-treated group showed markedly increased hepatic tumor burden. Steatosis was comparable with similar inflammatory marker levels. DSS induced chronic, low-grade colitis with disrupted ZO-1 despite modest H&E activity. Hepatic macrophages shifted toward an M2 phenotype at 31 weeks. Microbial profiling showed reduced α-diversity (Shannon/Simpson $p = 0.015$) and distinct β-diversity (PERMANOVA $p = 0.014$), with dramatic *Akkermansia* expansion and near-depletion of butyrate-producer *Blautia*. ANCOM-BC and Random Forest analysis confirmed these discriminatory taxa; network analysis indicated *Akkermansia* as a central hub replacing commensal communities. PICRUSt2 revealed KO-level differences (e.g., glucose-6-phosphatase) despite similar pathway proportions.
Conclusion: Chronic intestinal inflammation establishes increased gut permeability and persistent dysbiosis that reprograms hepatic macrophages toward an M2-dominant, tumor-permissive milieu and accelerates HCC on CDAHFD, largely independent of overt inflammatory upregulation. Targeting microbiome composition, barrier integrity, and macrophage polarization may mitigate dysbiosis-driven hepatic carcinogenesis.

Potential protective roles of carvedilol and its derivatives in metabolic dysfunction-associated steatotic liver disease - The molecular docking study

Bojan Korica[1], Vladimir Milivojevic[1], Dušan Malenov[2]. [1]*Clinic for Gastroenterology and Hepatology, University Clinical Centre of Serbia, Faculty of Medicine, University of Belgrade, Belgrade, Serbia;* [2]*University of Belgrade - Faculty of Chemistry, Belgrade, Serbia*
Email: koricabojan@gmail.com

Background and aims: The prevalence rate of metabolic dysfunction-associated steatotic liver disease (MASLD) is significantly increasing and represents a global health burden. Portal hypertension (PH) may develop in early stages of MASLD without significant liver fibrosis due to the complex and multifactorial pathogenesis of PH in MASLD. Carvedilol is a non-selective beta blocker recommended in PH to prevent PH decompensation, with known antioxidant properties; however, its effects in MASLD haven't been further explained. Our study aimed to investigate the potential effects of carvedilol and its methyl derivatives on MASLD pathogenesis-related proteins.
Method: Molecular docking was performed to examine intermolecular interactions of 7 signaling proteins in MASLD pathogenesis: Thyroid Hormone Receptor Beta (THR-beta), Glucagon-like peptide-1 receptor (GLP-1R), HMG-CoA reductase, peroxisome proliferator-activated protein alpha and gamma (PPAR-alpha; PPAR-gamma), and Liver × Receptor alpha and beta (LXR-alpha; LXR-beta), with carvedilol and its derivatives (N-methylcarvedilol, N,N-dimethylcarvedilol). Protein structures were taken from the Protein Data Bank and adjusted to physiological pH. Carvedilol structures were optimized in implicit water solvent. Docking was performed using AutoDock Vina 1.2 with a whole-protein search space and exhaustiveness of 25.
Results: The highest binding affinity was obtained for carvedilol with PPAR-alpha (−9.1 kcal/mol), and it is established through strong hydrogen bonds with Thr88 and Ala138, T-shaped π-π interaction with Tyr139, and C-H/π and N-H/π interactions with Val 137 and Asn24, respectively. The same affinity was shown for carvedilol with PPAR-gamma (−9.1 kcal/mol), which was obtained through strong hydrogen bonds with Cys100 and Ser104, S···π interaction with Met144, as well as C-H/π interaction with Leu145. High binding potential was obtained for carvedilol and LXR-beta (−9.0 kcal/mol), as well as for N-methylcarvedilol with LXR-alpha (−8.3 kcal/mol), LXR-beta (−8.5 kcal/mol), PPAR-alpha (−8.3 kcal/mol) and PPAR-gamma (−9.0 kcal/mol).
Conclusion: Carvedilol and its derivatives have shown strong binding potential to active sites of proteins involved in MASLD pathogenesis (especially with LXR-beta, PPAR-alpha, and PPAR-gamma). This strongly suggests their potential role in lipid metabolism and anti-inflammatory effects in the concomitant treatment of MASLD and PH.

SAT-171-YI

Sex as a key modifier of age- and diet-driven MASLD progression in a murine model: histological and transcriptomic insights

Lucia Lameroli Mauriz[1,2], Andrea Scelza-Figueredo[3,4], Miranda Orellano[3], Brian Martinez Ruiz[1,4], Juan Bayo Fina[1,4], Esteban Fiore[1,4], María José Cantero[1], Bárbara Bueloni[1,4], Mailín Casadei[1,4], Matías A Avila[5,6,7], Luz Andreone[3,4], Guillermo Mazzolini[1,4,8], María Catalina Atorrasagasti[1,4]. Email: mcatalinaa@gmail.com

Background and aims: Age and sex are risk factors for metabolic dysfunction-associated steatotic liver disease (MASLD) severity and progression, yet their specific contributions to liver injury and molecular alterations remain poorly defined and often overlooked in preclinical models. Moreover, reliable markers predicting disease progression are lacking. This study aims to characterize sex-specific effects of age and diet on MASLD progression using histological and transcriptomic approaches in a preclinical murine model.
Method: Male and female C57BL/6N mice were divided into four experimental groups per sex: 2-month-old mice (young, Y) fed with chow diet (Y-CD), or high fat diet (Y-HFD), and 10-month-old mice (middle-aged, MA) fed with CD (MA-CD) or HFD (MA-HFD). Body weight and blood glucose were monitored for 20 weeks. Liver tissue was collected for histology and gene expression analysis by qPCR and RNAseq. Differentially expressed genes (adjusted p-value < 0,05 and |

logFC| > 0.585) were identified using Limma, followed by Gene ontology (GO) analysis (FDR < 0.05). Translational relevance was evaluated using the unbiased ranking MASLD Human Proximity Score (MHPS).
Results: MA mice developed more severe hepatic injury than Y mice after HFD. Insulin resistance driven by age and diet was observed in males. Serum ALT/AST increased exclusively in MA-HFD males. NAFLD Activity Score confirmed more advanced disease in MA mice, with extensive lipid accumulation, hepatocellular hypertrophy, inflammation, and fibrosis. Females showed milder hepatic damage. Transcriptomic analysis identified diet as the main driver in males, with age-dependent responses: Y-HFD males upregulated angiogenesis, ECM remodeling, and cell migration, whereas MA-HFD males showed enhanced inflammatory signaling and downregulation of energy metabolism. In females, transcriptomic changes were attenuated; Y-HFD upregulated lipid metabolism, unfolded protein response and apoptosis, while downregulating sterol and steroid biosynthesis, whereas MA-HFD showed limited pathway modulation. MHPS ranked middle-aged HFD males as most similar to human MASLD.
Conclusion: Age and sex critically shape hepatic responses to dietary stress in MASLD. MA male mice most closely recapitulate human disease, while distinct molecular responses in females highlight the importance of incorporating sex as a biological variable in MASLD research and biomarker development.

SAT-172
GPR84 antagonism shifts liver macrophage polarization from M1 to M2, increases liver triiodothyronine, and improves cholesterol levels and hepatic steatosis in a high-fat diet metabolic dysfunction-associated steatohepatitis mouse model
Martin Leduc[1], Alexis Ascah[1], Gary Bridger[1]. [1]*Caledon Bioscience Inc., Laval, Canada*
Email: m.leduc@liminalbiosciences.com

Background and aims: The GPR84 receptor is overexpressed in liver from patients with metabolic dysfunction-associated steatotic liver disease (MASLD) and participates in the regulation of pro-inflammatory responses and migration of immune cells. The GPR84 antagonist GLPG1205 was used to evaluate the efficacy of GPR84 inhibition in a high-fat diet (HFD) metabolic dysfunction-associated steatohepatitis (MASH) mouse model.
Method: Male C57BL/6N mice were fed a Gubra Amylin NASH (GAN) HFD or a control normal diet (ND) for 10 weeks and then separated into three groups treated with either GPR84 antagonist GLPG1205 (30 mg/kg, p.o., BID) (HFD + GLPG1205 group, n = 12) or vehicle (ND, n = 8, and HFD, n = 11) for an additional 6 weeks. Serum and tissue samples were collected at endpoint for analysis.
Results: Liver weight/body weight and fat mass composition were increased by HFD compared to ND and significantly reduced by GLPG1205. Serum cholesterol (total, LDL and HDL) as well as liver total and free cholesterol and cholesteryl ester levels were all reduced in the GLPG1205-treated mice ($p < 0.01$). Treated animals also had reduced serum tissue inhibitor of metalloproteinases (TIMP)-1) and increased serum adiponectin levels, returning to levels of ND controls. Liver steatosis and number of hepatic crown-like structures which were increased by HFD were markedly decreased following GLPG1205 treatment ($p < 0.001$). Analysis of liver immune cells by flow cytometry showed that compared to ND, HFD mice had increased leukocytes, neutrophils, and classically activated (M1) macrophages and decreased alternatively activated (M2) macrophages, which were all significantly reversed by GLPG1205. In addition, liver triiodothyronine (T3) levels were augmented by GLPG1205 ($p < 0.001$). Liver RNA sequencing analysis revealed that overall, fibrosis, inflammation and MASH-associated gene expression that was dysregulated in HFD compared to ND groups showed reversal back towards control levels in the GPR84 antagonist-treated group.
Conclusion: Pharmacological inhibition of GPR84 in HFD-fed mice significantly reduced liver leukocytes, neutrophils, and promoted a shift from M1 (pro-inflammatory) to M2 (anti-inflammatory, pro-tissue repair) polarized liver macrophages, increased liver T3 levels, reduced serum and liver cholesterol, and improved liver weight/body weight, fat mass composition, and liver steatosis. These findings suggest that GPR84 inhibition is a promising target in MASLD and hypercholesterolemia.

SAT-173
Hepatoprotective effects of Efruxifermin in the CDAA-HFD mouse model of advanced MASH with progressive fibrosis
Monika Lewinska[1], Jacob Nøhr-Meldgaard[1], Susanne Pors[1], Denise Oró[1], Louise Humle Kruse[1], Henrik H. Hansen[1], Michael Feigh[1]. [1]*Gubra, Hørsholm, Denmark*
Email: mle@gubra.dk

Background and aims: Efruxifermin (EFX), a long-acting FGF21 analogue, is currently in phase 3 clinical development for the treatment of metabolic dysfunction-associated steatohepatitis (MASH). The present study aimed to evaluate treatment effects of EFX in the non-obese, choline-deficient, L-amino-acid defined, high-fat diet (CDAA-HFD) mouse model of advanced MASH with progressive fibrosis.
Method: C57BL/6JRj mice were fed chow or CDAA-HFD (45 kcal% fat, 0.1% methionine, 1% cholesterol, 28 kcal% fructose) for 4 weeks prior to treatment start (before onset of liver fibrosis) and throughout the treatment period. Animals were randomized into treatment groups based on body weight. A CDAA-HFD baseline group (n = 12) was terminated prior to treatment start. CDAA-HFD fed mice (n = 12 per group) were subcutaneous dosed once a week with vehicle or EFX (1 mg/kg) for a total of 8 weeks. Terminal endpoints included plasma/liver biochemistry, AI-assisted histopathological scoring (NAFLD Activity Score (NAS), fibrosis stage), quantitative liver histology and RNA sequencing.
Results: At baseline CDAA-HFD animals displayed advanced MASH (NAS score of 6) with no or mild fibrosis (stage F0, 75% of animals; stage F1, 25% of animals). At termination, vehicle-dosed CDAA mice displayed advanced fibrosis (stage F2, 8% of animals; stage F3, 92% of animals). 8 weeks of EFX treatment had no effect on body weight, hepatomegaly or plasma ALT levels compared with vehicle controls. Notably, EFX significantly improved fibrosis stage (stage F2, 50% of animals; stage F3, 50% of animals) and produced marked reductions in quantitative fibrosis endpoints, including hydroxyproline content, and histological markers(PSR, collagen-1a1, α-smooth muscle actin). In contrast, EFX did not improve NAS, consistent with the absence of quantitative histological markers of steatosis (hepatic lipids, fraction of hepatocytes containing lipid droplets) and inflammation (galectin-3, CD45).
Conclusion: EFX improves biochemical and histological markers of fibrosis, but not steatosis or inflammation, in the non-obese CDAA-HFD mouse model of advanced MASH with progressive fibrosis.

SAT-174
HECTD3 attenuates metabolic dysfunction-associated steatohepatitis (MASH) by stabilizing PRDX4 via K63-linked polyubiquitination
Rui Jin[1], Qianwen Zhao[1], Jie Li[1]. [1]*Department of Infectious Diseases, Nanjing Drum Tower Hospital, Clinical College of Nanjing Medical University, Nanjing, China*
Email: 18810531268@163.com

Background and aims: Metabolic dysfunction-associated steatohepatitis (MASH) poses a significant global public health challenge, involving complex pathogenesis related to metabolic syndrome and

systemic inflammation. HECTD3, an E3 ubiquitin ligase, is known to regulate various inflammatory and fibrotic signaling pathways, but its role in MASH progression remains unclear. This study aims to investigate the function of HECTD3 in MASH and its underlying molecular mechanisms.
Method: Hepatocellular HECTD3 were over-expressed in mice via the AAV8 system, and male C57BL/6J mice were fed either a Choline-deficient, L-amino acid-defined, high-fat diet (CDAHFD) for 10 weeks, or a high-fat, high-fructose diet (HFHFD) diet for 16 weeks to induce MASH. THLE-2 and AML12 cell lines were used for in vitro studies. Multi-dimensional mass spectrometry combined with co-immunoprecipitation (co-IP) was employed to identify HECTD3-interacting proteins.
Results: HECTD3 protein expression was significantly downregulated in the livers of CDAHFD-or HFHFD-fed mice and in PA-stimulated hepatocytes. Hepatocyte-specific overexpression of HECTD3 markedly alleviated MASH progression, including reduced lipid accumulation and significantly attenuated fibrosis. Consistently, HECTD3 overexpression decreased lipid deposition in PA-treated hepatocytes. Co-IP coupled with MS suggested PRDX4 as a potential binding partner of HECTD3, which was further confirmed by both endogenous and exogenous co-IP assays. Our in vitro data showed that PRDX4 overexpression significantly reduced PA induced lipid accumulation and inflammation in AML12 cells. Immunofluorescence and western blot analysis revealed that hepatocyte-specific HECTD3 overexpression increased PRDX4 protein levels in the livers of MASH model mice. Consistently, in vitro experiments further demonstrated elevated PRDX4 protein levels in HECTD3-overexpressing hepatocytes, and cycloheximide chase assays indicated that HECTD3 overexpression prolonged the half-life of PRDX4 protein. We further detected that HECTD3 overexpression significantly increased the total ubiquitination level of PRDX4, particularly the level of K63-linked polyubiquitin chains.
Conclusion: HECTD3 interacts with PRDX4 and stabilizes its protein expression by mediating its ubiquitination, specifically via K63-linked polyubiquitination. As a crucial positive regulator of PRDX4, HECTD3 plays a protective role in the development and progression of MASH and may represent a novel potential therapeutic target for MASH treatment.

SAT-175
Genetically engineered mesenchymal stem/stromal cells overexpressing fibroblast growth factor 2 inhibit MASH progression by activating the AMPK-ACC1 pathway
Yifan Yang[1], Yu Ouyang[2], Changyong Li[2]. [1]*Department of Biochemistry and Molecular Biology, School of Basic Medical Sciences, Wuhan University, Wuhan, China;* [2]*Department of Physiology, School of Basic Medical Sciences, Wuhan University, Wuhan, China*
Email: lichangyong@whu.edu.cn

Background and aims: Mesenchymal stem/stromal cells (MSCs) have attracted much attention in the treatment of liver diseases including metabolic dysfunction-associated steatohepatitis (MASH). However, many MSC clinical trials have failed to meet their efficacy endpoint. This study aims to investigate the role of human umbilical cord-derived MSCs (UC-MSCs) on MASH progression and the underlying molecular mechanisms, as well as to explore key strategies for enhancing the therapeutic efficacy of UC-MSCs in treating MASH.
Method: MASH mouse model induced by a high-fat and high-cholesterol (HFHC) diet was generated to evaluate the therapeutic efficacy of UC-MSCs and UC-MSCs-derived extracellular vesicles (UC-MSC-EVs). Transcriptome sequencing and label-free quantitative proteomics techniques were employed to identify enriched signaling pathways and differentially expressed proteins. Gain-of-function and loss-of-function experiments were conducted to elucidate the role of fibroblast growth factor 2 (FGF2) secreted by UC-MSCs during the progression of MASH.
Results: Administration of UC-MSCs and UC-MSC-EVs significantly inhibited MASH progression as indicated by reduced hepatic steatosis, inflammation and fibrosis in HFHC-fed mice. The transcriptome analysis showed that after the treatment with UC-MSCs, the AMPK-ACC1 signaling pathway was the most significantly enriched pathway. The label-free quantitative proteomics suggested that UC-MSC-EVs delivered FGF2 to hepatocytes, leading to the activation of AMPK-ACC1. Moreover, knockdown of FGF2 weakened the regulatory effects of UC-MSC-EVs on AMPK-ACC1 phosphorylation and lipid deposition, while overexpression of FGF2 enhanced their therapeutic effect. More importantly, genetically engineered UC-MSCs over-expressing FGF2 robustly activated the AMPK-ACC1 cascade, thereby inhibiting the progression of MASH.
Conclusion: Our study demonstrates that FGF2 delivered via UC-MSC-EVs can alleviate hepatic steatosis, inflammation and fibrosis in MASH mice through activating the AMPK-ACC1 pathway. These data delineate an EV-mediated mechanism underlying UC-MSC therapeutic activity in MASH and provide a rationale for developing FGF2-rich cell-free EV-based therapeutic intervention for MASH.

SAT-179
Enhancing treatment of metabolic dysfunction-associated steatohepatitis: combination of GLP-1R agonist with others
Hui Li[1], Jiliang Zhang[1], Sitong Zhang[1]. [1]*WuXi AppTec, Shanghai, China*
Email: li_hui0122@wuxiapptec.com

Background and aims: Metabolic Dysfunction-Associated Steatohepatitis (MASH) is a progressive liver disorder characterized by fat accumulation, chronic inflammation, and fibrosis. The GLP-1R agonist semaglutide has finally been approved for MASH, becoming the second therapy approved by the US FDA for MASH. However, the therapeutic options for treating MASH remain limited and their efficacy needs improvement, leading to an urgent need for novel interventions. This study aims to explore the therapeutic potential of the GLP-1R agonist and the GLP-1/GIP/glucagon receptor triple agonist, in combination with THR-β agonist and FGF21 analog in a murine model of MASH.
Method: A murine MASH model was induced using a high-fat diet combined with carbon tetrachloride (CCl4). The experimental design included a healthy control group (vehicle-treated) and various MASH cohorts receiving vehicle, GLP-1RA alone, or GLP-1RAs in combination with THR-β agonist or FGF21 analog. Each treatment regimen was specifically tailored in terms of dosage and frequency. After 6 weeks of treatment, liver tissues were collected and assessed for steatosis, inflammation, and fibrosis using histological, digitalized, and molecular techniques.
Results: Compared to the model group, combination therapies incorporating GLP-1RAs demonstrated significant improvements. They reduced the NAS score by 3–4 points and the liver fibrosis score (LFS) by 1–3 points. Specifically, GLP-1RAs combined with resmetirom showed the most substantial improvements, with markedly reduced liver inflammation, steatosis, and fibrosis (NAS reduction from 5 to 1–2 and LFS reduction from 5 to 2). More importantly, digital histology results indicated a clear reduction of fibrosis around both the portal tract and septal areas, signifying reduced liver damage, fibrosis reversal, and structural recovery. These findings underscore the potential of combination therapy to more effectively mitigate the pathological features of MASH.
Conclusion: Our study suggests that combination therapies involving GLP-1 receptor agonists, such as Semaglutide, with other

pharmacological agents hold promise for the treatment of MASH. By addressing the multifaceted pathophysiology of the disease, especially liver fibrosis, these combination therapies could offer a more comprehensive and effective treatment strategy, paving the way for future clinical development and therapeutic innovation.

SAT-180

Intracellular and non-immune regulatory mechanisms: molecular function of complement C3 in hepatic triglyceride metabolism

Yinling Li[1,2], Haitao Wang[3], Xiaobing Dou[2], Junping Shi[1]. [1]*The Affiliated Hospital of Hangzhou Normal University, Hangzhou, China;* [2]*Zhejiang University of Traditional Chinese Medicine, Hangzhou, China;* [3]*Queen Mary University of London, London, United Kingdom*
Email: lyl_cmu1h@163.com

Background and aims: Complement C3 is classically known for its innate immunity role. Clinical observations shown its elevation in MAFLD, suggests a link between C3 and lipid metabolism, though the mechanisms remain unclear. Recent evidence highlights non-canonical, intracellular functions of complement components in cellular homeostasis. Our preliminary data shown that genetic C3 deletion triggers spontaneous hepatic steatosis in mice, which worsens under HFD, indicating C3 can autonomously regulate TG metabolism and challenging the traditional "lipid→inflammation→C3" paradigm. This study aims to identify specific C3 subtype and mechanism involved, informing optimized gene-editing therapies targeting C3 in MAFLD.
Method: Male $C3^{-/-}$ and $C5L2^{-/-}$ mice (C57BL/6J) with WT littermates, and $C3aR^{-/-}$ mice (BALB/c) with WT controls (8–16 weeks), were sourced from Jackson Laboratory. Hepatic TG was assessed by Oil Red O staining and GPO-PAP assay, and FFA kinetics were tracked via ^{3}H-isotopic. Subcellular localization and forms of C3 were analyzed using immunoelectron microscopy along with redox and glycosylation assays. C3 interacting proteins were identified by CoIP/MS, and functional domains were mapped using truncation and point mutation constructs.
Results: In the early stage of MAFLD, sera and hepatic complement C3 levels were elevated. However, cellular and animal experiments confirmed that deletion of C3 exacerbates TG accumulation, and $C3^{-/-}$ mice developed spontaneous hepatic steatosis. This intriguing finding suggests that C3 may possess an autonomous regulatory function in hepatic lipid metabolism. Further mechanistic exploration revealed that C3 acts independently of its cleavage products and does not affect FFA uptake, indicating that the intact, full-length C3 exerts its function within hepatocytes. Protein interaction studies demonstrated that C3 interacts with the GRP78 and participates in the regulation of hepatic lipid homeostasis by maintaining the ubiquitination level of GRP78, thereby modulating its protein stability.
Conclusion: Our study reveals an intracellular, non-canonical, distinct from classical innate immunity role of intact complement C3 in maintaining hepatic lipid homeostasis. C3 interacts with ER chaperone GRP78 to sustain its ubiquitination and stability, forming a C3–GRP78 regulatory axis that protects against steatosis. These findings challenge the classical "lipid→inflammation→C3" dogma and position C3 as a direct metabolic regulator, offering a novel target for MAFLD therapy.

SAT-181

GIPC1 interacts with GPER1 to promote fatty acid oxidation and ameliorate hepatic steatosis: a novel target in MASLD

Yifang Li[1], Jian Jiao[1]. [1]*China-Japan union hospital of Jilin university, Changchun, China*
Email: yifang22@mails.jlu.edu.cn

Background and aims: Metabolic dysfunction-associated steatotic liver disease (MASLD) is emerging as a leading cause of end-stage liver disease. Despite the recent approval of phase III agents for MASH, the multifactorial etiology of MASLD/MASH has driven current drug development toward multi-target strategies. GAIP-interacting protein C-terminal 1 (GIPC1) is a scaffolding protein that regulates the expression and transport of cell-surface receptors, and G-protein-coupled estrogen receptor 1 (GPER1) is a novel estrogen transmembrane receptor. However, the roles of GIPC1 and GPER1 in MASLD pathogenesis are not well understood. Here, we examined the molecular regulatory mechanisms of GPER1 and GIPC1 in MASLD using human liver tissues, animal and cellular models.
Method: First, we detected the expression levels of GIPC1 and GPER1 in human liver tissue, then we demonstrated their interaction. We then showed the effects of GPER1 on MASLD using the GPER1-specific agonist G1 and the specific antagonist G15. Subsequently, we showed that GIPC1 mediates GPER1's protective role against MASLD through its silencing and overexpression. Finally, we investigated the molecular mechanisms by which GIPC1 improves hepatic steatosis and fatty acid oxidation using AMPK inhibitor.
Results: We found that GIPC1 is a downstream target of GPER1 that mediates its protective effect on MASLD. The expression level of GIPC1 in male liver tissue is significantly lower than that in female liver tissue, demonstrating a sex difference. GPER1 activation upregulates the expression of fatty acid oxidation (FAO) -related proteins, as well as the phosphorylated AMP-activated protein kinase (p-AMPK) and GIPC1, which ameliorates hepatocyte steatosis and lipid deposition. Silencing GIPC1 attenuated hepatic steatosis and down-regulated the expression of proteins associated with FAO. Pretreating cells overexpressing GIPC1 with compound C aggravated lipid droplet deposition, significantly elevated TG content, and down-regulated the expression of FAO-related proteins in hepatocytes to varying degrees. These results indicate that the positive effects of GIPC1 overexpression on MASLD are dependent on AMPK alpha pathway activation.
Conclusion: GIPC1 promotes fatty acid oxidation and ameliorates hepatic steatosis by activating the AMPK alpha pathway. The mechanism and sexual dimorphism characteristics between GPER1-GIPC1 provide new targets to achieve individualized prevention and treatment of MASLD.

SAT-182

Investigating lung inflammation following bacterial infection in mice with metabolic dysfunction-associated steatohepatitis

Zuobin Liu[1], Dimitrios Patseas[1], Eoin Mitchell[1], Viktoras Konstantellos[1], Aran Singanayagam[2], Evangelos Triantafyllou[1]. [1]*Imperial College London, Department of Metabolism, Digestion and Reproduction, London, United Kingdom;* [2]*Imperial College London, Department of Infectious Disease, London, United Kingdom*
Email: z.liu23@imperial.ac.uk

Background and aims: Metabolic dysfunction-associated steatotic liver disease (MASLD) and metabolic dysfunction–associated steatohepatitis (MASH), the more inflammatory form of MASLD, represent major causes of chronic liver disease characterized by systemic metabolic and immune dysregulation. However, the extra-hepatic organ injury in MASLD/MASH, with or without bacterial infection, has yet to be adequately studied. Both clinical studies and pre-clinical mouse models have shown an increased risk of infections in MASLD, with susceptibility positively associated with disease severity. Respiratory tract infections rank among the most common types of infections. Here, we aimed to investigate lung inflammation and immune alterations during MASLD after bacterial infection.
Method: Wild-type (C57BL/6J) male mice were fed a Choline-Deficient, L-Amino-Acid defined High-Fat-Diet (CDA-HFD) or normal diet (ND) for up to 8 weeks. Systemic Escherichia coli (E. coli) bacteria were administered intravenously (10^7 CFU per 20 g

body weight) at 6 weeks after dietary intervention. Mice were culled at 7 and 14 days post-infection (d.p.i.); liver and lung tissues were harvested for immunophenotypic (flow cytometry; myeloid and lymphoid subsets) and histological or immunofluorescence analyses.
Results: CDA-HFD induced the development of MASH-like pathological features in mouse liver characterized by increased serum ALT/AST levels, severe steatosis and inflammation compared with ND-fed mice. In the lung, the magnitude of immune cell alterations was more pronounced in CDA-HFD mice. Peak inflammation was identified at 7 d.p.i. in both diet groups, indicated by the highest total immune cell counts and inflammation and tissue damage-associated cell subsets including neutrophils, Ly6C$^{hi/int}$ monocytes, CD8^{+} T cells and NK cells, which returned to baseline levels by day 14. In addition, interstitial macrophages, but not alveolar macrophages, were numerically expanded on 7 d.p.i. and returned baseline by day 14. No change was observed in eosinophils and CD4^{+} T cells. Notably, gamma-delta T cells were significantly increased at day 7 and remained at elevated levels through 14 d.p.i.
Conclusion: Our findings demonstrate more pronounced immune changes in the lungs from CDA-HFD-fed mice following systemic bacterial infection, particularly within specific immune cell subsets. Future work will focus on lung inflammation, the role of particular subsets, and immune responses to secondary infection.

SAT-183
Cellular membrane tension regulates liver sinusoidal endothelial cell defenestration in early MASLD
Xiaoyu Zhang[1,2], Ning Li[1,2], Mian Long[1,2]. [1]*Insitute of Mechanics, Chinese Academy of Sciences, Beijing, China;* [2]*School of Engineering Science, University of Chinese Academy of Sciences, Beijing, China*
Email: zhangxiaoyu@imech.ac.cn

Background and aims: The fenestrae of liver sinusoidal endothelial cells (LSECs) are essential for lipid exchange between hepatocytes and blood. In early metabolic dysfunction-associated steatotic liver disease (MASLD), defenestration of LSECs exacerbates hepatic steatosis, yet the precise regulatory mechanisms remain unclear. Cellular membrane tension is a key mechanical property that regulates membrane deformation–related biological processes. Given the excessive lipid uptake observed in MASLD, we hypothesized that it alters the plasma membrane composition of LSECs, driving changes in membrane tension which in turn triggers defenestration. This study aimed to elucidate the role of membrane tension in regulating defenestration, a key early pathological feature of MASLD.
Method: Primary mouse LSECs were isolated from healthy or Amylin liver NASH (AMLN) diet-induced early MASLD mice. Membrane tension was modulated by altering the osmotic pressure or the plasma membrane lipid composition and quantified using membrane tether assays or Flipper-TR fluorescent probe. Fenestra dynamics and number were visualized using AFM imaging.
Results: Feeding with AMLN diet for 2 weeks, the liver progressed into simple steatosis. At this stage, the cholesterol content in plasma membrane and membrane tension of LSECs increased and the fenestra number decreased, suggesting an association between plasma membrane composition, membrane tension and fenestrae in LSECs. *In vitro,* disruption of lipid raft integrity or chelating plasma membrane cholesterol decreased membrane tension and increased fenestra number. Direct modulation of membrane tension by hypotonic or hypertonic shock demonstrated that low membrane tension induced by hypertonic shock increased the fenestra number via reducing cell height. Molecular dynamics simulations of a planar lipid bilayer further showed that reduced intermembrane distance facilitated membrane contact and stalk formation, thereby reducing existing energy barriers. Notably, reduction of membrane tension restored the fenestrae, as well as the phenotype and function, of defenestrated LSECs isolated from mice with early MASLD.
Conclusion: Membrane tension negatively regulates LSEC fenestrae. Changes in membrane composition in early MASLD may contribute to their defenestration via membrane tension. This study provides mechanobiological insights into the regulatory mechanisms governing fenestra dynamics in LSECs and the pathogenesis of MASLD.

SAT-184
Synergistic fat mass loss in diet-induced obese mice when thyroid hormone receptor-β agonist ALG-055009 was administered in combination with incretin receptor agonists
Jieun Song[1], Kusum Gupta[1], Peter Althoff[1], Lillian Adame[1], Dinah Misner[1], Tse-I Lin[2], Lawrence Blatt[1], Julian Symons[1], Sushmita Chanda[1], Xuan Luong[1]. [1]*Aligos Therapeutics, Inc., South San Francisco, United States;* [2]*Aligos Belgium BV, Leuven, Belgium*
Email: xluong@aligos.com

Background and aims: ALG-055009 is a potent, selective thyroid hormone receptor (THR)-β agonist that has demonstrated significant reductions in liver fat (placebo-adjusted median relative reductions up to 46.2%) and atherogenic lipids in clinical subjects with presumed metabolic dysfunction-associated steatohepatitis and stage 1–3 liver fibrosis. Thyroid hormone is crucial in regulating metabolism, and THR-β activation has been shown to enhance energy expenditure and promote weight loss. Here, the ability of ALG-055009 to augment the weight loss effects of approved incretin receptor agonists (RAs) was assessed in diet-induced obese (DIO) mice.
Method: Mice were fed a high-fat diet for 25 weeks to induce obesity. In Phase I, mice were treated once daily with either vehicle, oral 1 mg/kg ALG-055009, subcutaneous incretin RAs, 10.0 nmol/kg semaglutide (SEMA), 3.0 nmol/kg tirzepatide (TIRZEP_lo), 10.0 nmol/kg tirzepatide (TIRZEP_hi), or combinations of ALG-055009 with incretin RAs for 4 weeks. In Phase II, SEMA treatment was discontinued in the SEMA monotherapy and SEMA + ALG-055009 groups after 4 weeks, while ALG-055009 treatment was maintained, and animals were monitored for 4 additional weeks. Assessments included body weight (BW), fat and lean tissue mass, and tissue-specific gene expression.
Results: DIO mice treated with incretin RA or combinations of ALG-055009 and incretin RA lost significant BW. Combination of SEMA + ALG-055009 resulted in an additional 9% decrease in BW as compared to SEMA monotherapy. Combination of TIRZEP_lo or TIRZEP_hi with ALG-055009 yielded an added 12% and 6% loss in BW as compared to TIRZEP monotherapy, respectively. Combination therapy resulted in greater reductions in fat mass as compared to incretin RA monotherapy, while lean mass was unchanged. Furthermore, there was significant, synergistic upregulation of *Ucp1* gene expression in the white adipose tissue (WAT) of combination groups.
Conclusion: In DIO mice, ALG-055009 in combination with incretin RAs resulted in profound, synergistic weight loss, with up to 39–40% decreases in BW within 4 weeks. Notably, the additional weight loss conferred by ALG-055009 was from reduction in fat mass and not changes in lean mass. Initial evidence points to this synergistic response being due to increased energy expenditure via browning of WAT, a direct effect of THR-β activation. Overall, THR-β agonism is a potentially powerful, complementary mechanism to combat obesity, enhancing the magnitude and duration of weight loss by incretin RAs.

SAT-185

The UBC13–DOK3 axis drives Kupffer cells activation and promotes metabolic dysfunction-associated steatohepatitis

Yuan-Qiang Ma[1], Yoon-Seok Roh[1]. [1]*Chungbuk National University, Cheongju, Korea, Rep. of South*
Email: ysroh@cbnu.ac.kr

Background and aims: Metabolic dysfunction-associated steatohepatitis (MASH) is driven by chronic hepatic inflammation, in which Kupffer cells (KCs) play a central role. DOK3 is an anti-inflammatory adaptor that undergoes degradation in activated myeloid cells, but its role and regulation in MASH remain unclear. UBC13, a key E2 ubiquitin-conjugating enzyme, mediates K63-linked ubiquitination in inflammatory signaling. Here, we aimed to investigate how UBC13 regulates DOK3 stability thereby affecting KCs activation and MASH progression.
Method: DOK3 was examined in liver tissues from patients and mice with MASH. Stable *Dok3* and *Ubc13* deficient KCs were generated using CRISPR-Cas9–mediated genome editing. *Dok3* knockout mice, KCs-specific deletion of *Ubc13* mice generated by crossing $Ubc13^{fl/fl}$ mice with $Clec4f^{Cre}$ mice, and combined *Ubc13*|*Dok3* deficiency mice were subjected to a fast-food diet–induced MASH model. Spatial transcriptomic profiling of KCs-enriched regions was performed using GeoMx technology to characterize inflammatory signatures.
Results: Here we observed that DOK3 was highly expressed in human and mouse KCs and markedly downregulated in patients and mice with MASH. Importantly, DOK3 expression negatively correlated with serum ALT, AST levels. *Dok3* deficiency promotes KCs activation and MASH progression. Mechanistically, UBC13 facilitated TRAF6-dependent K63-linked ubiquitination of DOK3, thereby promoting its degradation via the autophagy-lysosome pathway in KCs. Loss of DOK3 disrupted SHP-1–SYK interaction, relieving inhibition of SYK signaling and driving M1 polarization of KCs. Consistent with the inhibition of the UBC13–TRAF6 axis to improve DOK3 stability in activated KCs, pharmacological inhibitor of TRAF6 (C25–140) and KCs-specific deletion of *Ubc13* ameliorated MASH in mice by preventing DOK3 degradation. Notably, we observed that UBC13 modulates MASH through a DOK3-dependent manner, given that the protective effects of *Ubc13* deletion were abolished in *Dok3* deficient mice.
Conclusion: We identify UBC13-driven K63-linked ubiquitination of DOK3 as a key mechanism that amplifies SYK signaling and KCs activation, highlighting the UBC13–DOK3 axis as a potential therapeutic target in MASH.

SAT-186

Sex-specific genetic architecture of liver fat content measured by proton density fat fraction in metabolic dysfunction-associated steatotic liver disease

Ayan Mandal[1], Kaulick Mitra[1], Anasuya Chakrabarty[2], Priyadarshi Basu[1]. [1]*BRIC-National Institute of Biomedical Genomics, Kalyani, India;* [2]*Ashoka University, Sonipat, India*
Email: am8@nibmg.ac.in

Background and aims: Metabolic dysfunction-associated steatotic liver disease (MASLD) shows pronounced sexual dimorphism in prevalence, severity and cardiometabolic outcomes. Proton density fat fraction (PDFF) is a quantitative imaging-derived biomarker of hepatic steatosis, yet sex-specific genetic determinants of PDFF remain incompletely characterised. We aimed to identify sex-specific genetic loci associated with PDFF and to evaluate sex-dependent shared genetic architecture between PDFF and MASLD-related metabolic and liver traits.
Method: Sex-stratified genome-wide association studies of inverse-rank normal transformed PDFF were conducted in 28,152 European-ancestry participants from the UK Biobank, including 13,668 males and 14,484 females. Analyses were performed using REGENIE, adjusting for age, age squared, alcohol intake, imaging batch and the first 20 genetic principal components. Genome-wide significance was defined as $p < 5 \times 10$ to the minus eight. Functional annotation was performed using Functional Mapping and Annotation, a web-based platform. Genetic correlations between PDFF and MASLD-related traits were estimated using linkage disequilibrium score regression.
Results: We identified multiple shared and sex-specific genetic loci associated with PDFF, with several loci reaching genome-wide significance exclusively in males or females, indicating sex-dependent genetic effects on hepatic fat accumulation. Genetic correlation analyses demonstrated significant shared heritability between PDFF and liver enzymes, adiposity measures and cardiometabolic traits, with notable differences in magnitude and direction between sexes. PDFF showed stronger genetic correlation with central adiposity and insulin resistance traits in males, whereas correlations with liver injury markers and hormonal traits were more pronounced in females. Pathway analyses highlighted sex-specific enrichment in lipid metabolism, insulin signalling and hormone-related biological processes.
Conclusion: These findings reveal marked sexual dimorphism in the genetic architecture and shared heritability of liver fat content measured by PDFF. Sex-specific genetic coupling between hepatic steatosis and metabolic traits highlights biologically distinct pathways in MASLD and supports the integration of sex-aware approaches in genetic studies and therapeutic development.

SAT-187

Efruxifermin ameliorates palmitate-induced hepatocyte lipotoxicity

Suyavaran Arumugam[1], Michail Kokkorakis[1], Tim Rolph[2], Erik Tillman[2], Wajahat Mehal[1]. [1]*Yale University School of Medicine, New Haven, United States;* [2]*Akero Therapeutics, a Novo Nordisk Company, Boston, United States*
Email: wajahat.mehal@yale.edu

Background and aims: Fibroblast Growth Factor 21 (FGF21) has pleiotropic metabolic effects and FGF21 analogs have significantly improved steatosis, inflammation, and fibrosis in clinical trials in patients with MASH. However, direct hepatocellular effects of FGF21 remain uncharacterized. We explored how FGF21 and the clinical-stage FGF21 analog efruxifermin (EFX) modulate free fatty acid (FFA)-induced dysfunction of human hepatocytes (heps) in vitro.
Method: HepG2 cells or primary human heps were exposed to palmitate from T = 0 h to T = 16 h, followed by addition of FGF21 or EFX. Cells were subsequently analyzed at T = 24 h, T = 32 h, and T = 48 h. Lipid droplet accumulation was assessed using BODIPY staining, and intrahepatocyte distribution of palmitate was assessed using fluorescent BODIPY C16-palmitate. FFA oxidation (FFAO) was quantified using FAOBlue staining. Mitochondrial reactive oxygen species (mtROS) were detected using MitoSOX Red, and mitochondrial membrane potential was measured via TMRE staining. Cellular and subcellular organization, including lipid and organellar localization, were visualized and quantified using confocal microscopy. Gene expression profiles were quantified across conditions over time using bulk RNA-seq.
Results: Palmitate exposure for 16 h resulted in significant increases in steatosis, FAO, and mtROS and reduced mitochondrial membrane potential. Treatment with FGF21 or EFX significantly attenuated steatosis. Confocal imaging revealed cytosolic lipid droplet localization of BODIPY C16-palmitate, which was redirected to mitochondria within 8 h after treatment with FGF21 or EFX. FGF21 and EFX significantly i) enhanced FAO in the palmitate-exposed heps within 8 h, ii) reduced mtROS and prevented the palmitate-induced decline

in mitochondrial membrane potential, and iii) upregulated genes associated with lipid oxidation and mitochondrial fusion. EFX induced a wide range of adaptive changes in the mitochondrial transcriptome of primary human heps exposed to palmitate, including upregulation of UCP2 and ACSL4.
Conclusion: Agonism of FGF21's receptors on isolated heps reverses steatosis by directing FFA to mitochondria and increasing their oxidation. Despite increased oxidative flux, mtROS did not increase. This may have been the result of i) improved mitochondrial efficiency, ii) increased consumption of ATP (and regeneration of ADP) to support higher rates of gluconeogenesis, and/or iii) activation of adaptive stress response pathways.

SAT-188-YI
Improving brain blood flow and reducing microglial activation as the mechanisms behind cognitive improvement following alpha 2A adrenergic receptor antagonism in a mouse model of metabolic dysfunction-associated steatotic liver disease
Anne Catrine Mikkelsen[1], Kristoffer Kjærgaard Amby[1], Cecilie Bay-Richter[2], Elizaveta Melnikova[3], Line Hansen[3], Vladimir Matchkov[3], Karen Louise Thomsen[1,4], Rajeshwar Prosad Mookerjee[1,4]. [1]*Department of Hepatology and Gastroenterology, Aarhus University Hospital, Aarhus, Denmark;* [2]*Translational Neuropsychiatry Unit, Aarhus University, Aarhus, Denmark;* [3]*Department of Biomedicine, Aarhus University, Aarhus, Denmark;* [4]*Institute for Liver and Digestive Health, University College London, London, United Kingdom*
Email: ancami@clin.au.dk

Background and aims: Cognitive dysfunction is a complication of metabolic dysfunction-associated steatotic liver disease (MASLD) without a specific treatment. Cerebrovascular changes are among the suggested causes for this complication of MASLD. This study investigated the effect of antagonism of the alpha2A adrenergic receptor (ADRA2a) as a modulator of cerebral blood flow.
Method: Male C57BL/6NTac mice were fed a modified Amylin-liver non-alcoholic steatohepatitis (AMLN) diet to induce MASLD or a standard diet (controls) for 36 weeks. Half of the MASLD mice received the ADRA2a antagonist Yohimbine in their drinking water for the final 10 weeks. Neurobehavioural tests were conducted to study cognitive function. At termination, laser speckle contrast imaging was used to study cerebral blood perfusion. Immunohistochemical analyses were used to study vasculature, microglia activation (involved in the neurovascular unit), and ADRA2a expression in the brain.
Results: ADRA2a antagonism ameliorated anxiety-like and depression-like behaviour in the MASLD mice. The blood perfusion of the cerebral parenchyma was reduced in the MASLD mice compared with control mice (blood flow index (BFI): 46.9 ± 4.0 arbitrary units (a.u.) vs. 53.2 ± 8.5 a.u., $p = 0.07$, which was completely reversed by ADRA2a antagonism (BFI: 52.1 ± 5.0 a.u., $p = 0.03$). The MASLD mice showed increased contractile tone of capillary pericytes in the brain (capillary diameter: 3.9 ± 0.3 µm vs. 4.8 ± 0.4 µm, $p = 0.02$), which was normalised by ADRA2a antagonism (4.4 ± 0.3 µm, $p = 0.04$), a plausible mechanism for the observed changes in blood perfusion. The microglia staining intensity was greater in the prefrontal cortex of the MASLD mice, implying higher microglia activation compared with control mice ($p = 0.008$), and the microglia had higher expression of ADRA2a ($p = 0.02$ vs. control mice). Microglia activation was reduced by ADRA2a antagonism ($p = 0.07$ vs. MASLD mice), further complimenting the reduced contractile effect on cerebral vasculature.
Conclusion: Ten weeks of ADRA2a antagonism in a MASLD mouse model ameliorated cognitive dysfunction. Our data suggest that this effect was achieved by increasing cerebral blood perfusion through normalisation of capillary pericyte tone and by reducing microglial activation. This paves the way for further mechanistic studies evaluating the role of ADRA2a antagonism, and future clinical translation into MASLD patients at risk of cognitive dysfunction.

SAT-189
Preventive effects of milk-derived exosomes on MASH progression through intestinal barrier protection and gut microbiota modulation
Tatsuya Nakatani[1], Shinya Sato[1], Masafumi Oyama[1], Kosuke Kaji[1], Tadashi Namisaki[1], Hitoshi Yoshiji[1]. [1]*Department of Gastroenterology, Nara Medical University, Kashihara, Japan*
Email: k182324@naramed-u.ac.jp

Background and aims: Metabolic dysfunction-associated steatohepatitis (MASH) has emerged as a major cause of liver cirrhosis and hepatocellular carcinoma. Exosomes are small extracellular vesicles, 50–150 nm in diameter, secreted by cells and known to carry miRNAs, mRNAs, proteins, and micropeptides that mediate intercellular communication. Recently, milk-derived exosomes (B-mEVs) have attracted attention due to their reported effects on improving intestinal barrier function in animal models of intestinal inflammation and their potential anticancer activity. In this study, we investigated the effects of B-mEVs on liver fibrosis, intestinal barrier function, and gut microbiota composition in a murine model of MASH-associated liver fibrosis.
Method: To induce liver fibrosis associated with MASH, female C57BL/6J mice (7 weeks old) were fed a choline-deficient, L-amino acid-defined, high-fat diet (CDAHFD) for 8 weeks. Subsequently, B-mEVs (1.2 mg/kg) were orally administered every other day for 4 weeks before sacrifice. Liver fibrosis was assessed histologically, and intestinal tight junction proteins (TJPs) and intestinal permeability were evaluated. Mice were divided into four groups: (1) Control diet, (2) Control diet + B-mEVs, (3) CDAHFD, and (4) CDAHFD + B-mEVs. The preventive effects of B-mEVs on MASH-related liver fibrosis and their impact on intestinal barrier integrity and gut microbiota composition were examined.
Results: In the CDAHFD group, hepatic steatosis, inflammation, and fibrosis were observed compared to the control group. These pathological changes were partially attenuated in the CDAHFD + B-mEVs group. Regarding intestinal effects, the CDAHFD group showed reduced expression of intestinal TJPs such as ZO-1, Occludin, and Claudin-2, accompanied by a marked increase in intestinal permeability (as measured by FITC-dextran). In contrast, the CDAHFD + B-mEVs group demonstrated enhanced TJP expression and improved intestinal permeability.
16S rRNA gene sequencing of fecal samples revealed that administration of B-mEVs led to changes in α-diversity compared to the CDAHFD group, while β-diversity remained unchanged. Furthermore, the administration of milk exosomes increased the abundance of the genus *Akkermansia*.
Conclusion: Milk-derived exosomes ameliorated CDAHFD-induced intestinal hyperpermeability and showed potential in improving MASH-associated liver fibrosis. These findings suggest that B-mEVs may exert protective effects against MASH progression through modulation of the gut–liver axis.

SAT-190
Long-term intake of bicarbonate-sulfate-calcium-magnesium mineral water improves MASLD-related outcomes by modulating intestinal permeability, systemic inflammation, and oxidative stress
Mario Romeo[1], Carmine Napolitano[1], Marcello Dallio[1], Fiammetta Di Nardo[1], Annachiara Coppola[1], Alessia Silvestrin[1], Giusy Senese[1], Claudio Basile[1], Marco Niosi[1], Alessandro Federico[1].

[1]*Hepatogastroenterology Division, Department of Precision Medicine, University of Campania Luigi Vanvitelli; Piazza Miraglia 2, 80138, Naples (Italy), Naples, Italy*
Email: mariomeo@virgilio.it

Background and aims: Fonte Essenziale®—a mineral water enriched in bicarbonate, sulfate, calcium, and magnesium—has shown potential in modulating the gut-liver axis and gut microbiota in hepatic steatosis. However, its long-term effects on intestinal permeability (IP), IP-related systemic inflammation (SI), and oxidative stress—key contributors to steatosis—remain unexplored in Metabolic dysfunction-Associated Steatotic Liver Disease (MASLD).
Method: Eighty-seven MASLD patients were randomized into two groups: group A received Fonte Essenziale® (400 ml/day, fasting) plus a controlled nutritional regimen (physical exercise and diet) for 12 months, followed by a 6-month washout; group B received the controlled nutritional regimen alone. IP markers, SI cytokines (IL-1β, IL-6, TNF-α), oxidative stress (dROMs/BAP), and clinical data, including Controlled Attenuation Parameter (CAP), were collected at baseline (T0), 12 months (T12), and post-washout (T18). Baseline in-IP was defined by fecal zonulin >110 ng/ml and serum LPS-binding protein (LBPp) >10 µg/ml; im-IP was defined by normalization of both. CAP reduction ≥30% indicated a significant steatosis improvement.
Results: Thirty-eight patients in group A and 39 in group B completed the study. At T12, group A showed significant reductions in fecal zonulin (p: 0.0163) and serum LBPp ($p < 0.0001$), with increased occludin and claudin-1 levels (all $p < 0.0001$). im-IP prevalence was higher in group A (p: 0.0037). IL-1β, TNF-α, IL-6, LPS, and dROM/BAP decreased significantly in group A and among those achieving im-IP (all $p < 0.05$). CAP reduction (T0 vs T12, $p < 0.0001$) and improvements in insulin and HDL levels (all $p < 0.0001$) were observed in group A. Multivariate analysis (adjusted for sex, age, smoking, BMI, diabetes, MASLD-related drugs, and baseline CAP) identified water intake (aHR: 2.104, p: 0.001) and im-IP (aHR: 1.214, p: 0.024) as independent predictors of steatosis improvement. All benefits persisted at T18.
Conclusion: Prolonged Fonte Essenziale® intake significantly improved hepatic steatosis and MASLD-related outcomes by modulating IP, SI, and oxidative stress.

SAT-191

Discovery of MI-676, novel direct target of constitutive androstane receptor (CAR) for therapeutic treatment of metabolism associated steatotic liver disease (MASLD)

Dharani Sai Sreekanth Nellore[1], Alzbeta Štefela[1], Hirsova Petra[2], Stanislav Micuda[3], Radim Nencka[4], Petr Pavek[1]. [1]*Charles University, Faculty of Pharmacy, Hradec Králové 3, Czech Republic;* [2]*Mayo Clinic, Rochester, Minnesota, United States;* [3]*Faculty of Medicine - Charles University, Hradec Králové 3, Czech Republic;* [4]*IOCB Prague, Prague 6, Czech Republic*
Email: nellored@faf.cuni.cz

Background and aims: Lipotoxic apoptosis driven by saturated fatty acids is a central pathogenic mechanism in metabolism associated steatotic liver disease (MASLD). While activation of the constitutive androstane receptor (CAR) has been associated with hepatoprotection, the mechanistic consequences of selective human CAR activation under lipotoxic stress remain unclear. This study examined whether MI-676, a novel human CAR agonist, protects hepatocytes from palmitate-induced apoptosis and to define the underlying molecular pathways.
Method: For the research study, we used differentiated HepaRG, CAR-KO HepaRG, HepG2, Huh7, cells and primary human hepatocytes that were treated with MI-676, and controls, followed by 0.6 mM palmitoic acid exposure. We assessed nuclear and membrane integrity by DAPI staining; Annexin V/PI flow cytometry and caspase-3/7 assays. Further, to confirm CAR activation and elucidate downstream signaling, we isolated mRNA (TRI-reagent) of HepaRG cells, and RT-qPCR was carried out using Fast Advanced Master Mix and TaqMan probes. Protein expression levels were analyzed by SDS-PAGE western blotting with validated antibodies using HepaRG cells. Data represent ≥3 independent experiments and were analyzed by one-way ANOVA.
Results: MI-676 markedly attenuated palmitate-induced nuclear fragmentation and apoptosis in CAR-expressing hepatocytes, evidenced by reduced DAPI nuclear damage, lower Annexin V/PI staining, and decreased caspase-3/7 activity; these cytoprotective effects were absent in CAR-KO cells. MI-676 selectively induced CYP2B6 without transactivating CYP3A4, confirming human CAR specificity. Mechanistically, MI-676 upregulated INSIG-1, limited SREBP-1 maturation and ER stress, and increased anti-apoptotic BCL-2 and MCL-1 transcriptional levels. The concurrent activation of AKT and GADD45B, enhanced MDM2 phosphorylation, leading to XIAP upregulation, and p53 suppression indicate engagement of convergent pro-survival pathways.
Conclusion: In conclusion, MI-676 is a CAR agonist that attenuates palmitate-induced ER stress and apoptosis, exerting dual protective effects: (1) suppression of SREBP-driven lipogenesis and ER stress, and (2) coupling this suppression of lipogenesis with activation of a GADD45B–Src–PP2A–MDM2–XIAP and CAR–AKT–MDM2 survival axis, that overall attenuates P53. These findings provide a robust mechanistic framework for further preclinical evaluation of MI-676 as a hepatoprotective agent in MASLD.

SAT-195

Rifaximin prevents metabolic dysfunction-associated steatohepatitis by suppressing deoxycholic acid-mediated macrophage-hepatocyte dialogue

Mei-Tong Nie[1], Chuan Yin[1], Hongyan Qin[2], Xin Zhang[1], Weifen Xie[1]. [1]*Department of Gastroenterology, Changzheng Hospital, Naval Medical University, Shanghai, China, Shanghai, China;* [2]*State Key Laboratory of Cancer Biology, Department of Medical Genetics and Developmental Biology, Airforce Medical University, Xi'an, China, Shanghai, China*
Email: weifenxie@medmail.com.cn

Background and aims: Metabolic dysfunction-associated steatohepatitis (MASH), a progressive form of metabolic dysfunction-associated steatosis liver disease (MASLD), presents a major therapeutic challenge with limited effective treatments. While the antibiotic rifaximin shows preclinical promise, its precise molecular mechanisms and clinical efficacy remain poorly defined.
Method: We employed high-fat, high-fructose (HFF) diet and choline-deficient, L-amino acid-defined high-fat diet (CDA-HFD) mouse models integrated with targeted bile acid metabolomics and single-nucleus RNA sequencing. Molecular interactions were validated via docking and surface plasmon resonance. Mechanistic insights were confirmed using $Ccr2^{-/-}$, hepatocyte-specific Hnf1-alpha knockout ($Hnf1\text{-}alpha^{L-KO}$), and $S1pr2^{-/-}$ mice. Finally, a proof-of-concept clinical trial evaluated rifaximin's efficacy and safety in patients with MASH.
Results: Rifaximin significantly reduced deoxycholic acid (DCA) levels. Mechanistically, DCA acts as a potent S1PR2 agonist on monocyte-derived macrophages (MoMFs), triggering their hepatic infiltration and the secretion of myeloid differentiation protein 1 (MD-1). MD-1 suppresses hepatocyte HNF1-alpha expression through TLR4 activation. Rifaximin-mediated restoration of HNF1-alpha was essential for therapeutic success, as HNF1-alpha deficiency exacerbated steatosis and sustained a vicious cycle of MoMF

recruitment. In MASH patients, rifaximin treatment led to rapid resolution of hepatic steatosis and injury, with efficacy strongly correlating with reduced serum DCA and MD-1 levels.
Conclusion: Rifaximin attenuates MASH by disrupting a pathogenic DCA-MoMF-HNF1-alpha signaling crosstalk, and our proof-of-concept clinical trial demonstrates that rifaximin treatment leads to rapid and progressive resolution of hepatic steatosis and injury in patients with MASH, with favorable safety and tolerability.

SAT-196
Prime editing enables isogenic modeling of PNPLA3-I148M-associated lipotoxicity in hepatocytes
Haruna Noguchi[1], Takuro Uchida[1,2], Naoki Wakita[3], Mitsumasa Takenaga[4], Tetsushi Sakuma[3], Kei Mori[1], Tomoko Tokumaru[1], Tomoko Saito[1], Masao Iwao[1], Mie Arakawa[1], Mizuki Endo[1], Kazuhiro Mizukami[1]. *[1]Department of Gastroenterology, Faculty of Medicine, Oita University, Yufu, Japan; [2]Division of Travel Medicine and Health, Research Center for GLOBAL and LOCAL Infectious Diseases, Oita University, Yufu, Japan, [3]Graduate School of Agriculture, Kyoto University, Kyoto, Japan; [4]Graduate School of Integrated Sciences for Life, Hiroshima University, Higashi-Hiroshima, Japan*
Email: tuchida@oita-u.ac.jp

Background and aims: The PNPLA3-I148M (rs738409 C > G) variant is a well-established genetic determinant of hepatic steatosis, fibrosis, and hepatocellular carcinoma. However, its precise functional impact on hepatocyte physiology remains incompletely understood. Here, we employed a prime editing system to generate isogenic HepG2 clones representing all PNPLA3 genotypes in an identical genetic background.
Method: We generated the prime editing system for PNPLA3-I148M, which carries all the elements for prime editing such as prime editor (modified PEmax), pegRNA, and ngRNA. In addition, The EGFP gene was fused to the prime editor with an intervening autocleavage site and served as a convenient means to measure prime editor expression. We then introduced the genome editing on the rs738409 genome in hepatoma cells and analyzed the effects of PNPLA3 mutations on steatosis and lipid-induced changes between homozygous 148M variant allele carriers (G/G), noncarriers (C/C), and heterozygous (G/C) under free fatty acid treatment by RNA sequencing.
Results: Prime editing targeting the PNPLA3-I148M variant was successfully achieved in HepG2 cells and enabled modification of the transcriptomic profile in the HepG2 isogenic clones. The PCA revealed a separation of CC from both GG and GC, indicating a genotype-dependent restructuring of the transcriptome. Following palmitic acid (PA) treatment, we evaluated genotype-specific responses to lipotoxic stress. Lipid droplet accumulation and cell viability assays described that clones harboring the G allele (GG, GC) exhibited enhanced lipid storage and reduced sensitivity to PA-induced toxicity compared to wild-type (CC) clones. Transcriptomic profiling revealed distinct expression patterns among genotypes, consistent with differential regulation of lipid handling and stress adaptation programs. Heterozygous clones displayed intermediate phenotypes, suggesting a gene dosage-dependent effect of PNPLA3-I148M on hepatocellular lipotoxicity.
Conclusion: We demonstrate that prime editing enables a precise approach for modeling disease-associated genetic variants in human hepatocytes, offering a platform to investigate genotype-specific cellular responses. By combining precise genome editing with human cell modeling, this study provides new insight into the biology of a key risk allele and establishes a platform for personalized therapeutic strategies targeting genetically defined subgroups of liver disease.

SAT-197
Impact of PFAS on lipid metabolism in MASLD is mediated through steroids and bile acids
Pauli Tikka[1], Aidan McGlinchey[2], Sami F. Qadri[3], Ilia Evstafev[1], Alex Dickens[1], Hannele Yki-Jarvinen[3], Tuulia Hyötyläinen[2], Matej Orešič[1,2]. *[1]University of Turku, Turku, Finland; [2]32moc, Örebro, Sweden; [3]University of Helsinki, Helsinki, Finland*
Email: matej.oresic@oru.se

Background and aims: Endogenous steroid hormones are key regulators of hepatic lipid metabolism, insulin sensitivity, and inflammatory responses. As potential mediators of environmentally induced metabolic dysfunction, we investigated the associations between steroid hormones and metabolic dysfunction–associated steatotic liver disease (MASLD) severity, the effects of per- and polyfluoroalkyl substances (PFAS) on steroid hormone levels, and whether hormone alterations link PFAS exposure to downstream changes in lipid and bile acid (BA) metabolism.
Method: Using sex-stratified analyses, we examined relationships among circulating steroid hormone concentrations, MASLD histological features, hepatic lipid and BA profiles, and PFAS exposure in a human cohort of 104 patients with MASLD.
Results: Steroid hormones were strongly associated with MASLD severity in a sexually dimorphic manner. Dihydrotestosterone, particularly in females, showed consistent inverse associations with steatosis, fibrosis, necroinflammation, and insulin resistance. Dehydroepiandrosterone exhibited sex-divergent patterns, associating positively with multiple lipid classes in males and with secondary BAs in females, suggesting involvement of a gut–liver–steroid axis. PFAS exposure was associated with altered steroid hormone levels, predominantly in females, with most significant associations indicating suppression of steroidogenesis. These PFAS-associated hormone changes were further linked to alterations in hepatic lipid and BA metabolism, supporting their role as metabolic intermediates. Overall, females demonstrated stronger PFAS–hormone–BA associations, whereas males showed more limited, lipid-focused effects. Causal mediation analysis further corroborated indirect effects of PFAS exposure on lipids and BAs via steroids. Specifically, testosterone/epi-testosterone mediated the impact of PFAS on increased ether phospholipid levels ($P < 0.001$), while estradiol mediated the impact of PFAS on increased hepatotoxic lithocholic acid levels ($P < 0.001$).
Conclusion: Our findings indicate that PFAS exposure is associated with broad, sex-specific disruption of steroid hormone pathways, which may contribute to MASLD progression through downstream effects on lipid and BA metabolism. These results highlight the relevance of endocrine-disrupting chemicals in MASLD pathophysiology and emphasize the need to consider sex-specific mechanisms in future mechanistic and therapeutic studies.

SAT-198-YI
Metabolic ferroptosis as targetable signature for the genetic subtype of MASLD
Erika Paolini[1], Marica Meroni[1], Miriam Longo[1], Sara Badiali[2], Marco Maggioni[3], Anna Ludovica Fracanzani[4], Paola Dongiovanni[1]. *[1]Medicine and Metabolic Diseases, Fondazione IRCCS Cà Granda, Ospedale Maggiore Policlinico, Milan, Italy; [2]Department of Surgery, Fondazione IRCCS Ca' Granda Ospedale Maggiore Policlinico, Milan, Italy; [3]Department of Pathology, Fondazione IRCCS Ca' Granda Ospedale Maggiore Policlinico, Milan, Italy; [4]Department of Pathophysiology and Transplantation, Università degli Studi di Milano, Medicine and Metabolic Diseases, Fondazione IRCCS Cà Granda, Ospedale Maggiore Policlinico, Milan, Italy*
Email: paola.dongiovanni@policlinico.mi.it

Background and aims: The co-presence of the I148M-PNPLA3, rs641738-MBOAT7 and E167K-TM6SF2 polymorphisms enhances the risk of severe MASLD. Emerging evidence highlighted that ferroptosis is essential for developing MASLD/MASH since it promotes oxidative stress, lipid peroxidation and inflammation although the underlying

mechanisms are still unknown. Thus, this study investigated the possible crosslink between ferroptosis and the three mutations in hepatic biopsies of MASLD patients, through a spatial transcriptomic (ST) approach.
Method: ST was performed by Visium CytAssist and data were analyzed using Spaceranger (10x Genomics). Patients, featured by a similar histological severity (NAS≥4) and comparable comorbidities (gender, age, BMI, absence of T2D), were wild type (WT), homozygous for PNPLA3, MBOAT7, TM6SF2 polymorphisms and carriers of the 3 at-risk variants (3NRV) (n = 2/group).
Results: All samples were integrated and clustered at 0.5 resolution allowing the identification of 7 clusters (cl), annotated as follows: cl0 enriched in periportal HEPs; cl1 in immune cells; cl2 in pericentral HEPs; cl3 in cholangiocytes; cl4 in endothelial cells (ENDOs); cl5 in immune cells; cl6 in NPCs (HSCs, immune cells and ENDOs); cl7 in HEPs. Firstly, we observed that cl4 was more abundant in PNPLA3, MBOAT7, TM6SF2 and 3NRV samples compared to WT, whereas cl6 was mainly enriched in patients carrying the 3 at-risk variants *vs* all. Then, we conducted a Pathway-enrichment analysis by considering differentially expressed genes (DEGs; Log2FC>0.5 and padj FDR<0.05) of 3NRV in all clusters *vs* the other samples. The former exhibited increased lipid metabolism, oxidative damage, inflammation, fibrosis, and ferroptosis reflecting a worse clinical *scenario*. By focusing on the ferroptosis pathway, we found that in patients carrying TM6SF2 and MBOAT7 variants, it was mainly espressed in immune cells whereas in *PNPLA3* and 3NRV, also in HEPs. Moreover, cl6 showed the strongest upregulation of a "metabolic" ferroptosis, driven by lipid buildup and mitocondrial dysfunction. It was designed by a signature of 53 unique genes, which was uregulated only in 3NRV patients, thus rappresenting a pathognonomic feature of the "genetic" subtype of MASLD.
Conclusion: The co-presence of *PNPLA3*, *MBOAT7*, and *TM6SF2* variants may accelerate liver injury by triggering a lipid-metabolism and mitochondrial ferroptosis. Thus, ferroptosis could be a potential druggable signature to tackle 3NRV MASLD patients.

SAT-199-YI
Three-dimensional mapping of hepatocellular carcinoma links bile canalicular defects to MASLD-associated tumorigenesis
Cristian Perez Gallardo[1,2], Dilan Martinez Torres[1,2], Valeria Candia-Campano[1,2], Karen Almendras-Durán[1,2], Sebastián Fuller-Vargas[1,2], Jorge Vergara-Estrada[2,3], Ricardo Velasco[4], Felipe Aguilera-Muñoz[1,2], Hernán Morales-Navarrete[4], Fabián Segovia-Miranda[1,2]. Email: cristianfperez@udec.cl

Background and aims: Metabolic dysfunction-associated steatotic liver disease (MASLD) is the most common liver disease worldwide and progresses through various stages that can culminate in hepatocellular carcinoma (HCC). Previous studies have shown that bile canaliculi (BC), a bile-carrying microscopic network, are altered in the early stages of MASLD, potentially leading to accumulation of bile acids (BA), known carcinogens. However, the structural organization of BC in advanced stages such as HCC, and its possible contribution to tumour development, remain poorly understood. Could bile canalicular alterations promote MASLD-associated HCC development?
Method: A MASH–HCC mouse model was generated by neonatal streptozotocin injection and high-fat diet. Serum metabolism, hepatic gene expression, and bile acid levels were assessed by biochemical assays and HPLC. Liver microarchitecture—including bile canaliculi, sinusoids, and hepatocytes—was reconstructed in 3D across disease stages using multiphoton microscopy and deep-learning-based analysis, with specific imaging of tumour–adjacent regions. Mouse and human RNA-seq datasets were used to evaluate bile acid–related transcriptional changes.
Results: The MASH–HCC model exhibited hyperglycemia, inflammation, increased proliferation, and evident tumour formation, accompanied by elevated total and individual serum bile acids. 3D reconstruction revealed profound bile canalicular network disruption within tumours and at tumour–adjacent interfaces, consistent with impaired bile flow, and local bile acid accumulation. These structural alterations were supported by public mouse and human RNA-seq datasets showing upregulation of bile acid–related genes in tumours compared to healthy tissue.
Conclusion: We found BC alterations that can be linked to BA accumulation in tumour tissue and tumorigenesis, supported by molecular analysis of BA metabolism. Overall, our findings provide new insights into the pathophysiology of MASLD-associated HCC and suggest potential therapeutic strategies.

SAT-200
Humanized immune system mice for preclinical modeling of liver fibrosis and metabolic dysfunction-associated steatohepatitis
Clothilde Philouze[1], Omayra Martin Rodriguez[1], Anaïs Meynet-cordonnier[1], Sebastien Tabruyn[1], Dan Georgess[1].
[1]*Archamps, France*
Email: clothilde.philouze@tcbioservices.com

Background and aims: Developing models that pertinently reflect immune system contributions to liver disease is essential for evaluating therapeutic candidates targeting inflammation, fibrogenesis and metabolic dysfunction. We aimed to characterize two rapid induction strategies in humanized immune system NCG mice (HIS-NCG) to generate distinct phenotypes of liver injury, advanced fibrosis and metabolic dysfunction-associated steatohepatitis (MASH).
Method: HIS-NCG mice engrafted with human $CD34^+$ hematopoietic stem cells were subjected either to repeated carbon tetrachloride (CCl_4) exposure over 23 days or to a 14-day high-fat diet deficient in methionine and choline (HF-MCD). Clinical condition, circulating alanine aminotransferase, liver histopathology, fibrosis stage, steatosis, human $CD68^+$ macrophage infiltration and circulating galectin-3-binding protein (LGALS3BP) were assessed to define the resulting phenotypes.
Results: Both injury paradigms caused rapid health deterioration and marked biochemical evidence of hepatic damage. CCl_4 consistently produced advanced fibrosis, with most animals developing extensive bridging fibrosis or cirrhotic architecture in the absence of steatosis or human macrophage infiltration. In contrast, the HF-MCD diet induced the signature multi-component phenotype of MASH, including pronounced steatosis, a NAFLD Activity Score (NAS) of 6, low-grade fibrosis and substantial infiltration of human $CD68^+$ macrophages. Elevated LGALS3BP further supported immune-mediated inflammation and fibrogenesis.
Conclusion: These two humanized immune system mouse models provide complementary tools for the preclinical investigation of therapies targeting immune-driven pathways in liver disease. The CCl_4 model recapitulates advanced fibrotic architecture, whereas the HF-MCD diet encompasses metabolic stress and human immune activation. In addition, a dual-humanized configuration integrating both human immune system and hepatocytes is also available. This expanded platform enables the evaluation of combination strategies relevant to both MASH and infectious hepatitis.

SAT-201

Single-cell integration of transcriptomics and mtDNA sequencing identifies pan-cellular mosaic mitochondrial heteroplasmy as a hallmark of MASH

Carlos Pirola[1], Silvia Sookoian[1]. [1]*Translational Research in Health Center, Universidad Maimonides, Buenos Aires, Argentina, National Scientific and Technical Research Council, Buenos Aires, Argentina, CABA, Argentina*
Email: pirola.carlos@maimonides.edu

Background and aims: Metabolic dysfunction-associated steatohepatitis (MASH) is characterized by chronic metabolic and mitochondrial stress. While mitochondrial impairments are well-documented in liver tissue, the landscape of mitochondrial DNA (mtDNA) heteroplasmy across diverse hepatic cell types remains poorly defined. We leveraged single-nucleus RNA sequencing (snRNA-seq) to quantify mtDNA heteroplasmy throughout the entire cellular atlas of the MASH liver.
Method: We analyzed a publicly available 10x Genomics snRNA-seq dataset (GSE212837) comprising liver samples from individuals with MASH and healthy controls. Following quality control and cell annotation, mtDNA heteroplasmy was quantified per cell using the maximum alternative allele fraction and the count of variants with frequency ≥ 0.1. These metrics were integrated into heteroplasmy scores. We assessed differences in heteroplasmy distributions across hepatocytes, macrophages, endothelial cells, cholangiocytes, and fibroblasts using Mann–Whitney tests with false discovery rate correction.
Results: Analysis of 117,793 cells revealed a systemic shift toward increased mtDNA heteroplasmy in MASH. Hepatocytes exhibited the most profound shift ($p = 1.0 \times 10^{-50}$) with an excess of cells in the upper heteroplasmy quantiles. Significant heteroplasmy increases were also observed in endothelial cells ($p = 1.0 \times 10^{-28}$), macrophages ($p = 4.3 \times 10^{-18}$), and fibroblasts ($p = 8.5 \times 10^{-11}$). Cholangiocytes showed a modest but significant increase. Across all lineages, MASH was characterized by an expansion of high-heteroplasmy cell subpopulations, with substantial shifts observed in *MT-ATP6* (cholangiocytes) and *MT-CO1* (resident NK cells and hepatocytes). Heteroplasmic variants were predominantly concentrated in Complex I, III, and IV genes and ribosomal RNAs (*MT-RNR1/2*). By definition, somatic-like variants exhibited cell-type-specific restricted prevalence. This accumulation of mosaic alterations suggests that mitochondrial genomic instability in MASH is driven by localized somatic mutagenesis, in addition to substantial germline inheritance.
Conclusion: Mitochondrial DNA heteroplasmy is a pan-cellular hallmark of MASH, extending beyond hepatocytes to the broader liver microenvironment. This systemic mitochondrial genomic instability suggests a novel axis of cellular remodeling, positioning targeted mitochondrial preservation as a critical therapeutic strategy to arrest MASH progression.

SAT-202

Unraveling the therapeutic mechanism of hyodeoxycholic acid in metabolic dysfunction-associated steatotic liver disease-to-hepatocellular carcinoma: a multi-omics approach identifies key targets and a prognostic gene signature

Wenying Qi[1], Qiuyue Wang[1], Xinyu Zhao[1], Chunfeng Mei[2], Meilan Huang[1], Jiatu Zhong[1], Fan-E Cheng[1], Xiangyun Zou[3], Size Li[1], Shihao Zheng[3], Yong'an Ye[1]. Email: yeyongan@vip.163.com

Background and aims: Hyodeoxycholic acid (HDCA), a secondary bile acid with reported anti-inflammatory and anti-fibrotic properties, has emerged as a potential modulator of metabolic dysfunction-associated steatotic liver disease (MASLD) progression. However, the molecular mechanisms by which HDCA influences lipid metabolism and intercellular communication during MASLD-to-hepatocellular carcinoma (HCC) transition remain poorly characterized. This study aimed to systematically investigate the therapeutic targets and mechanisms of HDCA in MASLD-HCC progression using integrated bioinformatics and experimental validation.
Method: HDCA target prediction via five databases (e.g., SwissTargetPrediction) identified 654 potential proteins. Differentially expressed genes during MASLD-HCC progression were analyzed using Gene Expression Omnibus datasets (GSE126848, GSE135251, GSE164760). Subsequent analyses included functional enrichment, prognostic modeling with 101 machine learning combinations, single-cell RNA-seq (GSE189175), molecular docking, and 100-ns molecular dynamics simulations. For in vivo validation, a MASLD-HCC mouse model was established in male C57BL/6J mice using a high-fat diet, 5% fructose water, and weekly diethylnitrosamine injections (50 mg/kg) for 8 weeks. Mice (n = 10/group) were randomized to receive vehicle, low- (50 mg/kg) or high-dose (100 mg/kg) HDCA, or resmetirom (positive control) by gavage for 8 weeks. Outcomes assessed serum biochemistry, liver histopathology, tumor burden, and target validation.
Results: Intersection analysis identified 69 candidate genes enriched in fatty acid metabolism and steroidogenesis pathways. A 5-gene signature (CBS, HSD3B, SLCO1A2, HMOX1, CYP26B1) showed robust prognostic performance across three independent cohorts. Single-cell analysis revealed HMOX1 expression in macrophages and CBS in cholangiocytes, while hepatic stellate cells and macrophages exhibited elevated signature activity in disease groups. Molecular docking confirmed stable HDCA binding to all signature proteins, with highest affinity for CYP26B1. In a MASLD-HCC mouse model, both high- and low-dose HDCA treatments significantly reduced hepatic tumor nodules, improved liver function, lowered fibrosis scores, and downregulated signature gene expression.
Conclusion: HDCA exerts hepatoprotective effects in MASLD-HCC by targeting the CYP26B1-centered 5-gene signature, reducing tumor burden and improving liver pathology, positioning it as a promising therapeutic candidate.

SAT-203

Deoxycholic acid promotes inflammation-to-cancer transition in metabolic dysfunction-associated steatohepatitis through a multi-omics identified gene signature

Wenying Qi[1], Fan-E Cheng[1], Size Li[1], Qiuyue Wang[1], Xinyu Zhao[1], Chunfeng Mei[1], Linshuang Dou[1], Jinyu Li[1], Meilan Huang[1], Jiatu Zhong[1], Li Hou[1]. [1]*Dongzhimen Hospital of Beijing University of Chinese Medicine, Beijing, China*
Email: houli1203@126.com

Background and aims: Deoxycholic acid (DCA), a secondary bile acid elevated in metabolic dysfunction-associated steatohepatitis (MASH), is known to drive hepatocyte injury and inflammatory responses. However, its mechanistic role in promoting the transition from MASH to hepatocellular carcinoma (HCC) remains incompletely understood. This study aimed to identify DCA-associated inflammatory mediators and gene signatures that facilitate MASH-related hepatocarcinogenesis through integrated multi-omics analysis and experimental validation.
Method: DCA targets were predicted and cross-referenced with transcriptomic data from metabolic dysfunction-associated steatotic liver disease (MASLD), MASH, and HCC to identify candidate genes. Prognostic modeling was performed using The Cancer Genome Atlas

(TCGA) data. Binding was evaluated via molecular docking and dynamics simulations. In vivo validation used a MASH-HCC mouse model induced by high-fat diet and diethylnitrosamine for 16 weeks. Starting from week 9, mice were treated with DCA, lenvatinib, or polyene phosphatidylcholine, followed by histopathological and molecular analyses.

Results: By integrating 677 predicted DCA targets with differentially expressed genes (DEGs) from MASH, MASLD, and HCC cohorts, 77 candidate genes were identified. Cox regression analysis highlighted 30 genes with prognostic significance, from which a 7-gene signature (HMMR, AKR1B10, CYP26B1, et al.) was constructed, showing robust prognostic performance. Single-cell analysis revealed elevated activity of this signature in hepatic stellate cells and T lymphocytes within MASH-HCC samples. CellChat analysis indicated enhanced laminin signaling between hepatic stellate cells and cholangiocytes in disease groups compared to controls. Molecular docking confirmed stable binding of DCA to all seven signature proteins. In the MASH-HCC mouse model, compared with the positive control drug, DCA administration significantly exacerbated hepatic fibrosis ($p < 0.05$), increased pro-inflammatory cytokines(interleukin-6 and tumor necrosis factor alpha, $p < 0.05$), and upregulated the 7-gene signature expression, confirming its functional role in the inflammation-cancer transition.

Conclusion: DCA accelerates MASH-driven hepatocarcinogenesis through a functionally validated 7-gene signature that orchestrates inflammatory responses and intercellular communication. These findings establish DCA and its downstream targets as potential therapeutic candidates for preventing MASH-related HCC progression.

SAT-204

Network pharmacology and multi-omics reveal the hepatoprotective mechanism of pig bile in metabolic dysfunction-associated steatotic liver disease via the gut-liver axis

Wenying Qi[1], Li Hou[1], Bo Jia[1], Qiuyue Wang[1], Xinyu Zhao[1], Chunfeng Mei[1], Shihao Zheng[1], Fan-E Cheng[1], Yaxi Zhang[2], Size Li[1].
[1]Dongzhimen Hospital of Beijing University of Chinese Medicine, Beijing, China; [2]Dongzhimen Hospital, Beijing University of Chinese Medicine, Dongzhimen Hospital, Beijing University of Chinese Medicine, Beijing 100700, China, Liver Diseases Academy of Traditional Chinese Medicine, Beijing University of Chinese Medicine, Key Laboratory of Chinese Internal Medicine of Ministry of Education and Beijing, Dongzhimen Hospital, Beijing University of Chinese Medicine, Beijing, China
Email: lisize5500@163.com

Background and aims: Metabolic dysfunction-associated steatotic liver disease (MASLD) and its progressive form, metabolic dysfunction-associated steatohepatitis (MASH), represent a major global health burden with limited therapeutic options. Pig bile has been traditionally used for hepatoprotection, yet its mechanism of action via the gut-liver axis remains poorly understood. This study aimed to elucidate the molecular mechanisms by which pig bile delays MASLD/MASH progression.

Method: Fifty 6-week-old male db/db mice were randomly divided into 5 groups (10 mice/group): normal diet, high-fat diet (HFD) +fructose, HFD+fructose+porcine bile (equivalent dose), HFD+fructose+porcine bile (double dose), and HFD+fructose+positive control (polyenphosphatidylcholine). After 8 weeks of modeling, mice received 8 weeks of oral administration. Potential therapeutic targets were identified by integrating network pharmacology with transcriptomic data from MASLD models. Gut microbiota composition was analyzed via 16S rRNA sequencing. Spearman correlation analysis assessed relationships between microbial abundance and serum levels of alanine aminotransferase (ALT), aspartate aminotransferase (AST), low-density lipoprotein (LDL), and lipopolysaccharide (LPS). Core targets were identified through protein-protein interaction network analysis and subsequently validated by quantitative polymerase chain reaction and western blotting.

Results: Network pharmacology identified 128 overlapping targets between pig bile bioactive compounds and MASLD-associated genes. Kyoto Encyclopedia of Genes and Genomes (KEGG) pathway enrichment showed significant involvement in peroxisome proliferator-activated receptor gamma (PPARG) signaling and bile acid metabolism. Three core targets were obtained: Sterol Regulatory Element Binding Protein 1c (SREBP1c), PPARG, and C-X-C motif chemokine ligand 2 (CXCL2). In vivo validation confirmed that pig bile significantly attenuated hepatic steatosis and lobular inflammation, upregulated SREBP1c and PPARG expression ($p < 0.05$), and increased intestinal occludin and claudin-1 levels ($p < 0.05$). Gut microbiota analysis revealed that Colidextribacter abundance was positively correlated with ALT ($p < 0.01$) and LPS levels ($p < 0.05$).

Conclusion: Porcine bile improves the progression of MASLD by regulating the gut-liver axis and targeting *SREBP1c*, *PPARG* and *CXCL2*. These research findings provide a mechanistic basis for the application of porcine bile-derived compounds in the treatment of metabolic liver diseases.

SAT-205

JiguCao capsule alleviates metabolic dysfunction-associated steatotic liver disease through modulation of gut-liver axis and toll-like receptor 4 signaling

Wenying Qi[1], Xiaobin Zao[2], Hening Chen[3], Yue Chen[4], Ruijia Liu[1], Xin Sun[5], Tingyu Zhang[1], Linshuang Dou[1], Yaxi Zhang[1], Xiaoke Li[5].
[1]Dongzhimen Hospital of Beijing University of Chinese Medicine, Beijing, China; [2]Dongzhimen Hospital, Beijing University of Chinese Medicine, Dongzhimen Hospital, Beijing University of Chinese Medicine, Beijing 100700, China, Liver Diseases Academy of Traditional Chinese Medicine, Beijing University of Chinese Medicine, Key Laboratory of Chinese Internal Medicine of Ministry of Education and Beijing, Dongzhimen Hospital, Beijing University of Chinese Medicine, Beijing, China; [3]Yongshun Community Health Service Center, Beijing, China, Dongzhimen Hospital, Beijing University of Chinese Medicine, Beijing 100700, China, Liver Diseases Academy of Traditional Chinese Medicine, Beijing University of Chinese Medicine, Beijing, China; [4]School of Chinese Medicine, Li Ka Shing Faculty of Medicine, the University of Hong Kong, Hong Kong, China; [5]Dongzhimen Hospital, Beijing University of Chinese Medicine, Beijing 100700, China, Liver Diseases Academy of Traditional Chinese Medicine, Beijing University of Chinese Medicine, Beijing, China
Email: lixiaoke@vip.163.com

Background and aims: Metabolic dysfunction-associated steatotic liver disease (MASLD) represents a growing global health burden, with gut-liver axis dysfunction and lipopolysaccharide (LPS)-mediated toll-like receptor 4 (TLR4) pathway activation recognized as key pathogenic drivers. JiguCao capsule (JCF), a traditional Chinese medicinal formulation, has demonstrated hepatoprotective properties in clinical practice, yet its molecular mechanisms remain incompletely understood. This study aimed to elucidate the therapeutic mechanisms of JCF in MASLD, with particular focus on LPS-TLR4 signaling and gut-liver axis homeostasis. The funding for this study was sourced from the World Federation of Chinese Medicine Societies (targeted entrustment), with project numbers WFCMS2024026 and WFCMS2024027.

Method: MASLD was induced in wild-type and TLR4-knockout C57BL/6J mice via a 16-week high-fat diet with 5% fructose water. Mice ($n = 10$ per group) were randomized to receive normal diet, MASLD model with vehicle, JCF (low and high dose), or polyene phosphatidylcholine (positive control) by gavage. Assessments included serum biochemistry, hepatic histopathology, and western blotting for TLR4 pathway components. Multi-omics analyses comprised 16S ribosomal RNA gene sequencing for gut microbiota, ultra-high-performance liquid chromatography-tandem mass spectrometry for bile acid profiling, hepatic transcriptomics, and proteomics. Molecular docking evaluated interactions between JCF bioactive components and TLR4.

Results: JCF treatment significantly attenuated MASLD severity, reducing body weight gain ($p < 0.01$), hepatic steatosis scores, and serum Alanine Aminotransferase, Aspartate Aminotransferase,and LPS levels compared with vehicle-treated MASLD mice($p < 0.01$). Histological analysis demonstrated reduced lipid accumulation and inflammatory infiltration. JCF enhanced intestinal barrier function by upregulating tight junction proteins claudin-1 and occludin ($p < 0.01$). Western blotting revealed suppressed TLR4-MyD88-NF-kappaB pathway activation in JCF-treated mice. Notably, the therapeutic effects of JCF were significantly attenuated in TLR4-knockout mice, confirming TLR4 pathway dependency.
Conclusion: JiguCao capsule ameliorates MASLD progression through TLR4-dependent suppression of hepatic inflammation, restoration of gut-liver axis homeostasis, and modulation of lipid metabolism. These findings provide mechanistic insights supporting the therapeutic potential of JCF as a multi-target intervention for MASLD.

SAT-206

Lysimachia christinae attenuates metabolic dysfunction-associated steatotic liver disease progression through immune-metabolic modulation: an integrative network pharmacology and experimental study

Wenying Qi[1], Li Hou[1], Xinyu Zhao[1], Qiuyue Wang[1], Bo Jia[1], Fan-E Cheng[1], Size Li[1], Xiangyun Zou[2], Meilan Huang[1], Jiatu Zhong[1], Xiaobin Zao[2]. *[1]Dongzhimen Hospital of Beijing University of Chinese Medicine, Beijing, China; [2]Dongzhimen Hospital, Beijing University of Chinese Medicine, Dongzhimen Hospital, Beijing University of Chinese Medicine, Beijing 100700, China, Liver Diseases Academy of Traditional Chinese Medicine, Beijing University of Chinese Medicine, Key Laboratory of Chinese Internal Medicine of Ministry of Education and Beijing, Dongzhimen Hospital, Beijing University of Chinese Medicine, Beijing, China*
Email: A3417@bucm.edu.cn

Background and aims: Metabolic dysfunction-associated steatotic liver disease (MASLD) affects over 30% of people globally with limited treatments. Lysimachia christinae, a traditional hepatoprotective herb, has unclear mechanisms. This study integrated network pharmacology, multi-omics, and experimental validation to systematically elucidate its therapeutic targets and pathways in MASLD.
Method: Active compounds of Lysimachia christinaewere identified via the Traditional Chinese Medicine Systems Pharmacology database for target prediction. Transcriptomic datasets (GSE135251, GSE162694) and single-cell RNA sequencing (RNA-seq) data (GSE136103) were analyzed to detect MASLD-related differentially expressed genes and to perform cell-type-specific enrichment. Machine learning algorithms, including Least Absolute Shrinkage and Selection Operator, Support Vector Machine-Recursive Feature Elimination, and Random Forest, were employed to prioritize candidate targets. After eight weeks of modeling with a high-fat diet supplemented with 5% fructose in drinking water, db/db mice were administered Lysimachia christinaeextract (200/400 mg/kg/day) or polyene phosphatidylcholine for 8 weeks ($n = 10$ per group), with db/m mice serving as the negative control.
Results: Network pharmacology analysis identified quercetin as the principal active component, with enrichment in peroxisome proliferator-activated receptor (PPAR) signaling pathways. Based on the 30 intersecting genes identified from the transcriptome dataset and single-cell sequencing, including C-X-C motif chemokine ligand 10 (CXCL10) and PPAR alpha (PPARA), they were significantly enriched in lipid metabolism and inflammatory response pathways ($p < 0.05$). Machine learning algorithms consistently identified CXCL10 as the top-ranked candidate target. In db/db mice, Lysimachia christinae treatment significantly reduced hepatic steatosis scores ($p < 0.01$), serum alanine aminotransferase levels ($p < 0.05$), and CXCL10 messenger RNA expression in liver tissue compared with vehicle-treated controls.
Conclusion: Lysimachia christinae ameliorates MASLD progression by modulating immune-metabolic crosstalk, with CXCL10 identified as a key mechanistic target and potential therapeutic biomarker. This integrative framework provides a methodological template for systematic investigation of herbal medicine mechanisms.

A novel gamma-aminobutyric acid type A receptor modulator attenuates liver fibrosis with profound anti-obesity action

Elisabeth Rohbeck[1], Corinna Niersmann[2,3], Bedair Dewidar[2,3], Volker Lauschke[4,5], Margriet Ouwens[3,6], Michael Roden[2,3,7], Juergen Eckel[1]. *[1]CMR CureDiab Metabolic Research GmbH, Düsseldorf, Germany; [2]Institute for Clinical Diabetology, German Diabetes Center, Leibniz Center for Diabetes Research at Heinrich-Heine-University Düsseldorf, Düsseldorf, Germany; [3]German Center for Diabetes Research (DZD), Partner Düsseldorf, München-Neuherberg, Germany; [4]Department of Physiology & Pharmacology, Section for Personalized Medicine and Drug Development, Karolinska Institutet, Stockholm, Sweden; [5]Dr Margarete Fischer-Bosch Institute of Clinical Pharmacology, Stuttgart, Germany; [6]Institute of Clinical Biochemistry and Pathobiochemistry, German Diabetes Center (DDZ), Düsseldorf, Germany; [7]Department of Endocrinology and Diabetology, Medical Faculty and University Hospital Düsseldorf, Heinrich-Heine-University Düsseldorf, Düsseldorf, Germany*
Email: juergen.eckel@curediab.de

Background and aims: Obesity-associated metabolic dysfunction–associated steatotic liver disease is a major driver of progressive liver fibrosis. Gamma-aminobutyric acid type A ($GABA_A$) receptor signaling has emerged as a potential modulator of liver injury and metabolic dysfunction. We investigated the anti-fibrotic and metabolic effects of the novel small molecule HK3, a positive allosteric modulator of the $GABA_A$ receptor.
Method: The effects of HK3 and its derivative HK1 were assessed in human spheroids and activated human hepatic stellate cells. Steatosis, inflammation and fibrosis were evaluated using immunoblotting, enzyme-linked immunosorbent assays, quantitative PCR and RNA sequencing. In vivo efficacy was examined in a carbon tetrachloride–induced fibrosis model and a diet-induced obesity mouse model. Effects on mitochondrial respiration were studied in differentiated adipocytes and visceral adipose tissue using extracellular flux analysis and high-resolution respirometry.
Results: HK3 significantly reduced intracellular lipid accumulation, inflammatory cytokine release and collagen production in human MASH spheroids. In hepatic stellate cells, HK3 and HK1 attenuated transforming growth factor beta–induced pro-fibrotic and inflammatory gene expression and reduced cell migration. In vivo, HK3 prevented fibrosis progression in toxic liver injury and decreased body fat mass and circulating cholesterol levels in obese mice. Finally, HK3 increased mitochondrial proton leak and reduced coupling efficiency in adipocytes and visceral adipose tissue.
Conclusion: HK3 combines anti-fibrotic, anti-inflammatory and anti-steatotic effects across multiple preclinical models. These findings support $GABA_A$ receptor modulation as a multi-target therapeutic strategy for obesity-associated metabolic dysfunction–associated steatotic liver disease.

SAT-212

Modulation of interactions between mitochondria and the endoplasmic reticulum by resmetirom in MASLD

Théo Rousseaux[1,2], Cyrielle Caussy[2,3], Jennifer Rieusset[1,2]. *[1]CarMen Laboratory, INSERM U1060, INRAE U1397, Université Claude Bernard Lyon 1, Pierre-Bénite, France; [2]Lyon Hepatology Institute, IHU EVEREST, Lyon, France; [3]Hospices Civils de Lyon, Département Endocrinologie, Diabète et Nutrition, Hôpital Lyon Sud, Pierre-Bénite, France*
Email: jennifer.rieusset@univ-lyon1.fr

Background and aims: Poor calcium coupling between the endoplasmic reticulum (ER) and mitochondria, at contact points called

mitochondria-associated ER membranes (MAMs), plays a role in the development of insulin resistance and metabolic dysfunction-associated steatotic liver disease (MASLD). Recently, resmetirom (a thyroid hormone receptor agonist, THR-beta) has been approved as a treatment for fibrotic metabolic dysfunction-associated steatohepatitis (MASH). We investigated whether the mechanism of action of resmetirom depends on the integrity of hepatic MAMs.

Method: We studied the effect of resmetirom (1 µM) on MAMs (in situ PLA), lipid accumulation (Bodipy), insulin resistance (Western blot P-AKT/AKT), lipid metabolism (RT-PCR) in Huh7 cells under preventive (24-hour co-treatment with 200 µM palmitate) and curative (8 hours of 100 µM palmitate, followed by 24 hours of resmetirom) conditions.

Results: The efficacy of resmetirom treatment is demonstrated by the induction of THR-β target genes DIO1 in Huh7 cells. Palmitate induces an increase in lipid droplet size (+ 113%, $p < 0.0001$), which is partially prevented by resmetirom (+ 59%, $p = 0.0001$), i.e., delta −25%, $p < 0.0001$. Similarly, the reduction in MAMs induced by palmitate (−46%, $p < 0.0001$) is partially prevented by resmetirom (−26%, $p < 0.0001$), i.e., delta +37%, $p < 0.0001$. In addition, resmetirom increases the P-AKT/AKT ratio in the presence of palmitate (delta + 48%). Finally, resmestirom stimulates the expression of key lipid metabolism genes, such as CPT1A. Under curative conditions, resmetirom reduces palmitate-induced steatosis (delta − 13%, $p < 0.05$) and the integrity of MAMs is currently being analyzed.

Conclusion: These preliminary results suggest that resmetirom could prevent and improve lipid accumulation and hepatic insulin resistance induced by palmitate through the regulation of the integrity of MAMs. An in vivo protocol in a MASLD mouse model, with or without hepatic MAM disruption induced by a molecular spacer, will serve to confirm these data.

SAT-213

Multimodal analysis bridges liver histological features identified by AI based digital histology tools and -omic signatures in a Japanese MASH cohort

Ruixue Hou[1], Ali Ebrahimi[1], Vandana Gupta[1], Hiroaki Yashiro[1], Jen-Chieh Chuang[1], Zoltan Derdak[1], Saman Farahmand[1], Shinichi Aishima[2], Hideyuki Hyogo[3], Yuichiro Eguchi[4], Eisuke Murakami[5], Masato Yoneda[6], Haakan Wennbo[1], Paresh Thakker[1], Bernard Allan[1], Hirokazu Takahashi[3], Atsushi Nakajima[7], Maria D. Paraskevopoulou[1], Banishree Saha[1].

Email: ruixue.hou@takeda.com

Background and aims: Metabolic dysfunction-associated steatohepatitis (MASH) is a growing global health burden with limited therapies. Although invasive, liver biopsy remains the reference standard for staging MASH and assessing treatment response in drug development. Digital pathology (DP) enables reproducible, continuous quantification of liver histology than conventional pathologist scoring but still relies on biopsy. Non-invasive tests (NITs) and novel biomarkers from high-throughput serum proteomics offer a promising alternative. In this study, we integrate, for the first time, PathAI- and HistoIndex (HI)-based DP with standard NITs and serum proteomics in a Japanese MASH cohort.

Method: Biopsies from 250 clinically and histologically confirmed MASLD/MASH subjects (Saga, Yokohama City, and Hiroshima Universities) were analyzed. Fibrosis stage (CRN) and NAFLD Activity Score (NAS) were assessed by a central pathologist (CP). PathAI's AIM-MASH, HistoIndex (HI)'s stain free SHG/TPE imaging, collagen proportionate area (CPA) quantification and AI/ML models were deployed to identify and characterize DP features. Serum proteomics was performed using 11K-protein SomaScan platform. Spearman correlations linked DP/CP features to protein levels, followed by pathway analysis and paired liver transcriptomic validation.

Results: Key histological features of fibrosis stage read by CP have strong correlation with fibrosis measured by PathAI, HI and CPA. Correlations were stronger for GNN (Graph Neural Network) continuous score ($r = 0.84$, $p < 0.001$) and qFibrosis (0.83, $p < 0.001$) values as compared to categorical scores. GNN-CRN continuous score, qFibrosis value and CP, were correlated strongly with NITs such as FIB-4, Type IV collagen 7S, and Hyaluronic acid ($p < 0.05$). Serum proteomics correlated with FIB-4, APRI, collagen biomarkers and CP/DP features. Serum proteomics identified consistent proteins (e.g., ADAMTSL2, C7, GARS1, and THBS2) and fibro-inflammatory pathways, which were validated in paired tissue transcriptomics with high concordance. Overall, our results demonstrate that serum proteins can recapitulate key histologic features captured by digital pathology, including PathAI's AIM-MASH and HI's SHG/TPEF readouts.

Conclusion: Omic-derived signatures map to specific DP-derived histological features and enable the identification of serum biomarker candidates that may help in better diagnosis and monitoring of pathophysiological changes in MASH.

SAT-214

PARP1 rs747657 C > G variant protects against metabolic dysfunction in MASLD

Federico Salomone[1], Miriam Longo[2], Fabio Galvano[3], Paola Dongiovanni[2]. *[1]Azienda Sanitaria Provinciale di Catania, Catania, Italy; [2]Medicine and Metabolic Diseases, Fondazione IRCCS Ca' Granda Ospedale Maggiore Policlinico, Milan, Italy; [3]BIOMETEC, Università degli Studi di Catania, Catania, Italy*
Email: federicosalomone@rocketmail.com

Background and aims: Impaired metabolic homeostasis and cardiovascular risk are intrinsic to the definition of metabolic dysfunction-associated steatotic liver disease (MASLD), however genetic factors conferring susceptibility to a high-risk cardiometabolic profile in MASLD remain to be established. In this study, we aimed to examine the impact of PARP1 rs747657 C > G variant on cardiometabolic parameters in subjects with MASLD.

Method: The PARP1 rs747657 variant was genotyped in 1431 individuals referred to an outpatient Metabolic Liver Diseases Unit in Milan. Transcriptomic analysis was performed by RNAseq in liver samples from 167 bariatric patients, whereas Poly-ADP-ribosylated protein levels were assessed in liver samples from 21 bariatric patients. *In vitro* experiments in HepG2 treated with free fatty acids with or without 3-aminobenzamide, a PARP1 inhibitor, were performed to assess the role of PARP1 in the regulation of lipoprotein homeostasis in the liver.

Results: Subjects with CC and CG/GG genotypes were respectively 658 (46%) and 773 (54%) in the whole cohort. At multivariate analysis adjusted for gender, age, BMI, IFG/T2D, statin use and TM6SF2 E167K variant, PARP1 CG/GG genotype was associated with lower total cholesterol ($\beta = -0.10$ {−0.17–0.04}, $p = 0.001$), lower LDL ($\beta = -0.08$ {−0.13–0.02}, $p = 0.0078$), and lower triglycerides ($\beta = -0.08$ {−0.14–0.03}, $p = 0.002$). The rs747657 C > G variant was also inversely associated with fasting glucose levels ($\beta = -2.04$ {−3.7–0.39}, $p = 0.015$) and with the presence of IFG/T2D (OR = 0.73, 95% C.I {0.54–

0.99}, p = 0.04). Consistently with less dyslipidemia and diabetes, carriers of the G allele had a lower intima-media thickness (0.85 ± 0.21 vs 0.81 ± 0.19 mm, p = 0.04). Subjects with the CG/GG genotypes display lower mRNA levels of PARP1 and lower levels of Poly-ADP-ribosylated proteins. Treatment of HepG2 with 3-aminobenzamide, a PARP1 inhibitor, reduces LDL/VLDL fraction and APOB release in the medium and enhances LDL-R expression.
Conclusion: PARP1 rs747657 C > G variant, leading to lower PARP1 expression and lower polyADPribosylation of target proteins, protects against dyslipidemia and insulin resistance in MASLD, indicating a role for PARP1 in conferring susceptibility to metabolic dysfunction.

SAT-215
PFOA exposure promotes lipid peroxidation–driven inflammatory niche formation in a metabolically vulnerable liver
Wenhua Shao[1], Mayuko Shimizu[2], Hirohisa Ogawa[2], Takeo Minamikawa[3], Takahiro Takayama[4], Koichi Inoue[4], Koichi Tsuneyama[2]. *[1]Department of Molecular Pathology, Tokushima university graduate school of biomedical sciences, Tokushima, Japan; [2]Department of Pathology and Laboratory Medicine, Tokushima university graduate school of biomedical sciences, Tokushima, Japan; [3]Institute for advanced biosciences, Osaka university, Osaka, Japan; [4]Laboratory of Clinical & Analytical Chemistry, College of Pharmaceutical Sciences, Ritsumeikan University, Shiga, Japan*
Email: tsuneyama.koichi@tokushima-u.ac.jp

Background and aims: Metabolic dysfunction-associated steatohepatitis (MASH) creates a liver microenvironment enriched in polyunsaturated fatty acids and susceptible to oxidative stress. Per- and poly-fluoroalkyl substances (PFAS)are persistent environmental pollutants suspected to modify liver disease progression; however, their pathological impact on the hepatic inflammatory microenvironment in metabolic liver disease remains unclear. We aimed to investigate whether perfluoroalkyl substance exposure exacerbates oxidative injury and promotes inflammatory niche formation in a metabolically vulnerable liver.
Method: A dietary mouse model of MASH induced by an iHFC diet was exposed to perfluorooctanoic acid (PFOA), a representative PFAS, with appropriate control groups. Liver weight, macroscopic appearance, and histopathological changes were evaluated. Hepatocellular injury, lobular inflammation, and macrophage infiltration were semi quantitatively scored. Lipid peroxidation was assessed by immunohistochemistry for 4-hydroxynonenal (4-HNE) adducts. Macrophage distribution and cytokine expression were analyzed using immunohistochemistry for Mac 2, TNF-alpha, and IL-6. Quantitative and spatial analyses of intrahepatic PFOA accumulation using mass spectrometry-based methods and Raman spectroscopic imaging are currently ongoing.
Results: PFOA exposure aggravated hepatomegaly in the MASH model. Histologically, exposure significantly increased hepatocellular degeneration, lobular inflammation, and macrophage infiltration compared with diet induced disease alone. Widespread hepatocellular accumulation of 4-HNE adducts indicated enhanced lipid peroxidation in metabolically stressed livers. Notably, Mac 2 positive macrophages formed prominent intrahepatic clusters enriched for TNF-alpha and IL-6, suggesting the formation of localized inflammatory niches. These macrophage aggregates were spatially associated with areas of intense oxidative injury, supporting a feed forward interaction between lipid peroxidation and sustained inflammation.
Conclusion: PFAS exposure exacerbates oxidative liver injury and promotes cytokine rich macrophage inflammatory niche formation in MASH. These findings suggest that environmental toxicants act as disease modifiers by amplifying lipid peroxidation driven inflammation in metabolically vulnerable livers. Ongoing quantitative and imaging analyses will further clarify the relationship between hepatic toxicant burden and inflammatory niche formation.

SAT-216-YI
Early life malnutrition programs long-term metabolic dysfunction and progressive fatty liver disease
Vinesh Sharma[1,2], Vikram Patial[1,2]. *[1]Pharmacology and Toxicology Laboratory, Dietetics & Nutrition Technology Division, CSIR-Institute of Himalayan Bioresource Technology, Palampur, India; [2]Academy of Scientific and Innovative Research (AcSIR), Ghaziabad, India*
Email: vineshs317@gmail.com

Background and aims: Early life malnutrition refers to inadequate intake of essential nutrients during critical development periods from fetal life through infancy and early childhood. However, later exposure to energy-dense, fat and carbohydrate-rich diets increases susceptibility to metabolic disorders due to altered metabolic adaptation established during early development. The present study aims to investigate how early life undernutrition programs long-term metabolic alterations later in life in C57BL/6 mice.
Method: The study comprised six experimental groups designed to evaluate the comparative effects of early-life protein restriction and subsequent high-fat feeding on metabolic function and progressive liver pathology. The dual dietary burden was introduced in mice by feeding a 5% low-protein diet immediately after weaning for eight weeks, followed by a high-fat diet for sixteen weeks.
Results: Animals exposed to an early-life *LP* diet followed by *HfD* (*LP+HfD*) initially showed intermediate weight gain but reached body and organ weights comparable to the *HfD* group by 24 weeks. Serum liver injury markers were elevated in *HfD*, *LP*, and *LP+HfD* groups compared with controls, with the highest levels in the *LP+HfD* group, while glucose and total protein were reduced in the *LP* group. Histopathological analysis revealed pronounced hepatic steatosis, inflammation, and fibrosis in *HfD, LP*, and *LP+HfD* groups, with significantly larger and more abundant lipid vacuoles in the *LP+HfD* group. Genes related to *de novo* lipogenesis were upregulated across *HfD*-fed groups, whereas profibrogenic, inflammatory, and oxidative stress markers were predominantly elevated in *LP* and *LP+HfD* groups. Notably, gut microbiome analysis demonstrated a significant depletion of beneficial short-chain fatty acid–producing bacteria in the *LP+HfD* group; however, significant increases were observed in the concentration of bacteria related to fatty acid synthesis and inflammatory response, highlighting a potential mechanistic link between early-life malnutrition, gut dysbiosis, and aggravated metabolic liver injury.
Conclusion: Early-life protein restriction followed by high-fat feeding exacerbates metabolic dysfunction and accelerates progressive liver injury. This nutritional mismatch promotes severe steatosis, inflammation, fibrosis, insulin dysregulation, and gut microbiome dysbiosis, highlighting the critical role of early nutritional programming in increasing susceptibility to chronic metabolic liver disease later in life.

SAT-217-YI
Targeting SIRP-alpha signaling pathway as a novel therapeutic strategy for metabolic dysfunction-associated steatohepatitis
Shaoping She[1], Xue Zhang[2], Liying Ren[1], Ran Fei[1], Dongbo Chen[1], Feng Liu[1], Huiying Rao[1], Hongsong Chen[1]. *[1], Beijing, China; [2]Peking University People's Hospital, Peking University Hepatology Institute, Infectious Disease and Hepatology Center of Peking University People's Hospital, Beijing, China*
Email: sheshaoping@126.com

Background and aims: Metabolic dysfunction-associated steatohepatitis (MASH), affecting over 30% of adults globally, drives advanced liver disease, posing a major public health challenge. Signaling regulatory protein alpha (SIRP-alpha), as a ligand for CD47, is an immune checkpoint expressed on macrophages and other myeloid cells. While our previous work identified SIRP-alpha inhibits hepatocellular carcinoma progression by preventing T-cell apoptosis, its specific role in the pathogenesis of MASH has not yet been elucidated.

Method: The expression of SIRP-alpha was detected in liver tissues from patients with MASH and two established murine models of MASH: a Western diet combined with carbon tetrachloride injection (WD + CCl_4) and a high-fat methionine-choline-deficient diet (HFMCD). To evaluate the functional role of SIRP-alpha in MASH progression, we employed systemic SIRP-alpha gene knockout mice for in vivo studies. The direct cellular effects of SIRP-alpha were examined in vitro using the human hepatocyte cell line THLE-2 and the human hepatic stellate cell (HSC) line LX-2. Furthermore, an integrated multi-omics approach, combining single-cell RNA sequencing with serum metabolomics, was employed to elucidate the molecular mechanisms through which SIRP-alpha regulates MASH progression.
Results: In this study, we found that SIRP-alpha expression was significantly upregulated in both MASH patients and WD + CCl_4 or HFMCD-induced mouse MASH models. SIRP-alpha deficiency led to a marked aggravation of MASH pathology in mice, evidenced by worsened steatosis, inflammation, and fibrosis. In vitro studies demonstrated that SIRP-alpha overexpression significantly suppressed the secretion of pro-inflammatory cytokines and the accumulation of lipid droplets induced by combined free fatty acid and lipopolysaccharide stimulation in THLE-2 cells. Conversely, SIRP-alpha silencing in THLE-2 cells exacerbated these pathological phenotypes. We also found that SIRP-alpha overexpression promoted the apoptosis of LX-2 cells, whereas its knockdown exerted an anti-apoptotic effect. Mechanistically, integrated multi-omics analyses indicated that SIRP-alpha modulates the mitochondrial apoptosis pathway by altering the Bcl-2/Bax signaling axis in HSCs.
Conclusion: Our findings demonstrate that SIRP-alpha exerts a protective role in MASH by reducing hepatocyte steatosis and inflammation, and promoting HSCs apoptosis through the Bcl-2/Bax pathway. Targeting SIRP-alpha signaling may offer a therapeutic strategy for MASH.

SAT-218

Trace copper exposure within drinking water standards exacerbates liver injury in metabolic dysfunction

Mayuko Shimizu[1], Wenhua Shao[1], Hirohisa Ogawa[1], Koichi Tsuneyama[1]. *[1]Tokushima University Graduate School, Department of Pathology and Laboratory Medicine, Tokushima, Japan*
Email: ichimura.mayuko@tokushima-u.ac.jp

Background and aims: Hepatic accumulation of metals such as iron and copper is a well-established cause of liver injury through oxidative stress. Drinking water represents a major source of daily metal exposure, and regulatory standards have been implemented to ensure safety in the general population. However, whether metal intake below these regulatory limits remains biologically inert in individuals with metabolic liver disease is unknown. This study investigated the impact of trace iron or copper exposure within drinking water standards on the progression of metabolic dysfunction–associated steatotic liver disease (MASLD).
Method: MASLD was induced in Tsumura-Suzuki non-obese (TSNO) mice with a normal genetic background by feeding a high-fat, high-cholesterol diet. Simultaneously, mice were allowed free access for 12 weeks to distilled water supplemented with iron (0.3 mg/L) or copper (1.0 mg/L), concentrations aligned with Japanese drinking water quality standards ($n = 5$/group). MASLD control mice received distilled water alone.
Results: Both iron and copper exposure significantly exacerbated hepatic inflammation in MASLD mice compared with controls. Copper exposure, in particular, led to pronounced infiltration of lymphocytes and neutrophils, extensive hepatocellular ballooning, and elevated serum alkaline phosphatase levels. Importantly, neither hepatic nor serum copper levels differed from controls, excluding pathological copper accumulation. Despite this, immunohistochemical analyses consistently revealed pronounced macrophage infiltration and robust hepatic accumulation of 4-hydroxynonenal, a marker of oxidative stress, in all copper-exposed mice. These findings suggest that copper induces excessive oxidative stress and inflammatory responses independently of hepatic copper accumulation.
Conclusion: Trace metal exposure within currently accepted safety limits is sufficient to aggravate hepatic inflammation in the context of metabolic dysfunction, independent of overt metal accumulation. These findings challenge the assumption that regulatory threshold levels are universally safe and suggest that individuals with MASLD may represent a susceptible population requiring reconsideration of environmental metal exposure. Our study underscores the emerging need to integrate metabolic vulnerability into risk assessment frameworks for drinking water quality.

SAT-219

Hepatic 5-HT2B receptor antagonism mediates the anti-steatotic and antifibrotic effects of psilocybin in preclinical MASH models

Anna Signor[1], Martina Colognesi[1], Giovanna Finzi[2], Daniela Gabbia[1], Andrea Mattarei[1], Stefano Comai[1], Gianfranco Pasut[1], Franco Folli[3], Paolo Manfredi[4,5], Sara De Martin[1]. *[1]Dept. Pharmaceutical and Pharmacological Sciences, University of Padova, Padova, Italy; [2]Unit of Pathology, Azienda Socio-Sanitaria Territoriale (ASST) dei Sette Laghi, Varese, Italy, Varese, Italy; [3]Dept. of Health Sciences, University of Milan, Milano, Italy; [4]MGGM Therapeutics, Kerhonkson, New York, United States; [5]Levomecor Inc, Miami Beach, United States*
Email: sara.demartin@unipd.it

Background and aims: Psilocybin's active metabolite psilocin is a serotonin (5-HT) analogue acting as a partial 5-HT2A/2C receptor agonist and a selective 5-HT2B antagonist. While psilocybin is primarily known for its central psychedelic effects mediated by 5-HT2A agonism, several 5-HT receptor subtypes are expressed in the liver, where serotonin regulates lipid metabolism and fibrogenesis. In particular, 5-HT2B signaling has been implicated in hepatic stellate cell activation, yet its role in MASLD/MASH progression remains poorly defined. We here investigated the molecular mechanisms and therapeutic potential of psilocybin in preclinical models of MASH.
Method: Psilocin (10microM) was tested in vitro on PA:OA-induced lipid accumulation in HepG2 cells, including 5-HT2A-mutant cells generated by CRISPR/Cas9 and compared with a selective pharmacological 5-HT2B inhibitor. LX-2 stellate cells were analyzed for fibrotic markers by immunocytochemistry and RT-PCR. In vivo, mice fed a Novel Gubra Amylin NASH (GAN) diet received oral, sub-psychedelic psilocybin (0.05 mg/kg) from week 5 to 22. Liver morphology and molecular markers were assessed by histology, transmission electron microscopy, and gene expression analyses.
Results: Psilocin reduced lipid accumulation in HepG2 cells, an effect preserved in 5-HT2A-mutant cells ($p < 0.05$ vs PA:OA) and fully recapitulated by selective 5-HT2B inhibition ($p < 0.01$ vs PA:OA). In LX-2 cells, Col1a1 protein and ACTA2 and MMP2 transcripts were significantly reduced ($p < 0.001$, $p < 0.001$, $p < 0.0001$ vs TGF-beta-activated cells, respectively). In GAN-fed mice, psilocybin restored rough endoplasmic reticulum (RER) and mitochondrial ultrastructure, reduced micro- and macrovesicular steatosis, and decreased hepatic ACTA2 expression ($p < 0.05$ vs GAN).
Conclusion: By selectively modulating hepatic lipid accumulation and early fibrogenic pathways through 5-HT2B antagonism, psilocybin may attenuate MASLD progression toward MASH. Its oral efficacy at non-psychedelic doses highlights serotonergic modulation as a novel and translatable therapeutic strategy in metabolic liver disease.

Comparing obesity related cancer incidence in metabolic dysfunction–associated steatotic liver disease patients undergoing pharmacologic versus bariatric interventions

Diwanshu Soni[1], Leith Ghani[1], Majd Aboona[1], Pooja Rangan[1], Mark Wong[1], Karn Wijarnpreecha[1], Rohit Nathan[1], Moises Nevah Rubin[1], Michael Fallon[1], Farah Husain[1], Ma Ai Thanda Han[1]. [1]*University of Arizona College of Medicine- Phoenix, Phoenix, United States*
Email: diwanshu.soni97@gmail.com

Background and aims: Patients with metabolic dysfunction-associated steatotic liver disease (MASLD) have an increased risk of obesity-related cancers involving the esophagus, stomach, colon and rectum, hepatobiliary, gallbladder, pancreas, breast, uterus, endometrium, ovary, kidney, brain, thyroid, and multiple myeloma. Bariatric surgery, Glucagon-Like Peptide-1 receptor agonists (GLP-1 RA), or Sodium-Glucose Cotransporter 2 inhibitors (SGLT2i) have been shown to reduce obesity-related cancer risk, but their comparative effects in MASLD are unknown. This study compares obesity-related cancer incidence in MASLD patients by intervention to inform management.
Method: This retrospective, multicenter study within the Banner Health System identified MASLD patients using ICD codes for non-alcoholic fatty liver disease and 1 of 5 metabolic criteria. We defined obesity-related cancers as follows: colon, rectal, breast, kidney, esophageal, gallbladder, pancreatic, ovarian, endometrial, thyroid, hepatocellular, and stomach cancer, multiple myeloma, meningioma and cholangiocarcinoma. ICD codes were used to identify obesity-related cancers. Only patients who received at least one intervention and followed up 12 months or more post-intervention were included. Interventions included bariatric surgery, GLP-1 RA, SGLT2i, or any combination of more than one therapy. Medication reconciliation confirmed SGLT2i and GLP-1 RA use. The bariatric surgery population was identified using relevant procedure ICD codes. Competing risk analysis was used to compare the incidence of obesity related cancer after 12 months of intervention in each group vs bariatric surgery alone after adjusting for confounders.
Results: This study includes 14,589 patients: 4.6% underwent bariatric surgery, 45.4% received therapy with GLP-1 RA, 27.2% were treated with SGLT2i, and 22.8% received combination therapy. Univariate analysis showed bariatric surgery had a significantly lower 12-month obesity related cancer incidence compared to SGLT2i but not significant to GLP1-RA, or combination therapy. Multivariate analysis showed there is no statistically significant difference in incidence of obesity-related cancer between different groups of intervention.
Conclusion: There is no strong evidence suggesting whether one therapy is more superior than the other given results are not statistically significant. Future studies with longer follow up and larger sample size are needed to validate these results and guide clinical decision making.

SAT-221-YI

Liver-specific deletion of Gpr146 and Angptl3 reduces plasma lipids and prevents development of diet-induced hepatic steatosis in mice

Umesh Tharehalli[1], Boyan Zhang[1], Antoine Rimbert[2], Nicolette Huijkman[1], Niels Kloosterhuis[1], Marieke Smit[1], Bart van de Sluis[1], Jan Albert Kuivenhoven[1]. [1]*Department of Pediatrics, Univeristy Medical Center Groningen, Groningen, Netherlands;* [2]*Nantes Université, CNRS, Inserm, l'institut du thorax, Nantes, France*
Email: u.tharehalli.mathada@umcg.nl

Background and aims: Increased hepatic secretion of very low-density lipoprotein (VLDL) is a shared pathogenic driver of metabolic dysfunction-associated steatotic liver disease (MASLD) and atherosclerotic cardiovascular disease (ASCVD). Hepatic cholesterol is exported in VLDL particles, converted to low-density lipoproteins (LDL) in the circulation, and returned to the liver, making this pathway a central regulator of cholesterol homeostasis and a major therapeutic target. G-protein–coupled receptor 146 (GPR146) is a novel regulator of cholesterol biosynthesis, and loss-of-function (LOF) variants and inactivation reduce LDLc. Angiopoietin-like protein 3 (ANGPTL3) is a liver-secreted inhibitor of VLDL lipolysis, and its inactivation lowers LDLc. We investigated whether combined hepatic targeting of GPR146 and ANGPTL3 reduces circulating lipids and prevents hepatic steatosis.
Method: Liver-specific deletion of *Gpr146* and *Angptl3* was achieved in mice using somatic gene editing to generate double liver knockout (DLKO) animals. Mice were maintained on a chow or high-fat diets (HFD; 60% kcal from fat). Plasma lipids, hepatic lipid content, histology, and alanine aminotransferase (ALT) levels were assessed.
Results: DLKO mice exhibited marked reductions in circulating cholesterol (58% on chow, 55% on HFD) and triglycerides (74% on chow, 48% on HFD) compared to controls. Hepatic fat content was reduced by 52% in chow-fed DLKO mice without evidence of liver injury. Under HFD conditions, DLKO mice showed a 32% reduction in hepatic fat and a 50% decrease in lipid droplet area (Oil Red O staining). Plasma ALT levels were significantly lower in HFD-fed DLKO mice.
Conclusion: Dual hepatic inhibition of GPR146 and ANGPTL3 produces additive reductions in circulating and hepatic fats, and protects mice against diet-induced hepatic steatosis without inducing liver injury. These findings highlight combined targeting of GPR146 and ANGPTL3 as a promising strategy for simultaneous addressing of MASLD and ASCVD. Future studies should determine whether this approach can reverse established fatty liver disease and define the underlying mechanisms.

Email: anna.alisi@opbg.net

Background and aims: Metabolic dysfunction-associated steatotic liver disease (MASLD) is the most prevalent chronic liver disease worldwide, with an estimated prevalence of 10% of children affected. Despite growing interest in identifying effective therapies, current treatments for children are limited to lifestyle modifications aimed at reducing weight. However, some compounds with antioxidant and anti-inflammatory properties, such as vitamin E (VitE) and hydroxytyrosol (Hxt), were able to minimize steatosis and limit disease progression in children. Patient-derived liver organoids (PDLOs) offer a good model for testing new therapies and investigating disease pathogenesis while preserving patient-specific traits. Here, we analysed the protective effects of promising natural compounds, including Hxt, VitE, caffeine (Caf), and ginsenoside Rg1 (Rg1), in an organoid model of MASLD.
Method: Undifferentiated PDLOs were generated from healthy liver tissue obtained from paediatric patients and, subsequently, differentiated into hepatocyte organoids (HO). Palmitic and oleic acids (PA/OA; 1:2 ratio) were administered to HO for 48 hours for modelling in vitro steatosis. Antioxidant compounds (Hxt+VitE, Caf, Rg1) were

then administered at different doses to assess their efficacy against lipotoxicity. Cell viability was evaluated using a CellTiter assay, while lipid accumulation and reactive oxygen species (ROS) levels were quantified by BODIPY 493/503 and CM-H_2DCFDA staining, respectively. Expression of lipogenic and antioxidant genes was evaluated by qPCR.
Results: The PA/OA treatment effectively reproduced key MASLD features, including increased lipid accumulation, reduced cell viability, reflecting cytotoxicity, and altered expression of lipogenic and β-oxidation genes (e.g., *SREBF1, FASN, PPARA, CPT1A*). All tested natural compounds significantly attenuated PA/OA-induced lipid accumulation and intracellular ROS levels. Among compounds, the combination of Hxt+VitE was the most effective in down-regulating the expression of lipogenic and β-oxidation genes, and antioxidant (e.g., *NRF2, SOD2, CAT*) genes.
Conclusion: We found that Hxt plus VitE effectively counteracts lipotoxic and oxidative stress responses in our paediatric HO model that may offer a robust preclinical platform to identify novel therapeutic strategies for MASLD in children. Further implementation of the HO model could be obtained by adding the pro-fibrogenic hepatic stellate cells.

SAT-226
Annexin A1 deficiency exacerbates hepatic metabolic and oxidative dysregulation in streptozotocin-induced diabetic mice
Diego Santos[1,2], Kelly Bem[3], Alex Rosini-Silva[4], Artur Silva-Neto[1], Caroline Faria[5], Antonio Campos[3,6], Rafael Silva[7], Luiz Souza-Ferreira[8], Carlos Lenz-Cesar[3,6], Lila Oyama[1], Patricia Lima[2], Jose Sanches-Junior[1,9], Andreia Porcari[4], Helena Barbosa[3], Cristiane Gil[1,7]. *[1]Federal University of Sao Paulo, Sao Paulo, SP, Brazil; [2]Queen's University, Kingston, ON, Canada; [3]State University of Campinas, Campinas, SP, Brazil; [4]São Francisco University, Braganca Paulista, SP, Brazil; [5]São Paulo University, Sao Paulo, SP, Brazil; [6]Federal University of Ceara, Fortaleza, CE, Brazil; [7]São Paulo State University, Sao Jose do Rio Preto, SP, Brazil; [8]Universidade Federal de São Paulo, São Paulo, Brazil; [9]Federal University of ABC, Santo Andre, SP, Brazil*
Email: dias.diego@unifesp.br

Background and aims: Diabetes mellitus (DM) is a global public health problem that leads to systemic dysregulations affecting several tissues, including severe liver complications. In murine model, insulin resistance induced by a high-fat diet demonstrated that the absence of endogenous annexin A1 (AnxA1) exacerbates the characteristics of T2D. However, treatment with human recombinant AnxA1attenuates the development of insulin resistance in animals. Despite these important findings, its role in hepatocytes in DM1 has been little explored. This study aims to evaluate the role of AnxA1 in hepatocyte biology in a streptozotocin (STZ)-induced DM1 mouse model.
Method: Male C57BL/6 wild-type (WT) and AnxA1 knockout (AnxA1 −/−) mice were randomly distributed into control (CTR) and diabetes mellitus (DM) (n = 6 animals/group). DM was induced in mice with intraperitoneal injection of STZ (65 mg/kg × 5 days) or vehicle. After 12 weeks, livers were collected for different analyses. The procedures were approved by the UNIFESP Animal Experimentation Ethics Committee (n° 5520161123).
Results: In DM animals present decrease of body weight, increase of glycemic levels and decrease with triglycerides and VLDL, exclusively in DM AnxA1$^{-/-}$ mice. Increased triglycerides in the liver of DM AnxA1$^{-/-}$ justifies the decrease in plasma triglycerides. Livers showed higher levels of reactive oxygen species and SOD, but decreased catalase levels, in DM AnxA1−/− mice. Changes in mitochondrial dynamics and activity were observed, including increased fission, decreased mitochondrial number, and decreased complex V expression in DM AnxA1−/−, indicating greater hepatocyte damage via oxidative stress. We also observed increased glycogen in centrilobular veins and upregulation of *Pck1* and *Glut2* in the livers of DM AnxA1 −/−, indicating a greater gluconeogenic response. Finally, metabolomic analysis indicated relevant alterations in metabolic pathways in DM animals, mainly in alpha-linolenic and linoleic metabolism, catecholamine and carnitine biosynthesis, and oxidation of branched-chain fatty acids in DM AnxA1$^{-/-}$ mice, indicating greater fatty acid oxidation, liver regeneration, and a pro-inflammatory profile.
Conclusion: AnxA1 deficiency intensified oxidative imbalance, mitochondrial dysfunction, glycogen disruption, and compromise-dimmunometabolism, revealing the importance of hepatic homeostasis. AnxA1 emerges as a promising therapeutic target for mitigating diabetes-induced liver damage.

SAT-227
Transcriptomic analysis revealed distinct mechanisms underlying the synergistic effect of a fatty acid synthase inhibitor and resmetirom combination in LDL receptor knockout MASH mice
Wen-Wei Tsai[1], Shipra Gupta[1], Eveline Gart[2], Martine C. Morrison[2], Katharine Grimmer[1], Eduardo Martins[1], Marie O' Farrell[1]. *[1]Sagimet Biosciences, San Mateo, United States; [2]TNO, Leiden, Netherlands*
Email: wen-wei.tsai@sagimet.com

Background and aims: Increased *de novo* lipogenesis drives development of MASH, with fatty acid synthase (FASN) being the key enzyme in this pathway. Oral FASN inhibitor denifanstat demonstrated significant improvements in fibrosis and MASH resolution and prevented progression to cirrhosis in the Ph2b FASCINATE-2 MASH trial. The thyroid hormone receptor beta agonist resmetirom (Res), FDA-approved for MASH with F2/F3 fibrosis, increases lipid oxidation which decreases liver fat. In previous mouse studies, the combination of a FASN inhibitor and Res showed an increased improvement of liver histology in diet-induced MASH. This transcriptomic profiling study aimed to identify molecular mechanisms by which a FASN inhibitor and Res contributed to disease improvement.
Method: Male Ldlr-/- mice were fed a fast-food diet (FFD) for 18 weeks to induce MASH features and treated with TVB-3664 (a FASN inhibitor surrogate for denifanstat, 5 mg/kg, PO, QD) or Res (MGL-3196, 3 mg/kg, PO, QD) alone or in combination for 10 weeks. RNA-sequencing was performed using liver tissues.
Results: Combination treatment with TVB-3664 and Res demonstrated a greater effect than either agent alone, including greater improvements in ALT/AST, LDL-cholesterol lowering, and liver steatosis, inflammation and fibrosis in Ldlr-/- MASH mice. Principal component analysis (PCA) revealed a clear distinction in gene expression profiles between healthy normal chow and diseased FFD-fed groups. Both TVB-3664 and Res single treatments shifted the gene profile toward a healthier state. Notably, TVB-3664 or Res targeted distinct gene pathways underlying distinct aspects of disease, and the combination further amplified the move away from the disease state. Pathway analysis showed all treatments reversed many FFD-induced inflammatory and fibrosis regulators, such as TGF-beta, Col1a1 and alpha SMA, with the most pronounced effects in the combination group. TVB-3664 specifically deactivated inflammatory and fibrotic pathways, including hepatic fibrosis signaling and extracellular matrix organization; Res affected lipid metabolism, such as cholesterol biosynthesis and mitochondrial function.
Conclusion: Transcriptomic analysis confirmed that combination of a FASN inhibitor and resmetirom increased the anti-inflammatory and anti-fibrotic effects, and enhanced metabolic correction associated with lipid and cholesterol synthesis in a mouse model of MASH and dyslipidemia. These findings support future clinical evaluation of this combination therapy in MASH.

SAT-228

Sex-specific systemic inflammatory responses to high-fat diet are shaped by hepatic estrogen receptor alpha signalling

Hio Lam Phoebe Tsou[1], Clara Meda[2], Sara Della Torre[2], Antonio Riva[1].
[1]*Roger Williams Institute of Liver Studies, London, United Kingdom;*
[2]*Università degli Studi di Milano, Milan, Italy*
Email: a.riva@researchinliver.org.uk

Background and aims: Chronic inflammation contributes to metabolic-associated steatotic liver disease (MASLD) severity and progression. Hepatic estrogen receptor alpha (ERa) signalling limits liver disease development in pre-menopausal women compared to men or post-menopause, but its influence on systemic inflammation in response to hepatic lipid accumulation remains unclear.
Method: To evaluate this, sex-specific differences in systemic concentrations of 45 plasma cytokines were measured by Luminex in male and female liver-specific ERa-knockout (LERKO) C57BL/6J mice or control animals (ERa-floxed) exposed to high-fat diet (HFD) or normal chow/diet (ND) for 16 weeks (n = 80 total, 10 per group).
Results: Considering diet alone, HFD increased CXCL1, EGF, LDLR, and CCL3 ($p = 4.0 \times 10^{-4}$-2.6×10^{-2}) and decreased interleukin (IL)-27, IL-9, Flt3, and FGF-basic ($p = 3.0 \times 10^{-3}$-4.9×10^{-2}) in controls; in HFD-fed LERKO animals only BAFF was elevated compared to ND ($p = 2.0 \times 10^{-2}$). Considering sex alone, all males had higher GDF15, VEGF, CCL3, EGF, FGF-basic, and IL-1b ($p = 9.0 \times 10^{-6}$-4.4×10^{-2}) and lower IL-5, Eotaxin, and LDLR ($p = 6.0 \times 10^{-3}$-4.7×10^{-2}) compared to females, but only control males had, additionally, more IL-9, IL-2, CXCL10, IL-16, IL-27, RANTES, Flt3, IL-17A, and IL-1a ($p = 2.0 \times 10^{-5}$-4.9×10^{-2}) and less BAFF, CCL19, and Chitinase-3L1 ($p = 1.0 \times 10^{-4}$-1.1×10^{-2}); thus, systemic sex differences largely disappeared in LERKO animals, who resembled control females overall. Intriguingly, levels of M-CSF and LIX remained consistently elevated in LERKO males and females respectively regardless of diet, while HFD reduced male M-CSF ($p = 1.0 \times 10^{-2}$) and female LIX ($p = 9.0 \times 10^{-3}$) down to their respective opposite-sex levels in controls, suggesting liver-specific ERa as a physiological down-modulator of these myeloid/neutrophil-acting cytokines upon lipid overload. Notably, poorly detectable cytokines (<50% of animals) were measurable almost exclusively in males.
Conclusion: Liver-specific estrogen signalling shapes sex-specific systemic immunity and inflammatory adaptation to dietary lipids, preserving cytokine heterogeneity between sexes and modulating myeloid/neutrophil-mobilizing cytokines (M-CSF, LIX) in a sex-specific manner. Liver-specific estrogen signalling may thus act as a double-edged immunomodulator, limiting hepatic inflammation while enhancing systemic immunity, therefore sex-specifically contributing to disease establishment and progression in MASLD.

SAT-229-YI

Effects of farnesoid X receptor activation on the cellular microenvironment of human adipose tissue in metabolic disease

Lena Vosko[1,2], Emilian Jungwirth[1,2,3], Dagmar Silbert-Wagner[1], Judith Sommer[1], Lukas Gulden[1], Antonio Molinaro[4], Panzitt Katrin[1,2,5], Martin Wagner[1,2]. [1]*Research Unit for Translational Nuclear Receptor Research, Division of Gastroenterology and Hepatology, Medical University of Graz, Graz, Austria;* [2]*BioTechMed, Graz, Austria;* [3]*Center for Biomarker Research in Medicine, Graz, Austria;* [4]*Department of Molecular and Clinical Medicine/Wallenberg Laboratory, University of Gothenburg, Gothenburg, Sweden;* [5]*D&F Institute for Pathology, Medical University of Graz, Graz, Austria*
Email: lena.vosko@medunigraz.at

Background and aims: The bile acid-sensing farnesoid X receptor (FXR) adapts to metabolic changes in obesity, which is associated with metabolic dysfunction-associated steatotic liver disease. We previously demonstrated altered hepatic FXR binding and transcriptional activity in metabolic disease, promoting substrate utilization after ligand activation. Adipose tissue (AT) serves as energy reservoir and endocrine organ, but in obesity, it loses storage capacity and promotes systemic inflammation. While hepatic FXR signaling is well studied, its effects on human AT remain unclear. This study aimed to characterize, for the first time in humans, the cellular and transcriptional effects of FXR activation on subcutaneous AT (SAT) in metabolic disease.
Method: We performed single-nuclei RNA sequencing on SAT biopsies derived from non-obese and morbidly obese (BMI > 35 kg/m2) individuals treated with the FXR agonist obeticholic acid (25 mg/d OCA for 3 weeks) or placebo in a randomized double-blind trial.
Results: Sixteen SAT samples (four per group) yielded 34,529 quality-filtered nuclei. SAT from obese patients showed increased immune cell fractions and enriched pro-inflammatory pathways, with reduced adipocyte abundance. NR1H4 (FXR) expression was low or absent in most samples. Adipocytes and adipose stem and progenitor cells (ASPCs) each accounted for approximately 20% of nuclei. Subclustering revealed that OCA-treated obese patients exhibited reduced immune-related and angiogenic adipocyte subpopulations, accompanied by a significant downregulation of pro-inflammatory genes (CXCL17, CEBPB, HLA-DRB1) and pathways involved in inflammatory response in all adipocytes, whereas metabolic effects where minor. Within ASPCs, oxidative phosphorylation and mitochondrial energy pathways were suppressed. In addition, pro-inflammatory genes (CFB, PPIA, IFI6) and humoral immune response pathways were downregulated, and PPARG-positive committed preadipocytes with inflammatory signatures were less abundant.
Conclusion: This study provides the first single-nucleus map of FXR agonism effects on human AT and its stromal microenvironment. Overall, OCA reduced pro-inflammatory signaling across multiple SAT subpopulations. Minimal local FXR expression suggests that OCA-mediated effects are indirect, supporting the existence of a liver–adipose or intestine–adipose signaling axis modulating immune responses in adipocytes and progenitors.

Background and aims: Maternal obesity in pregnancy (MO) predisposes offspring to development of metabolic dysfunction-associated steatotic liver disease (MASLD) during their adulthood, with preclinical evidence demonstrating higher MASLD incidence in male offspring. Pathological effects of MO on hepatocyte precursors (hepatoblasts) *in utero* have been suggested, but analysis of fetal hepatoblasts (FHB) has been complicated as they only comprise a minority of embryonic liver cells.
Method: Here, we combine purification of differentiation-competent FHB with a Multi-Omics approach and magnetic resonance imaging and spectroscopy (MRI/MRS) to investigate the effects of MO on FHB and fetal livers. Additionally, we use primary human hepatocytes and a human hepatocyte cell line to investigate the regulation and protective effect of a candidate protein regarding oxidative stress and mitochondrial fragmentation.
Results: Upon MO, lipid-handling pathways are upregulated in FHB of both sexes. In contrast, we find that mRNAs and proteins involved in mitochondrial respiration and oxidative stress response are modulated in a sex-biased manner, with a higher antioxidant response in female FHB paralleled by higher H_2O_2 release of male fetal liver. Interferon-regulatory factor 9 (IRF9) expression is increased in female FHB upon exposure to MO, and retained in livers of adult female offspring in two independent models of maternal overnutrition in pregnancy. In line, female but not male primary human hepatocytes increase IRF9 expression upon acute palmitate treatment. We show that IRF9 is essential for cellular resistance against oxidative stress, and is necessary to prevent pathogenic diacylglycerol and sphingolipid accumulation, mitochondrial fission, and lipid-induced insulin resistance. Mechanistically, we demonstrate that IRF9 abundance is increased by the master regulator of the cellular antioxidant response, NRF2, and decreased by the lipotoxicity-associated microRNA miR20b-5p. We also link IRF9 expression to mitochondrial fission, which has been linked to hepatic insulin resistance and MASLD, and can impair developmental potential in stem cells.
Conclusion: Our study uncovers a sex-biased fetal response to a prenatal obesogenic environment that predisposes to hepatic steatosis during adult life. Further, we show that IRF9 is regulated in a sex-biased manner, and is essential to overcome acute oxidative stress and prevent accumulation of deleterious bioactive lipids and hence insulin resistance in human liver cells.

Email: jack.breen@perspectum.com

Background and aims: Quantifying inflammation is a key component of liver disease assessment, with grading systems such as the NAFLD activity score (NAS) in metabolic dysfunction-associated steatotic liver disease (MASLD) and metabolic-associated steatohepatitis (MASH), and modified Hepatic Activity Index (mHAI - Ishak) scoring for chronic hepatitis. NAS assesses lobular inflammation, while mHAI includes portal and interface inflammation. Pathologist agreement for inflammation grading is poor, with clinical trials often relying on consensus scoring. We present an automated approach to quantifying inflammation in lobular, portal, and interface regions across liver disease whole slide images (WSIs).
Method: WSIs from 63 patients with autoimmune hepatitis (AIH; mean age 21, 54% female, 56% on treatment), 87 with MASLD (mean age 55, 69% male), and 232 MASH (mean age 56, 58% female) were analysed to detect and classify nuclei using a previously fine-tuned deep learning tool (HoVer-NeXt). Inflammatory cells were then identified by removing hepatocyte nuclei and detecting regions of high nuclear density. Density of inflammatory cells in the portal tract, portal interface, and lobular regions of the liver was then measured using an automated portal tract segmentation approach. Agreement with pathologist scores was assessed using Spearman's rho (rs). Bonferroni corrections were applied for multiple comparisons.
Results: Automated assessment of inflammation moderately correlated with pathologist scores (lobular inflammation rs = 0.31, portal inflammation rs = 0.44, interface inflammation rs = 0.37; p-values<0.0001), representing an improvement over previously reported correlation (rs = 0.27, 0.22, and 0.44 respectively). Significant differences in inflammation between MASLD, MASH, and AIH were observed, with the clearest difference in interface inflammation (median density 171, 221, 335 cells/mm^2, respectively; Wilcoxon $p < 0.001$).
Conclusion: Building on our prior work, the proposed method for detecting inflammation in liver biopsies shows improved correlation with pathologist grading and better differentiation of disease states compared with previous approaches. Improving the consistency and accuracy of disease grading may increase operational efficiency in pathology workflows, streamline clinical trial assessments, and enhance sensitivity to treatment effects, supporting more precise clinical decision-making.

SAT-232
STING promotes the progression of metabolic dysfunction-associated steatotic liver disease by regulating the WIPI2/ATG5-p62 autophagy signaling axis

Xiaoxiao Wang[1], Wang Zilong[1], Rui Huang[1], Huiying Rao[1], Feng Liu[1].
[1]Peking University People's Hospital, Peking University Hepatology Institute, Infectious Disease and Hepatology Center of Peking University People's Hospital, Beijing Key Laboratory of Hepatitis C and Immunotherapy for Liver Diseases, Beijing International Cooperation Base for Science and Technology on NAFLD Diagnosis, Beijing, China
Email: liu1116m@sina.com

Background and aims: Macrophage dysfunction critically contributes to metabolic dysfunction–associated steatohepatitis (MASH) progression, yet the interplay between metabolic stress, innate

immunity, and autophagy remains unclear. This study examines the dynamic crosstalk between STING signaling and the WIPI2/ATG5–p62 autophagy pathway in lipid-loaded macrophages and a murine MASLD model to elucidate their roles in disease pathogenesis.
Method: In vitro, THP-1 and RAW264.7 cells were treated with low (0.2 mM OPA) or high (1 mM OPA) fatty acids to model steatosis. STING knockdown and p62 overexpression were performed, and proteins (STING, p-TBK1, WIPI2, ATG5, p62, LC3-II) were analyzed by immunoblotting. In vivo, MASH-fibrosis was induced via WDHF+CCl4 and MCD diets; histology (H&E, Sirius Red) and liver protein expression were assessed. scRNA-seq of liver immune cells from control and MASH mice characterized MoMFs.
Results: In mild/moderate steatotic macrophages, STING expression was upregulated. Concurrently, autophagy-related proteins WIPI2, ATG5, p62 and LC3-II were increased ($p < 0.05$). Knockdown of STING reversed these elevations, indicating STING positively regulates autophagy flux under mild lipid stress. In severe steatosis macrophages, STING pathway activation (increased STING and p-TBK1) was observed alongside decreased p62 levels ($p = 0.032$). Overexpression of p62 suppressed this STING pathway activation, revealing a negative feedback mechanism. In murine MASLD models, STING expression increased with disease severity, peaking during fibrosis. In contrast, autophagy markers (WIPI2, ATG5, p62) showed a biphasic response: an initial upregulation in early MASH, followed by a significant decline in advanced fibrosis, suggesting autophagy failure at late stages. scRNA-seq analysis of MASH-fibrotic livers revealed a increased heterogeneity of MoMFs. Importantly, within MoMFs, genes associated with both STING signaling and the core autophagy machinery (WIPI2, ATG5, p62) were co-upregulated, indicating their concurrent activation in the fibrotic microenvironment.
Conclusion: Our findings identify a stage-specific crosstalk between STING signaling and autophagy in macrophages during MASLD/MASH progression. In vivo, persistent STING activation coincides with progressive autophagy failure, particularly within the expanded pro-fibrotic MoMF population, likely driving chronic inflammation and fibrosis. Targeting the STING–autophagy axis in MoMFs may therefore represent a promising therapeutic strategy for MASH.

Email: k.f.vandegraaf@amsterdamumc.nl

Background and aims: Thyroid hormones (TH) enhance lipid metabolism but therapeutic application by systemic administration is limited due to cardiovascular and skeletal toxicity. Liver-specific delivery of TH, using TH mimetics or TH receptor (TR)-b agonists (Resmetirom), is therefore a promising frontier to improve hepatic lipid metabolism while minimizing off-target effects. Myrcludex B is a synthetic peptide targeting liver-specific bile salt transporter sodium taurocholate co-transporting polypeptide (NTCP) and has shown anti-steatotic potential in preclinical studies. We investigated whether liver-targeted delivery of triiodothyronine (T3), the active hormone, could be achieved while mitigating systemic toxicity through chemical conjugation of T3 to Myrcludex B (Myr-T3).
Method: FVB *oatp1a/1b*$^{-/-}$/*hOATP1B1*$^{+/+}$ mice were used to mimic human hepatic bile salt dynamics. Obesity was induced by 12 weeks of high-fat diet (HFD). Mice then received daily subcutaneous injections of Myr-T3 (100 nmol/kg), Myrcludex B (100 nmol/kg), T3 (50 nmol/kg), or vehicle for 6 weeks while continuing HFD. Cardiac toxicity was determined by in vivo echocardiography. To further assess liver specificity, a follow-up study was performed in C57BL/6J mice fed HFD, followed by 1-week treatment with lower dosing of Myr-T3 (25 nmol/kg), T3 (25 nmol/kg), or vehicle.
Results: HFD significantly increased liver-to-body weight ratios, plasma cholesterol levels, and hepatic steatosis. Myr-T3 treatment increased plasma bile acid levels (4.5-fold). Compared to T3 alone, Myr-T3 achieved greater cholesterol lowering (–15% vs –35%) but also increased cardiac toxicity to a greater extent. Hepatic steatosis, assessed by Oil Red O staining, was similar between all groups. Dosed at 25 nmol/kg, Myr-T3 and T3 reduced plasma cholesterol to comparable levels (61% vs 54%). Hepatic expression of T3-responsive genes was higher in the Myr-T3 group compared with T3 alone, whereas pituitary expression of T3-responsive genes was similar between these two groups.
Conclusion: Chemical conjugation of Myrcludex B and T3 preserves the biological activity of both components. However, the current design did not prevent systemic toxicity under high doses, and no clear improvement in liver specificity over T3 alone was observed at lower doses. While the concept demonstrates hepatic efficacy, structural optimization of the fusion is required to improve the organ specificity.

SAT-234
NK-Cell immaturity fuels ALCAM-dependent hepatocyte transformation and propels MASH-associated fibrosis toward carcinogenesis
Anliang Xia[1], Shuyan Sheng[1], Siyuan Liu[1], Shaobo Zhang[1], KaiPeng Hu[1], Beicheng Sun[1]. *[1]The First Affiliated Hospital of Anhui Medical University, Hefei, China*
Email: xiaanliang@ahmu.edu.cn

Background and aims: Metabolic dysfunction-associated steatotic liver disease (MASLD) progresses from steatosis to fibrosis, cirrhosis, and hepatocellular carcinoma (HCC). The marked resistance of MASH-derived HCC to immune checkpoint inhibitors highlights the need to elucidate how persistent metabolic injury reshapes the liver microenvironment to drive malignant transformation.
Method: We constructed a multi-stage single-cell and spatial transcriptomic atlas of MASLD to map immune-parenchymal co-evolution. CellChat and neighborhood analyses were used to identify dysfunctional NK-hepatocyte communication. ALCAM expression dynamics were validated in multiple MASLD mouse models. Hepatocyte-specific ALCAM knockout mice were generated to interrogate mechanisms using single-cell/spatial sequencing, CRISPR screening, and proteomics.
Results: NK cells track MASLD progression via a stage-specific shift from mature to immature phenotypes. Mature NK cells inhibit hepatocytic ALCAM via the CD6-ALCAM axis, while immature ones fail, leading to sustained ALCAM expression. MASH-associated fibrosis defines the disease continuum as the key bridge to HCC, featuring irreversible NK subset shifts and ECM stiffening that reprograms hepatocytes through biological and mechanical cues. ALCAM then drives hepatocyte oncogenesis via two mechanisms. Origin: Multi-omics reveal ALCAM-mediated microtubule remodeling and asymmetric division, yielding oncogenic progenitor-like cells. Fate: In fibrotic matrices, ALCAM heightens genomic instability, with

CRISPR-identified H2AX as a co-dependency factor sustaining G2/M repair, anoikis resistance, and aberrant clonal expansion.
Conclusion: NK-cell immaturity-induced ALCAM upregulation establishes a core positive-feedback circuit linking hepatocyte transformation with fibrotic microenvironmental evolution, thereby sustaining the progression of MASH-associated fibrosis toward carcinogenesis.

SAT-235
A novel covalent inhibitor targeting ASC oligomerization mitigates MASH by inhibiting NLRP3 inflammasome activation
Ying Hong[1], Cheng Luo[1], Cen Xie. [1]*Shanghai Institute of Materia Medica, Chinese Academy of Sciences, Shanghai, China*
Email: hybottle@126.com

Background and aims: The activation of the NLRP3 inflammasome plays a pivotal role in driving inflammation and fibrosis in metabolic dysfunction-associated steatohepatitis (MASH). Although various pathways can lead to NLRP3 activation, the oligomerization of the adaptor protein ASC constitutes a crucial, convergent step in the assembly of the inflammasome. Targeting this specific step directly offers a promising yet underexplored therapeutic strategy. This study aimed to identify and characterize a novel inhibitor that specifically obstructs ASC oligomerization and to assess its efficacy in a preclinical model of MASH.
Method: We developed and synthesized a library of small molecules utilizing a covalent-binding scaffold designed to target a critical cysteine residue on ASC. The lead compound, Compound A, underwent initial *in vitro* screening using LPS/ATP-stimulated macrophages to evaluate IL-1β secretion and ASC speck formation through immunofluorescence analysis. The covalent interaction of Compound A with ASC was verified *via* mass spectrometry. For *in vivo* assessment, C57BL/6J mice were subjected to a GAN diet for a duration of 26 weeks to induce advanced metabolic-associated steatohepatitis (MASH). Beginning in week 17, the mice received daily treatments of either Compound A (*i.g.*) or vehicle control.
Results: Compound A showed strong covalent binding to ASC, inhibiting NLRP3-dependent ASC oligomerization and IL-1β release in macrophages. In the MASH model, it significantly reduced body weight gain and hepatic lipid accumulation, as evidenced by lower liver triglyceride content and improved steatosis scores. Histologically, Compound A decreased lobular inflammation, fibrosis, and liver injury. It also improved systemic metabolic homeostasis, with treated mice showing better glucose tolerance, and enhanced insulin sensitivity. Mechanistically, Compound A disrupts ASC's interaction with NLRP3, preventing large ASC oligomer formation, which showed reduced ASC speck formation and Caspase-1 cleavage.
Conclusion: We have identified a first-in-class covalent inhibitor that specifically targets ASC oligomerization. This compound potently inhibits NLRP3 inflammasome activation and demonstrates significant efficacy in ameliorating inflammation, fibrosis, and steatosis in MASH model. Our findings validate the inhibition of the NLRP3-ASC axis as a viable therapeutic strategy and present a promising lead compound for the treatment of MASH.

SAT-236
Neddylation of STAT3 is a potential therapeutic target for MASLD
Ping Xie[1], Zhen Zhang[2], Fan Liu[1], Fei Zhao[3]. [1]*Capital Medical University, Department of Cell Biology, Beijing, China;* [2]*Department of Neurosurgery, Shandong Provincial Hospital affiliated to Shandong First Medical University, Jinan, China;* [3]*Department of Ultrasound, Beijing Jishuitan Hospital, Capital Medical University, Beijing, China*
Email: xiep@ccmu.edu.cn

Background and aims: Metabolic dysfunction associated steatosis liver disease (MASLD) increases the risk of developing steatohepatitis, liver cirrhosis, and liver cancer. Neddylation, a ubiquitin-like post-translational modification, has been proven to play a crucial role in tumor progression.
Method: The expression levels of neddylation modification in the MASLD model were evaluated by western blotting and immunohistochemistry. To investigate the role of neddylation in MASLD progression, the neddylation E1 inhibitor MLN4924 was administered to treat the MASLD mouse model. Subsequently, IP-MS and immunoprecipitation were conducted to identify STAT3 as a substrate of neddylation modification. Finally, the mechanisms and functional implications of STAT3 neddylation modification in the progression of MASLD were thoroughly examined through immunoprecipitation, western blotting and fatty acid uptake assays.
Results: Here, we suggested that dysregulation of neddylation was a critical aggravator of MASLD. The neddylation inhibitor MLN4924 effectively reduced lipid accumulation, and obviously suppressed the activation of JAK-STAT signaling pathway. Mechanistically, we identified the signal transducer and activator of transcription 3 (STAT3) as a neddylation substrate involved in MASLD. Our data showed that neddylation modification might be essential for STAT3 dimerization induced by acetylation and activation. Functionally, inhibition of neddylation modulates STAT3 downstream genes. More importantly, the combination of MLN4924 with a STAT3 inhibitor significantly blocked fatty acid uptake and upregulated apoptosis-related genes.
Conclusion: Our findings support a novel regulatory mechanism involving dysregulation of neddylation during MASLD progression and highlight its utility as a potential therapeutic target for MASLD.

SAT-237
Pemafibrate attenuates liver fibrosis and reduces predicted gut lipopolysaccharide biosynthesis and mucin degradation in a metabolic dysfunction-associated steatohepatitis rat model
Yasunori Yamamoto[1], Masaya Okada[2], Masakazu Hanayama[3], Taisei Murakami[1], Kazuki Niida[1], Teruki Miyake[1], Osamu Yoshida[1], Eiji Takeshita[1], Yoshio Ikeda[4], Yoichi Hiasa[1]. [1]*Ehime University Graduate School of Medicine, Toon, Ehime, Japan;* [2]*Seto Inland Sea Hospital, Imabari, Ehime, Japan;* [3]*Matsuyama Shimin Hospital, Matsuyama, Ehime, Japan;* [4]*Ehime University Hospital, Toon, Ehime, Japan*
Email: y79y81@gmail.com

Background and aims: Pemafibrate is a selective peroxisome proliferator-activated receptor α (PPAR α) modulator reported to improve liver enzymes and stiffness in metabolic dysfunction-associated steatohepatitis (MASH). PPAR α is expressed in the liver, intestinal epithelium, and mucosal immune cells, suggesting involvement in gut-liver crosstalk. We evaluated pemafibrate's effects on liver fibrosis and gut microbiota, including predicted microbial functions related to endotoxin and mucin metabolism, in a MASH rat model.
Method: A MASH rat model was induced by a high-fat, high-cholesterol diet. Rats received pemafibrate (0.1 mg/kg) or vehicle for 7 days. Liver fibrosis was quantified by Sirius Red and α-smooth muscle actin (α-SMA) staining. Hepatic expression of *Tgfb*, *Col1a1*, *Acta2*, *Timp1*, and *Serpine1* was quantified by real-time PCR. Fecal 16S rRNA sequencing and PICRUSt2-based KEGG orthology (level 4) were used to compare predicted functions related to lipopolysaccharide (LPS) biosynthesis and transport, mucin degradation, and short-chain fatty acid synthesis.
Results: Pemafibrate treatment significantly reduced liver fibrosis area compared to controls, with consistent suppression of fibrosis-related genes and hepatic stellate cell activation markers. Gut microbiota analysis revealed a significant decrease in inflammation-associated genera linked to LPS and hydrogen sulfide production, such as *Desulfovibrio*, *Pseudomonas*, and *Helicobacter*, in the pemafibrate group. Additionally, the abundance of the mucin-degrading *[Ruminococcus] torques group* was reduced. Consistent with these compositional changes, functional prediction analysis indicated that predicted lipid A biosynthesis and LPS transport pathways were reduced, and mucin degradation functions decreased.

Conversely, while some short-chain fatty acid-producing bacteria decreased, gene abundance for the terminal step of butyrate synthesis showed no significant difference, suggesting that butyrate production capacity—crucial for gut barrier protection—was preserved at the predicted functional level.
Conclusion: Pemafibrate attenuated liver fibrosis in a MASH rat model, accompanied by gut microbiota shifts and reduced predicted functions related to LPS biosynthesis/transport and mucin degradation. These findings suggest that selective PPAR α modulation may contribute to antifibrotic effects through gut-liver crosstalk and represent a promising gut-liver axis-targeted therapeutic approach for MASH.

SAT-238

Hepatic cholesterol metabolic dysregulation drives lean MASLD progression via PEPD secretion from expanded Marco+ macrophages

Yingcheng Yao[1], Junping Shi[2], Danyang Li[3]. *[1]Hangzhou Normal University, Hangzhou, China; [2]The Affiliated Hospital of Hangzhou Normal University, Hangzhou, China; [3]Chongqing Medical University, Chongqing, China*
Email: 185048440@qq.com

Background and aims: Lean MASLD represents a distinct subpopulation within the MASLD spectrum, yet its core metabolic vulnerabilities and pathogenic mechanisms remain understudied.
Method: Here, we integrate clinical, multi-omics, and animal model data to define cholesterol-driven pathology in lean MASLD.
Results: We demonstrate that cholesterol overload remodels liver zonation—specifically expanding zone 1—which critically promotes disease progression. Single-nucleus RNA sequencing and metabolomics reveal the expansion and spatial redistribution of $Marco^+$ macrophages, a metabolically active subset induced by taurocholic acid (TCA), in lean MASLD livers. These macrophages drive metabolic dysregulation via TMED10-mediated secretion of PEPD and other proteins (e.g., LNPEP, MFHAS1), facilitating macrophage-hepatocyte crosstalk and liver-adipose interactions. Clinically, serum PEPD levels are elevated in lean MASLD and may serve as a biomarker.
Conclusion: Our findings establish cholesterol-induced hepatic $Marco^+$ macrophages as key contributors to lean MASLD pathogenesis through PEPD secretion, offering novel therapeutic targets for this metabolically distinct phenotype.

SAT-239

STING aggravates liver fibrosis in chronic hepatitis B concurrent with metabolic dysfunction-associated steatotic liver disease by modulating gut microbiota and inducing macrophage-derived lysozyme expression

Binghui Yu[1], Suping Hai[1], Wenhui Wu[1], Qiang Gao[1], Xitang Li[1], Xizhe Zheng[1], Feiyang Xu[1], Junjian Hu[1], Qin Ning[1], Xiaojing Wang[1]. *[1]Department of Infectious Diseases, Tongji Hospital, Tongji Medical College and State Key Laboratory for Diagnosis and Treatment of Severe Zoonotic Infectious Disease, Huazhong University of Science and Technology, Wuhan, China*
Email: wxjmoon@hotmail.com

Background and aims: The coexistence of Metabolic Dysfunction-Associated Steatotic Liver Disease (MASLD) in individuals with Chronic hepatitis B (CHB) has been increasing annually. In the early stage of MASLD, high-fat diet (HFD)-induced impairment of the intestinal epithelial barrier may activate stimulator of interferon genes (STING). Interactions along the gut-liver axis are likely to contribute to adverse outcomes in this comorbidity. We hypothesize that STING activation during the early stage of the concurrent presence of CHB and MASLD exacerbates liver disease progression by altering the gut microenvironment.
Method: A mouse model of CHB concurrent with MASLD was established by hydrodynamic injection of pAAV/HBV1.2 combined with feeding a high-fat diet. The study utilized STING knockout mice ($Sting^{-/-}$), alongside their littermate controls. In vitro, THP-1 cells were administered a STING agonist, whereas LX-2 cells were subjected to lysozyme stimulation and appropriate controls were established for all treatments. The evaluation of STING and lysozyme-associated markers was conducted using Western blotting, immunofluorescence and enzyme-linked immunosorbent assay.
Results: At 8 weeks, CHB concurrent with MASLD mice exhibited moderate hepatosteatosis and lobular inflammatory infiltration compared to those in the CHB group. Compared to mice with CHB or MASLD alone, the comorbidity group exhibited more severe gut barrier disruption and altered microbiota composition. The comorbid mice showed increased abundances of Blautia, and decreased abundances of Alloprevotella relative to the CHB group. STING expression and activation were elevated in intestinal tissue. STING knockout restored gut barrier integrity and microbiota balance. Fecal microbiota transplantation from $Sting^{-/-}$ mice alleviated steatosis and reduced ALT, AST, and free fatty acid levels. STING was highly enriched in intestinal macrophages, and its activation promoted lysozyme expression. Elevated serum lysozyme and increased CD64/lysozyme co-localization were observed in the comorbidity model. In vitro, lysozyme stimulated LX-2 activation, upregulating collagen I and fibronectin.
Conclusion: Our study demonstrates that intestinal macrophage STING activation modulates gut microbiota in the early stage of the concurrent CHB and MASLD model and promotes liver fibrosis via lysozyme-induced hepatic stellate cell activation. Consequently, lysozyme may represent a potential therapeutic target for mitigating fibrosis in those comorbidity patients.

SAT-240

Development of a novel animal model for acute-on-chronic liver failure in metabolic dysfunction-associated steatotic liver disease: highlighting the critical role of neutrophil

Rui Zhao[1], Qi Yang[1], Hui Liu[2], Xiao Che[1], Chengxuan Yao[1], Xinli Mao[3], Manman Xu[1], Yu Chen[1]. *[1]Fourth Department of Liver Disease (Difficult & Complicated Liver Diseases and Artificial Liver Center), Beijing You'an Hospital, Capital Medical University, Beijing, China; [2]Department of Pathology, Beijing You'an Hospital, Capital Medical University, Beijing, China; [3]Department of Gastroenterology, Taizhou Hospital of Zhejiang Province Affiliated to Wenzhou Medical University, Linhai, China*
Email: chybeyond1071@ccmu.edu.cn

Background and aims: Acute-on-chronic liver failure (ACLF) is a high-mortality syndrome triggered by acute insults in patients with chronic liver disease. Coagulopathy in critically ill patients largely precludes tissue sampling, highlighting the urgent need for the establishment of etiologically relevant animal models. Metabolic dysfunction-associated steatotic liver disease (MASLD), a growing public health concern, can progress to cirrhosis and subsequently increase MASLD-ACLF prevalence. While animal models exist for MASLD or ACLF separately, none replicates ACLF development on a MASLD background.
Method: Reference to prior research, two MASLD models was established: B6-Alms1-del mice on a Western diet and C57/B6J mice on a choline-deficient high-fat (CDAHFD) diet. Varying modeling durations induced steatohepatitis or stage 3 fibrosis. After LPS/D-GalN acute insult, collected serum for liver function tests and liver tissues for histopathology, transcriptomics, and fluorescence-activated sorting of CD45+ cells for single-cell RNA sequencing. Multiplex immunofluorescence was utilized to assess intestinal barrier damage and the potential 'gut mucosal barrier failure' during ACLF progression.
Results: Compared to the MASLD group, the MASLD-ACLF group showed hepatic necrosis on H&E staining, along with typical histopathological features supporting ACLF diagnosis, concomitant with characteristic steatotic manifestations; mitochondrial dysfunction was observed via transmission electron microscopy. Liver fibrosis was assessed by alpha-SMA immunocytochemistry and sirius red

staining. Serum liver function markers were altered, decreased Muc-2 and Occludin indicated gut barrier impairment. Transcriptomics revealed changes in tissue remodeling, phagocytosis, bile acid metabolism, and neutrophil phenotype markers in the liver, with Hallmark analysis highlighting the IL-6-STAT3 pathway. Single-cell RNA sequencing analysis of stage 3 fibrosis underscored the important role of neutrophils in disease progression.
Conclusion: We successfully generated MASLD-ACLF models exhibiting steatohepatitis or stage 3 fibrosis. This study provides, for the first time, a reliable animal model platform representing different disease stages, which enables direct liver tissue access and permits dynamic, time-series investigations to facilitate exploration of disease mechanisms and therapeutic strategies.

Ferulic acid alleviates metabolic dysfunction-associated steatotic liver disease by targeting hydroxysteroid 17-beta dehydrogenase 13 to promote lipolysis
Yuqing Pan[1], Aojie Mao[1], Yiyang Hu[1], Yu Zhao[1]. [1]*Institute of Liver Diseases, Shuguang Hospital affiliated to Shanghai University of Traditional Chinese Medicine, Shanghai, China*
Email: cathy150@139.com

Background and aims: Hepatic lipid deposition serves as the core pathophysiological basis and initial driving factor for both the onset and progression of Metabolic dysfunction-associated steatotic liver disease (MASLD). Ferulic acid (FA), found in a variety of plants and traditional herbal medicines, has been shown to regulate hepatic lipid metabolism and ameliorate MASLD. However, its underlying mechanisms remain unclear. The objective of this study is to investigate the mechanisms by which FA alleviates lipid accumulation in hepatocytes, thereby providing a foundation to facilitate its translational application.
Method: An AML12 hepatocyte lipid deposition model was established using free fatty acid (FFA) induction. Cells were treated with 100 μM FA, and intracellular lipid accumulation was evaluated by measuring triglyceride (TG) levels, Oil Red O staining, and BODIPY fluorescent staining. To identify potential protein targets of FA, drug affinity responsive target stability coupled with mass spectrometry (DARTS + MS) was performed. The direct interaction between FA and hydroxysteroid 17-beta dehydrogenase 13 (HSD17B13) was further verified by surface plasmon resonance (SPR) analysis. In HEK 293T cells, co-immunoprecipitation (Co-IP) was used to examine whether FA promotes ubiquitination of HSD17B13 and modulates its interaction with adipose triglyceride lipase (ATGL). Finally, ATGL knockdown was carried out in AML12 cells to assess its effect on the lipid-lowering activity of FA.
Results: FA significantly reduced FFA-induced TG accumulation in hepatocytes, decreased the number, staining intensity, and size of lipid droplets. Subsequent DARTS + MS and SPR analyses confirmed a direct binding interaction between FA and HSD17B13. Although FA did not alter HSD17B13 mRNA levels, it significantly increased HSD17B13 protein expression. Furthermore, FA treatment elevated the phosphorylation level of ATGL protein, enhanced lipolytic activity. FA promoted ubiquitination of HSD17B13, reduced its binding to ATGL, and facilitated the interaction between ATGL and its activator CGI-58. Notably, in FFA-induced AML12 cells with ATGL knockdown, the TG-lowering effect of FA was substantially attenuated.
Conclusion: This study demonstrates that FA alleviates hepatic lipid deposition by targeting HSD17B13. The binding of FA promotes HSD17B13 ubiquitination, which disrupts its interaction with ATGL, enhances ATGL phosphorylation, and ultimately activates lipolysis.

SAT-242
ZEB2 promotes the progression of MASLD by inducing neutrophil extracellular traps formation
Guanggi Zhu[1], Qianwen Zhao[1], Chao Wu[1], Jie Li[1]. [1]*Nanjing Drum Tower Hospital, Affiliated Hospital of Medical School, Nanjing University, Nanjing, China*
Email: lijier@nju.edu.cn

Background and aims: The pathogenesis of metabolic dysfunction-associated steatotic liver disease (MASLD) is highly complex, with hepatic lipid accumulation being a critical factor driving its progression. The transcription factor E-box-binding zinc finger protein 2 (ZEB2) within hepatic stellate cells (HSCs) has shown its critical role in regulating hepatic fibrosis. However, its specific mechanisms in hepatocytes under the context of MASLD remain poorly understood.
Method: Liver samples from metabolic dysfunction-associated steatohepatitis (MASH) patients were obtained to assess ZEB2 expression by immunohistochemistry (IHC) and immunofluorescence (IF). Mouse primary hepatocytes were stimulated with palmitic acid (PA) and oleic acid (OA) and transfected with ZEB2 siRNA or a ZEB2 overexpression plasmid (Ad-ZEB2) to evaluate its role in MASLD. Hepatocyte-specific ZEB2 knockout mice were generated using the Cre/LoxP system. MASLD mouse models were established via high-fat, high-fructose diet (HFHFD) or choline-deficient, amino acid-restricted, high-fat diet (CDA-HFD). RNA sequencing (RNA-seq) was employed to identify ZEB2 target genes and elucidate its molecular mechanisms.
Results: IHC and IF revealed a significantly elevated ZEB2 expression in paraffin-embedded liver sections from MASH patients. *In vitro*, PA and OA stimulation markedly upregulated ZEB2 expression. ZEB2 knockdown significantly suppressed lipid accumulation and the inflammatory condition, whereas ZEB2 over-expression exacerbated it. *In vivo*, hepatocyte-specific ZEB2 knockout mice downregulated the expression of inflammatory cytokines-related genes (*IL-1, IL-6, TNF-α*), and decreased serum levels of liver enzymes. Pyruvic tolerance test and glucose tolerance test showed an improved performance in mice with ZEB2 knockout. Hematoxylin-eosin (HE) staining and IHC confirmed a reduced lipid deposition and diminished inflammatory infiltration, respectively. Further, RNA-seq analysis suggested that ZEB2 may regulate cell adhesion, thereby increasing neutrophil extracellular traps (NETs) formation and promoting MASH progression. Co-culture of ZEB2-overexpressing hepatocytes with neutrophils significantly enhanced intercellular adhesion and NETs formation, whereas ZEB2 inhibition attenuated these effects.
Conclusion: Targeting ZEB2 in hepatocytes effectively prevents MASLD development in mice, suggesting that ZEB2 may serve as a potential therapeutic target for MASLD.

SAT-243-YI
Platelet phenotype and function throughout the spectrum of metabolic dysfunction-associated steatotic liver disease
Mirko Zoncapè[1,2], Marco Castelli[3], Anna Mantovani[4], David Sacerdoti[2], Pietro Minuz[4], Andrea Dalbeni[4]. [1]*Clinica Medica 3, Azienda Ospedale Università di Padova, Padova, Italy;* [2]*Liver Unit, University of Verona and Azienda Ospedaliera Universitaria Integrata Verona, Verona, Italy;* [3]*Division of General Medicine C, Department of Medicine, University of Verona, Verona, Italy;* [4]*Division of General Medicine C, Department of Medicine, Azienda Ospedaliera Universitaria Integrata Verona, Verona, Italy*
Email: mirko.zonky@yahoo.it

Background and aims: Metabolic dysfunction-Associated Steatotic Liver Disease (MASLD) is a major cause of chronic liver disease, progressing from steatosis to cirrhosis. Platelets are increasingly recognised as contributors to its pathogenesis, yet their phenotype and function across disease stages remain unclear. We aimed to characterise platelet activation and function in MASLD with mild

fibrosis (≤F2) and advanced fibrosis/cirrhosis (F3-F4) versus healthy controls. A secondary aim was to assess coagulation factor profiles and the possible platelet role in their transport.
Method: In this cross-sectional study, 192 subjects were included: 62 healthy controls, 82 MASLD ≤F2, and 48 MASLD F3-F4. Platelet activation was assessed by urinary 11-dehydro-thromboxane B2 (11-dh-TXB2) and plasma soluble P-selectin; platelet adhesion under flow by microfluidics; and flow cytometry analysed fibrinogen receptor activation, Annexin V binding, and platelet-leukocyte aggregates. Coagulation parameters (PT, aPTT, fibrinogen, FVII, FVIII, FIX, FX, FXII, FXIII, and vWF) were measured in platelet-rich and platelet-poor plasma. Combination assays mixing patient platelets with control plasma, and vice versa, evaluated whether platelets contribute to coagulation factor transport.
Results: Both 11-dh-TXB2 and soluble P-selectin rose progressively with fibrosis severity and correlated with FIB-4 and liver stiffness ($p < 0.001$). Microfluidic assays showed enhanced platelet adhesiveness in MASLD ≤F2 and F3-F4 versus controls. Flow cytometry showed an increased proportion of Annexin V-positive procoagulant platelets in ≤F2 patients, while F3-F4 exhibited reduced fibrinogen receptor activation and lower platelet-monocyte aggregates, suggesting exhaustion. Advanced fibrosis/cirrhosis was associated with prolonged PT/aPTT and reduced FVII, FVIII, FIX, FX, FXII, and FXIII, alongside elevated vWF. Combination experiments demonstrated that differences were plasma-driven, excluding a relevant platelet-mediated transport role.
Conclusion: Distinct platelet phenotypes characterise MASLD progression. Early disease (≤F2) shows increased platelet activation and procoagulant potential, while advanced fibrosis/cirrhosis displays reduced responsiveness despite systemic activation and thrombocytopenia. Coagulation abnormalities mainly reflect plasma defects rather than platelet carriage. These findings identify platelets as active players in MASLD pathogenesis and support their potential as biomarkers and therapeutic targets in chronic liver disease.

SAT-244

Dysregulation of the urea cycle enzymes determines a more severe MASLD phenotype in a DIAMOND preclinical model

Email: czurita-ibis@us.es

Background and aims: (i) to characterize the DIAMOND model under different dietary regimens and (ii) to evaluate changes in urea cycle enzymes (UCEs) in DIAMOND.
Method: DIAMOND mice (n = 35) were randomized to three dietary regimens and duration: high-fat diet supplemented with fructose/glucose in drinking water (HF-HFD; 21w, 30w and 52w), choline-deficient high-fat diet supplemented with 0.1% methionine (CDA-HFD, 16w) or chow diet (21w, 30w and 52w). Anthropometric, biochemical, and hepatic profiles were evaluated, and animals were included in metabolic cages. TUNEL assay, a panel of pro-inflammatory and pro-fibrogenic markers, and hepatic expression of UCEs by qRT-PCR were performed. Finally, an oral glutamine challenge (OGC), microbiota analysis and histopathological evaluation by an expert pathologist were performed.
Results: HF-HFD mice developed metabolic syndrome, unlike CDA-HFD mice. HOMA-IR and HOMA-beta showed insulin resistance with partial depletion of beta-cell function in HF-HFD mice. CDA-HFD mice showed insulin sensitivity and normal beta-cell function. Both interventions increased profibrogenic, proinflammatory and apoptotic markers, especially in CDA-HFD and HF-HFD mice at 30 weeks. Both groups showed NAS Scores > 5, with ballooning and grade 1 of fibrosis. A decrease in the expression of UCEs was observed: carbamoyl phosphate synthetase I (CPS1) (fold change (FC) 0.66; $p = 0.05$), argininosuccinate synthase 1 (ASS1) (FC 0.57; $p < 0.05$) and argininosuccinate lyase (ASL) (FC 0.42; $p < 0.05$) in the presence of ballooning, and CPS1 (FC 0.58; $p < 0.01$), ornithine carbamoyltransferase (OTC1) (FC 0.82;$p < 0.05$) and ASL (FC 0.42; $p = 0.05$) in fibrosis. A significant increase in GLS1 was observed in the presence of ballooning (FC 2.50; $p < 0.01$) and fibrosis (FC 2.90; $p < 0.0001$). Ammonia production after SOG was significantly higher in CDA-HFD (AUC = 7269 ± 1276, $p < 0.05$) and HF-HFD at 52w (AUC = 10755 ± 1452, $p < 0.05$) compared to baseline controls (AUC = 3855 ± 187.7). Microbiota analysis revealed that groups differed in their bacterial species composition, and PICRUST analysis identified 17 differentially expressed pathways with ammonia as an intermediate or end product.
Conclusion: DIAMOND mice showed urea cycle dysregulation under different dietary interventions leading to a compromised ammonia metabolism. CDA-HFD induced a faster and more aggressive liver phenotype without the presence of metabolic syndrome, whereas HF-HFD more closely mirrored the metabolic phenotype seen in humans.

Glucagon-like peptide-1 receptor agonists and long-term liver outcomes in metabolic dysfunction-associated steatotic liver disease and type 2 diabetes: a large real-world analysis

Arunkumar Krishnan[1,2], Diptasree Mukherjee[1], Carolin V Schneider[3], Saleh A. Alqahtani[4,5]. *[1]Department of Supportive Oncology, Atrium Health Levine Cancer, Charlotte, NC, United States; [2]Department of Medicine, Wake Forest University School of Medicine, Winston-Salem, NC, United States; [3]Department of Gastroenterology, Metabolic Diseases and Intensive Care, University Hospital RWTH Aachen, Aachen, Saudi Arabia; [4]Liver, Digestive, and Lifestyle Health Research Section, and Organ Transplant Center of Excellence, King Faisal Specialist Hospital and Research Center, Riyadh, Saudi Arabia; [5]Division of Gastroenterology & Hepatology, Weill Cornell Medicine, New York, United States*
Email: drsaleh.a.alqahtani@gmail.com

Background and aims: Metabolic dysfunction-associated steatotic liver disease (MASLD) is now the most common chronic liver disease globally and frequently coexists with type 2 diabetes (T2D), conferring a several-fold increased risk of cirrhosis and hepatocellular carcinoma (HCC), particularly in those with advanced fibrosis. This study examined whether treatment with glucagon-Like peptide-

1 receptor agonists (GLP-1RAs) is associated with reduced risks of cirrhosis and HCC in adults with MASLD and T2D in a large real-world cohort.

Method: A retrospective, multicenter cohort study was conducted using the TriNetX federated electronic health record platform. Adults with MASLD and T2D without prior cirrhosis or HCC at baseline were included. GLP-1RA exposure was defined as continuous treatment for at least 6 months, with time zero at the date of GLP-1RA initiation or a matched index date for non-users. Individuals with pre-existing cirrhosis, HCC, significant alcohol use disorder, or other chronic liver diseases were excluded. Propensity score matching was used to balance demographics, body mass index, smoking status, glycated hemoglobin, cardiovascular disease, and non-invasive fibrosis markers. Cox proportional hazards models estimated adjusted hazard ratios (aHRs) with 95% confidence intervals (CIs) for incident cirrhosis and HCC.

Results: The matched cohort comprised 52,600 adults, of whom 19,200 received GLP-1RAs, with a median follow-up of 2,730 days. During follow-up, 760 participants developed cirrhosis and 165 developed HCC. Cirrhosis occurred in 2.4% of GLP-1RA users versus 3.5% of nonusers (aHR 0.72, 95% CI 0.61–0.84), while HCC occurred in 0.5% versus 0.9%, respectively (aHR 0.66, 95% CI 0.45–0.96). Relative risk reductions were greatest among patients with higher baseline fibrosis risk, consistent with prior MASLD cohorts in which earlier GLP-1RA use was linked to slower fibrosis progression and fewer major adverse liver outcomes.

Conclusion: In this large, real-world population with MASLD and T2D, GLP-1RA therapy was associated with substantially lower risks of incident cirrhosis and HCC, particularly in individuals with elevated baseline fibrosis risk.

Concurrent responses in multiple non-invasive tests for hepatic inflammation and fibrosis following pemvidutide treatment: 24-week responder analyses of the phase 2b IMPACT trial in metabolic dysfunction-associated steatohepatitis

Naim Alkhouri[1], Mazen Noureddin[2], Shaheen Tomah[3], Julio Gutierrez[3], John Suschak[3], M. Scot Roberts[3], Rachel Garner[3], Sarah Browne[3], M. Scott Harris[3], Christophe Arbet-Engels[3]. *[1]Summit Clinical Research, Clinical Research Institute of Ohio, San Antonio, TX, United States; [2]Houston Methodist Hospital, Houston Research Institute, Pinnacle Clinical Research, Houston, TX, United States; [3]Altimmune, Inc, Gaithersburg, MD, United States*
Email: nalkhouri@summitclinicalresearch.com

Background and aims: Pemvidutide is a balanced 1:1 glucagon/GLP-1 dual receptor agonist in development for the treatment of metabolic dysfunction-associated steatohepatitis (MASH). IMPACT was a phase 2b, randomized, placebo-controlled, double-blind trial in patients with biopsy-confirmed MASH and fibrosis stage F2 or F3 (NCT05989711). At as early as 24 weeks, pemvidutide treatment showed statistically significant MASH resolution and high rates of fibrosis improvement. Reductions in individual non-invasive tests (NITs) have been used as indicators of therapeutic effect, but composite analyses using multiple, overlapping NITs may provide a clearer assessment of therapeutic improvement as they increase stringency of the response and lower placebo response rates compared to individual NITs. Here we present 24-week responder analyses of composite NITs from the IMPACT trial.

Method: 212 patients were randomized 1:2:2 to receive once-weekly subcutaneous pemvidutide (1.2 mg or 1.8 mg) administered without dose titration, or placebo. Secondary endpoints included the NITs for liver fat content (LFC), ELF score, liver stiffness measurement (LSM), and alanine aminotransferase (ALT).

Results: The mean age was 53 years, the mean BMI was 39 kg/m^2, 58% were female, and 43% had type 2 diabetes. A greater proportion of patients receiving pemvidutide achieved concurrent responses in LFC (≥ 30% reduction), ALT (≥ 17 U/L reduction), and LSM (≥ 30% reduction) compared to placebo [1.2 mg (37.8%; $p < 0.0001$); 1.8 mg (21.6%; $p = 0.0014$); placebo (4.3%)]. Similarly, a greater proportion of patients receiving pemvidutide achieved concurrent responses in ELF score (≥ 0.5 reduction) and LSM (≥ 30% reduction) compared to placebo [1.2 mg (37.8%; $p = 0.0002$); 1.8 mg (22.7%; $p = 0.02$); placebo (8.3%)]. Notably, in a more stringent analysis of concurrent responses in LFC (≥ 50% reduction), ELF score (≥ 0.5 reduction), and LSM (≥ 30% reduction), pemvidutide resulted in a higher proportion of patients achieving a response compared to placebo [1.2 mg (29.7%; $p = 0.0001$); 1.8 mg (17.8%; $p = 0.0041$); placebo (2.9%)].

Conclusion: Pemvidutide treatment led to statistically significant increases in the proportion of patients achieving concurrent responses in multiple NITs of MASH resolution and hepatic fibrosis at 24 weeks.

TOP-177

Baseline ANTICIPATE score and response predicts liver outcome events in an 180 patient MASH cirrhosis cohort treated with resmetirom

Naim Alkhouri[1], Rebecca Taub[2], Xiaomin Lu[2], Jörn M. Schattenberg[3], Mazen Noureddin[4]. *[1]Summit Clinical Research, San Antonio, United States; [2]Madrigal Pharmaceuticals, Conshohocken, United States; [3]Universitätsklinikum des Saarlandes, Homburg, Germany; [4]Pinnacle Clinical Research, San Antonio, United States*
Email: rebeccataub@yahoo.com

Background and aims: Resmetirom (RES), a selective thyroid hormone receptor beta agonist, is an approved therapy for metabolic dysfunction associated steatohepatitis (MASH) with moderate to advanced liver fibrosis based on improvement in both NASH and fibrosis. We evaluated two years data in 180 patients with compensated MASH cirrhosis treated with RES to assess the ability of ANTICIPATE-NASH (Aceituno et al, Gastroenterology 2025) to predict clinically significant portal hypertension (CSPH) leading to liver related events (LRE).

Method: 180 patients with Child Pugh A MASH cirrhosis (based on MASH F4 on historic biopsy >66% or clinical diagnosis) were treated with 80 mg RES for up to 2 years (MAETRONAFLD- 1 (NCT04197479) year 1; open-label extension trial (NCT04951219) year 2. Of the 180 patients, 122 patients elected to enter treatment for year 2. Discontinuation rates were <10% per year. ANTICIPATE-NASH CSPH risk was determined at baseline (BL), year 1 and year 2. "Responder" was assessed as a shift to ≤25% CSPH risk or at least 30% improvement in ANTICIPATE-NASH. LRE were assessed at year 1 for the n = 180 and at 2 years in the n = 122 populations.

Results: BL characteristics were similar between the year 1 (n = 180) and year 2 (n = 122) populations, respectively: age, 62, 62, female 62.5%, 55.7%; BMI (kg/m2) 34.4, 34.4; T2D 72.8%, 69.7%; (median, (Q1, Q3): VCTE 20.3 kPa (15.6, 30.7), 20.1 (17.1, 31.3); MRE, 5.1 kPa (4.1,6.3), 5.2 kPa (4.4,6.3), platelets 142 (108, 199), 136 (101,187). For the year 1 population at BL 69.0% had CSPH risk>25%; 15.5%, >12% and ≤25%; 15.5%, <12%; after 1 year, 56.3% had CSPH risk>25%, 20.5%, >12% and ≤25%; 23.2%, <12%. 43.7% were responders. For the year 2 population at BL, 75.4.% had CSPH risk>25%; 12.3%, >12% and ≤25%; 12.3%, <12%; after 1 year, 59.6% had CSPH risk>25%, 19.3%, >12% and ≤25%; 21.1%, <12%; after year 2, 52.4% had CSPH risk>25%, 22.3%, >12% and ≤25%; 25.2%, <12%. 43.9% were responders after year 1 and 49.3% were responders after year 2. LRE during year 1 of the n = 180 population occurred in 1.7%, only in nonresponders with BL CSPH>25%. LRE after 2 years in the n = 122 population occurred in 2.2%, only in nonresponders with BL CSPH>25%.

Conclusion: In a well-compensated MASH cirrhosis population treated with RES for up to 2 years, ANTICIPATE-NASH in patients with BL CSPH risk >25% and non-response to treatment accurately predicted LRE. Treatment with RES significantly reduced ANTICIPATE-NASH in about half of treated patients.

FRI-139

Semaglutide provides liver health-related benefits in menopausal women living with MASH: a post hoc analysis of the ESSENCE trial part 1

Manal F. Abdelmalek[1], Maria Teresa Arias Loste[2], Burak Demirel[3], Gema Frühbeck Martinez[4], Anja Geerts[5], Lise Lotte Gluud[6], Alma Laura Ladrón de Guevara[7], Ewa Janczewska[8], Ole Kleist Jeppesen[3], Claudia Pinto Oliveira[9], Mary E. Rinella[10], Giada Sebastiani[11], Anca Trifan[12], Thea Vestergaard[3], Elisabetta Bugianesi[13]. *[1]Division of Gastroenterology and Hepatology, Mayo Clinic, Rochester, MN, United States; [2]Hospital Universitario Marques de Valdecilla, Clinical and Translational Research Group in Digestive Diseases, IDIVAL, Santander, Spain; [3]Novo Nordisk A/S, Copenhagen, Denmark; [4]Clínica Universidad de Navarra, Pamplona, Spain; [5]Hepatology Research Unit, Liver Research Center, Ghent University Hospital, Ghent, Belgium; [6]Department of Medicine, University of Copenhagen, Copenhagen, Denmark; [7]Centro de Investigación y Gastroenterología, Ciudad de México, Mexico; [8]ID Clinic, Myslowice, Poland; [9]Departamento de Gastroenterologia, Hospital das Clínicas (LIM07) da Faculdade de Medicina da Universidade de São Paulo, São Paulo, Brazil; [10]Division of Gastroenterology, Hepatology and Nutrition, University of Chicago, Chicago, IL, United States; [11]Department of Gastroenterology and Hepatology, McGill University, Montreal, Canada; [12]Institute of Gastroenterology and Hepatology, Iasi, Romania; [13]Department of Medical Sciences, University of Turin, Turin, Italy*
Email: Abdelmalek.manal@mayo.edu

Background and aims: Women in menopause with metabolic dysfunction-associated steatohepatitis (MASH) are at increased risk of advanced liver fibrosis and faster disease progression vs women in premenopause and men of similar age. This post hoc analysis of the ESSENCE trial assessed the effect of semaglutide 2.4 mg on liver histology and non-invasive tests (NITs) by menopause status.
Method: Analyses were performed in women in menopause (those not of child-bearing potential), women in premenopause (those of child-bearing potential), and males. Proportions of participants (pts) achieving resolution of MASH with no worsening of liver fibrosis and improvement in liver fibrosis with no worsening of MASH at week 72 were evaluated. Changes from baseline to week 72 in alanine aminotransferase (ALT), liver stiffness measurement by vibration-controlled transient elastography (VCTE), Enhanced Liver Fibrosis (ELF), and FibroScan-AST (FAST) were assessed.
Results: Semaglutide demonstrated numerically higher histologic response vs placebo across subgroups. For resolution of MASH with no worsening of liver fibrosis: menopause 52.0% vs 19.8%; premenopause 62.7% vs 34.8%; male 60.6% vs 32.0%. For improvement in liver fibrosis with no worsening of MASH: menopause 29.5% vs 18.2%; premenopause 42.4% vs 21.7%; male 34.8% vs 18.0%. For NITs, semaglutide demonstrated consistent and comparable improvements vs placebo across menopause (n = 375), premenopause (n = 82), and male (n = 343) subgroups, with most statistically significant. For ALT, estimated treatment ratios (ETRs) were menopause 0.66 (95% CI 0.59–0.74; $p < 0.0001$); premenopause 0.52 (0.37–0.73; $p = 0.0002$); male 0.61 (0.54–0.69; $p < 0.0001$). For VCTE, ETRs were 0.79 (0.70–0.88; $p < 0.0001$), 0.82 (0.61–1.09; $p = 0.1675$) and 0.80 (0.72–0.88; $p < 0.0001$), respectively. For ELF, estimated treatment differences (ETDs) were −0.63 (−0.79 to −0.47; $p < 0.0001$), −0.50 (−0.89 to −0.12; $p = 0.0115$) and −0.53 (−0.69 to −0.38; $p < 0.0001$), respectively. For FAST, ETDs were −0.19 (−0.25 to −0.12; $p < 0.0001$), −0.22 (−0.39 to −0.06; $p = 0.0088$) and −0.17 (−0.23 to −0.11; $p < 0.0001$), respectively.
Conclusion: Semaglutide was associated with improvements in liver histology and NITs in pts with MASH across menopause, premenopause and male subgroups. Menopause does not reduce the likelihood of achieving liver health improvements with semaglutide.

FRI-140

Isotemporal associations of sedentary behavior and physical activity with health-related quality of life in patients with metabolic dysfunction-associated steatotic liver disease

Hadeel Saad[1], Khalid A Alswat[1], Sulaiman Aljaloud[1], Maram Alkhammash[1], Amani Alsadoon[1], Abdullah Alansare[1,2,3]. *[1]King Saud University, Riyadh, Saudi Arabia; [2]King Saud University, Exercise Physiology, Riyadh, Saudi Arabia; [3]The Department of Exercise Physiology, College of Sports Science and Physical Activity, Riyadh, Saudi Arabia*
Email: aalansare@ksu.edu.sa

Background and aims: Emerging evidence suggests that higher sedentary behavior (SB), such as sitting for long periods, is associated with impaired health-related quality of life (HRQoL) in patients with metabolic dysfunction-associated steatotic liver disease (MASLD). Whether reallocating sedentary time to different intensities of physical activity (PA) is associated with improved HRQoL in patients with MASLD remains unexplored. We examined isotemporal associations between SB and PA intensities with overall and domain-specific HRQoL in patients with MASLD.
Method: In this cross-sectional study, adults with MASLD attending a hepatology clinic were enrolled. SB and PA intensities (i.e., light [LPA], moderate [MPA], and vigorous [VPA]) were objectively assessed using a wrist-worn accelerometer over seven consecutive days. The Chronic Liver Disease Questionnaire for Non-Alcoholic Fatty Liver Disease was used to evaluate the overall and domain-specific (i.e., abdominal symptoms, fatigue, systemic symptoms, emotion, worry, and activity) HRQoL. Adjusted isotemporal substitution models examined the associations of replacing 30 minutes/day of SB with equivalent durations of PA with overall and domain-specific HRQoL.
Results: Participants (n = 101; mean age = 50.0 years; 43% female) spent 12.8 hours/day in SB, while 69.3% of them met the recommended weekly PA levels. In isotemporal substitution models, reallocating 30 minutes/day from SB to LPA was significantly associated with improved overall HRQoL ($\beta = 0.103$; $p < 0.001$), abdominal symptoms ($\beta = 0.164$; $p < 0.001$), fatigue ($\beta = 0.096$; $p = 0.002$), systemic symptoms ($\beta = 0.091$; $p < 0.001$), emotion ($\beta = 0.075$; $p = 0.023$), activity ($\beta = 0.036$; $p = 0.042$). In contrast, substituting sedentary time with MPA or VPA was not significantly associated with HRQoL ($p > 0.05$ for all).
Conclusion: To our knowledge, this is the first study using isotemporal substitution modeling to demonstrate that replacing sedentary time with LPA is associated with better overall and domain-specific HRQoL in MASLD patients. These findings emphasize the need to target SB reduction through increasing LPA to improve HRQoL in patients with MASLD. Prospective and interventional studies are necessary to confirm these findings and explore causality.

FRI-141

Early real-world effectiveness of resmetirom in adults with metabolic dysfunction associated steatohepatitis and moderate-to-advanced fibrosis

Naim Alkhouri[1], Yestle Kim[2], Karissa Johnston[3], John O'Donnell[2], Reem Mustafa[4], Yael Silberberg[5], Karin Keren[5], Rajagopal Chadalavada[6], Pradeep Bekal[6], Romina Fakhraei[3]. *[1]Summit Clinical Research, San Antonio, United States; [2]Madrigal Pharmaceuticals, West Conshohocken, United States; [3]Broadstreet HEOR, Vancouver, Canada; [4]Vancouver, Canada; [5]Latica, Palo Alto, United States; [6]Gastro Health, Cincinnati, United States*
Email: rfakhraei@broadstreetheor.com

Background and aims: Resmetirom (Rezdiffra™), a thyroid hormone receptor-beta agonist, was conditionally approved in the US in 2024 for adults with noncirrhotic MASH and moderate-to-advanced fibrosis. This study described real-world effectiveness of resmetirom in a US gastroenterology practice, focusing on changes in blood biomarkers and clinical measures.

Method: A single-arm, retrospective cohort study using Latica real-world data repository was conducted. Adults with ≥ 1 resmetirom prescription (Apr 2024–2025; index date = first prescription) and ≥ 6 months of follow-up were included; those with end-stage liver disease in the 2 years pre-index were excluded. Baseline (12 months pre-index) demographics, comorbidities, concomitant medications, and laboratory measurements (AST, ALT, platelets, FibroScan AST [FAST] score, Vibration-Controlled Transient Elastography Liver Stiffness Measurement [LSM]) were captured and, when available, reassessed during follow-up. Treatment-related adverse events (AEs) and AE-related discontinuations were recorded.
Results: Of 1,278 resmetirom users, 712 (55.7%) met inclusion. Mean (SD) treatment duration was 5.7 (4.1) months. About 80% had ≥ 2 cardiometabolic risk factors, most often hypertension (77%) and obesity (71%). In patients with both baseline and follow-up values, mean FAST declined by 0.18 (n = 28), ALT by 13.6 U/L (n = 330), and LSM by 2.2 kPa (n = 70). Response thresholds were met in 42.9% for FAST (≥ 0.22 reduction), 46.7% for ALT (≥ 17 U/L or ≥ 20% reduction), and 41.4% for VCTE (≥ 30% reduction). Trends were similar across statin (n = 232) and non-statin users (n = 480); both improved in lipid markers [LDL (−19.3 vs −10.3) and total cholesterol (−16.9 vs −1.2 mg/dL)]. AST fell in both groups (−8.7 vs −3.4 U/L) and ALT changed in opposite directions (+4.0 vs −3.8 U/L). In GLP-1 concomitant users (n = 139) vs without (n = 573), ALT/AST declines were similar (~ −14/−8 U/L in both), BMI changed slightly (~ −1 kg/m^2 in both), FIB-4 fell slightly more without GLP-1 (−0.1 vs −0.5), LSM declined more with GLP-1 (−3.2 vs −1.9 kPa), and CAP declined in both groups (−39.5 dB/m vs −43.9 dB/m). Discontinuation for treatment-related AEs was rare (~2%), mostly due to diarrhea.
Conclusion: In this real-world analysis, resmetirom was associated with clinically meaningful improvements in blood and imaging biomarkers over ~6 months, suggesting earlier effectiveness than in the 52-week MAESTRO-NASH trial. Larger cohorts with longer follow-up are needed to assess long-term outcomes.

FRI-142

Study design, rationale, and baseline characteristics of the SYNCHRONY real-world trial: a phase 3 trial evaluating efruxifermin in participants non-invasively diagnosed with MASLD or MASH

Quentin M. Anstee[1], Reshma Shringarpure[2], Naga Chalasani[3], Doreen Chan[2], Ali Moulton[2], Brittany de Temple[2], Mark Burch[2], Meena Jain[2], Kitty Yale[2], Mazen Noureddin[4]. *[1]Newcastle University, Newcastle upon Tyne, United Kingdom; [2]Akero Therapeutics, a Novo Nordisk Company, San Francisco, United States; [3]Indiana University School of Medicine, Indianapolis, United States; [4]Houston Methodist Hospital, Houston, United States*
Email: quentin.anstee@newcastle.ac.uk

Background and aims: In Phase 2b clinical trials, treatment with efruxifermin, a bivalent FGF-21 analog, demonstrated improvement in fibrosis in participants with MASH and F2/F3 fibrosis or compensated cirrhosis (F4c). Three Phase 3 trials of efruxifermin in MASH are ongoing: SYNCHRONY Histology, Outcomes, and Real-World. As clinical practice increasingly relies upon non-invasive tests for diagnosis, risk stratification, and monitoring of patients with MASLD, the objectives of the SYNCHRONY Real-World trial are to evaluate the safety, tolerability, and efficacy of efruxifermin on non-invasive markers of liver fibrosis in participants with MASLD/MASH.
Method: This is an ongoing randomized, double-blind, placebo-controlled phase 3 trial of efruxifermin (NCT06161571) at 222 sites worldwide. The trial was designed to collect safety data on efruxifermin and included participants with a clinical diagnosis of MASH who may have been histologically ineligible for other phase 3 trials of efruxifermin. Eligible participants were randomized 2:1 to efruxifermin 50 mg QW SC or placebo for 52 weeks. Key entry criteria: 18–80 years, T2D or ≥2 components of metabolic syndrome, MASLD/MASH with histological fibrosis (F1-F4c) OR non-invasive diagnosis of fibrosis (LSM-VCTE ≥7.5 kPa, ELF ≥7.7, or LSM-MRE ≥2.5 kPa) and confirmation of elevated liver fat content (CAP ≥300 dB/m or ≥8% by MRI-PDFF). The primary endpoint is the safety and tolerability of efruxifermin. The key secondary endpoint is the proportion of participants with concordant ≥0.5 decrease in ELF and ≥30% decrease in LSM-VCTE.
Results: Enrollment was completed in January 2025. Overall, 773 participants were screened and 608 were randomized. At baseline, participants were 56 years of age, 54% female, 83% White, and 30% Hispanic or Latino ethnicity. A total of 57% had T2D with 23% established on GLP-1 receptor agonists and 52% on statins. At baseline, mean ± SD LSM was 12.3 ± 7.3 kPa and ELF was 9.5 ± 0.9. The majority of participants (99%) had available histology as many had failed screening for other trials of efruxifermin. At baseline, fibrosis stages were: F0, 1%; F1, 35%; F2, 33%; F3, 15%; and F4, 15%. Baseline NAS was 2.8 ± 1.2.
Conclusion: SYNCHRONY Real-World is one of three phase 3 trials evaluating the safety and efficacy of efruxifermin and includes participants representative of a broad spectrum of MASLD/MASH. Concurrent conduct of these trials allows for greater opportunities for participants to meet entry criteria. The results are expected in H1 2026.

FRI-147

Efficacy of a therapeutic physical exercise program in patients with metabolic dysfunction–associated steatotic liver disease: a randomized, open-label, bicenter study (SteatoAPA)

Marwin Farrugia[1], Sébastien Le Garf[1], Jocelyn Gal[2], Françoise Lermite[1], Anne-Sophie Rousseau[3], Quentin Serrano[1], Sébastien Raday[1], Renaud Schiappa[2], Ouizeman Dann[1], Régine Truchi[1], Chassang Madleen[1], Nicolas Chevalier[1], Stéphane Schneider[1], André-Jean Remy[4], Philippe Gual[1], Rodolphe Anty[1]. *[1]Hôpital L'Archet, Nice, France; [2]Centre Antoine Lacassagne, Nice, France; [3]UFR Staps, Nice, France; [4]Centre Hospitalier, Perpignan, France*
Email: anty.r@chu-nice.fr

Background and aims: Therapeutic physical exercise (TPE) is a cornerstone of lifestyle management in metabolic dysfunction–associated steatotic liver disease (MASLD), yet its additive benefit over dietary measures alone remains debated. We aimed to evaluate the efficacy of a 12-week TPE program combined with dietary intervention in patients with MASLD.
Method: This prospective, randomized (2:1), open-label, bicenter study (one university hospital and one general hospital) enrolled patients with MASLD diagnosed by a hepatologist based on ultrasound-proven hepatic steatosis, absence of significant alcohol consumption (≤30 g/day for men and ≤20 g/day for women), and exclusion of other chronic liver diseases. Participants were randomized to TPE plus dietary measures or dietary measures alone between 2021 and 2024.
The primary endpoint was a ≥10% reduction in continuous controlled attenuation parameter (CAP) measured by FibroScan®. Clinical, anthropometric, biochemical, quality-of-life (SF-36), physical performance, and non-invasive fibrosis assessments (liver stiffness and ELF score) were performed at baseline, at week 12 (end of TPE), and at week 36. Results are presented as medians. Non-parametric statistical tests were used.
Results: A total of 115 patients were included (75 women, 40 men; median age 59 years; BMI 31 kg/m^2; CAP 305 dB/m; liver stiffness 5.4 kPa; AST 29 U/L; ALT 40 U/L; GGT 32 U/L; ELF score 8.9), with 76 assigned to the TPE plus diet group and 39 to the diet-only group. In the intention-to-treat analysis, the primary endpoint was not met, as a significant reduction in CAP was observed in both groups. No serious adverse events occurred. Similar findings were observed in the per-protocol analysis, after exclusion of 23 patients (consent withdrawal n = 3, loss to follow-up n = 11, insufficient TPE adherence <70% n = 9). Although CAP decreased significantly in both groups at weeks 12 and 36, significant reductions in AST and ALT were observed

only in the TPE group. Furthermore, while SF-36 scores were comparable at baseline, several quality-of-life domains significantly improved at weeks 12 and 36 exclusively in the TPE group.
Conclusion: Although the primary endpoint was not achieved, this randomized study suggests an additive benefit of therapeutic physical exercise combined with dietary measures, compared with dietary intervention alone, on biochemical parameters and quality of life in patients with MASLD (NCT04835831).

FRI-148
Pharmacodynamics, pharmacokinetics, safety, and tolerability of AZD2389, a fibroblast activation protein inhibitor in participants with liver fibrosis and compensated cirrhosis
Vian Azzu[1], Samuel Daniels[1], Mathias Liljeblad[2], Mohammad Niazi[3], Amparo Casanova[4], David Janzén[3], Karin Björhall[5], Xiao Tu[6], Sepideh Hagvall[7], Deepa Arya[7], Erinn Reilly[8], Mahssa Karimi[9], Grisell Ortiz-Lasanta[10], Linda Martinez[11], Eric Lawitz[12], Armando Flor[6]. *[1]Translational Science and Early Clinical Development, CVRM, AstraZeneca BioPharmaceuticals R&D, Cambridge, United Kingdom; [2]Translational Science & Early Clinical Development, CVRM, AstraZeneca BioPharmaceuticals R&D, Gothenburg, Sweden; [3]Clinical Pharmacology and Safety Sciences, AstraZeneca BioPharmaceuticals R&D, Gothenburg, Sweden; [4]Biometrics Early Development, CVRM, AstraZeneca BioPharmaceuticals R&D, Mississauga, Canada; [5]Drug Metabolism Pharmacokinetics and Biomarker Bioanalysis, CVRM, AstraZeneca BioPharmaceuticals R&D, Gothenburg, Sweden; [6]Translational Science & Early Clinical Development, CVRM, AstraZeneca BioPharmaceuticals R&D, Gaithersburg, United States; [7]Global Patient Safety Biopharmaceuticals, Chief Medical Office, AstraZeneca Oncology R&D, Gaithersburg, United States; [8]Early Phase Clinical Operations CVRM, AstraZeneca BioPharmaceuticals R&D, Gaithersburg, United States; [9]Projects, Research and Early Development, CVRM, AstraZeneca BioPharmaceuticals R&D, Gothenburg, Sweden; [10]FDI Clinical Research, San Juan, United States; [11]Oracle Clinical Research, Atlanta, United States; [12]Texas Liver Institute, San Antonio, United States*
Email: vian.azzu@doctors.org.uk

Background and aims: Fibroblast activation protein (FAP) is an endopeptidase with increasing hepatic expression as liver fibrosis progresses. FAP cleaves proteins that regulate extracellular matrix turnover and metabolism, such as denatured collagens, alpha-2-antiplasmin, and FGF21. Pharmacological inhibition of FAP in animal models of MASH and liver fibrosis shows anti-fibrosis benefit, and Phase I studies of AZD2389, a small molecule FAP inhibitor, in healthy participants showed robust changes in target engagement and proof of mechanism biomarkers. BORANA is a Phase IIa, randomized, single-blind, and placebo-controlled study, conducted in participants with liver fibrosis and compensated cirrhosis to assess safety, tolerability, PK and plasma FAP inhibition of AZD2389.
Method: The BORANA study (NCT06750276) comprised two parallel cohorts. Cohort A enrolled participants with MASH and fibrosis, Cohort B enrolled participants with non-MASH steatotic liver disease (including MetALD, ALD, and treated HCV), with advanced fibrosis. Participants were randomized (2:1 in each cohort) to receive AZD2389 or placebo treatment for 28 days. The primary objective was to assess safety and tolerability. Secondary objectives evaluated PK, plasma FAP inhibition as target engagement, and cleaved alpha-2-antiplasmin as a proof-of-mechanism biomarker.
Results: In total 22 participants were randomized to cohort A (14 AZD2389; 8 placebo) and 18 participants to cohort B (12 AZD2389; 6 placebo). No serious adverse events (AEs), AEs leading to discontinuations, or clinically significant AEs related to AZD2389 were reported. AZD2389 was rapidly absorbed (C_{max} 0.5-1-hour post-dose). There was no accumulation in plasma Cmax or AUCtau, and no time-dependency in PK over repeated dosing. AZD2389 inhibited plasma FAP activity by >90% at Cmax and >80% at 24-hour trough. AZD2389 reduced the percentage of FAP-cleaved alpha-2-antiplasmin by 39 units from baseline, which returned to baseline after washout.
Conclusion: AZD2389 was safe and well tolerated in participants with steatotic liver disease and fibrosis. AZD2389 showed a favourable PK profile consistent with once-daily dosing, without plasma accumulation during repeated dosing. AZD2389 achieved robust FAP inhibition throughout the dosing period of 28 days, accompanied by a reduction in physiological in vivo FAP substrate alpha-2-antiplasmin.

FRI-149
Reducing CV risk in patients with MASH independent of baseline based on Lp(a) and LDL lowering by resmetirom
Meena Bansal[1], Rebecca Taub[2], Dominic Labriola[2], David Soergel[2], Yestle Kim[2], Naim Alkhouri[3], Mazen Noureddin[4], Seth Baum[5], Rohit Loomba[6]. *[1]Icahn School of Medicine at Mount Sinai, New York, United States; [2]Madrigal Pharmaceuticals, Inc., West Conshohocken, United States; [3]Summit Clinical Research, San Antonio, United States; [4]Houston Methodist Hospital, Houston, United States; [5]Florida Atlantic University, Boca Raton, United States; [6]University of California San Diego School of Medicine, La Jolla, United States*
Email: meena.bansal@mssm.edu

Background and aims: Patients with metabolic dysfunction-associated steatohepatitis (MASH) have high cardiovascular morbidity and mortality. Resmetirom, a selective thyroid hormone receptor-beta agonist, is approved for treatment of patients with noncirrhotic MASH with moderate to advanced liver fibrosis. Resmetirom reduces atherogenic lipids and lipoproteins. In a secondary analysis of the Phase 3 MAESTRO-NASH clinical trial, the effects of resmetirom over 52 weeks on MASH efficacy parameters, atherogenic lipids, lipoproteins, and safety were evaluated according to baseline statin use.
Method: Data from the MAESTRO-NASH and MAESTRO-NAFLD-1 trials were analyzed. Analyses assessed MASH and lipid responses, shift in LDL and lipoprotein(a) [Lp(a)] risk profiles, and standard safety assessments including serial liver enzymes and adverse events according to baseline statin use.
Results: Approximately half (49%) of MAESTRO-NASH participants were on statins at baseline. Efficacy endpoints, including NASH resolution, fibrosis improvement and liver fat reductions were similar independent of statin codosing. Lipid lowering, showed significant improvement with resmetirom irrespective of baseline statin use; the percentage change at 24 weeks of resmetirom 80 mg, 100 mg, corrected for placebo in combination with statins or alone were LDL-C (−12.0, −18.7 (statin); −15.3, −14.1 [no statin]), Apolipoprotein B (ApoB) (−16.4, −20.7; −17.9; −19.9) and Lp(a) (−32.2, −35.8; −19.3, −26.6). In patients on statins 44.4% with LDL-C ≥70 mg/dL at baseline shifted to LDL-C <70 mg/dl with 100 mg resmetirom; 36.3% and 37.5% with Lp(a) ≥30 or ≥50 mg/dL at baseline shifted to <30 or <50 mg/dL with 100 mg resmetirom. No significant statin-related adverse events were observed.
Conclusion: Independent of statin use, treatment with resmetirom was efficacious at multiple MASH endpoints and improved lipid profiles for LDL-C, ApoB and Lp(a).

FRI-150-YI
Adipose tissue insulin resistance is a marker and a major driver of severe metabolic dysfunction associated steatohepatitis
Nateneal Beyene[1], Joel Haas[2], Silvia Sabatini[3], Wilhelmus Kwanten[1], Ann Driessen[4], Eveline Dirinck[5], Bart Staels[2], Christophe De Block[5], Sven Francque[1], Amalia Gastaldelli[3], Luisa Vonghia[1]. *[1]Department of Gastroenterology and Hepatology, Antwerp University Hospital, Laboratory of Experimental Medicine and Pediatrics, University of Antwerp, Antwerp, Belgium; [2]Université de Lille, Inserm, CHU Lille, Institut Pasteur de Lille, U1011 EGID, Lille, France; [3]Metabolic Diseases Research Group and Multi-Omics Mass Spectrometry Lab, Institute of Clinical Physiology, CNR, Pisa, Italy; [4]Department of Pathology, Antwerp*

University Hospital, Antwerp, Belgium; [5]Department of Endocrinology, Diabetology and Metabolic Diseases, Antwerp University Hospital, Antwerp, Belgium
Email: natenealtamerat.beyene@uantwerpen.be

Background and aims: Adipose insulin resistance (ADIPO-IR index) and excess free fatty acids (FFA, from impaired lipolysis suppression) are associated with severe fibrosis in MASLD. Whether ADIPO-IR also marks hepatic necro inflammation and MASH severity is unknown. We aimed to determine if ADIPO-IR independently predicts MASH and fibrosis and explore its links to hepatic inflammation and response to intervention.
Method: The cohort included 375 individuals without diagnosis diabetes at enrollment with liver biopsy categorized: MASH n = 219, No-MASH n = 104 (including MASL n = 64) and CT n = 52 (healthy liver).
Participants were also characterized with ADIPO-IR (FFAxInsulin), waist/height, visceral (VAT) and subcutaneous adipose tissue (SAT) by tomography, glucose tolerance by OGTT and PNPLA3 variants. A subgroup underwent liver transcriptomic analysis. An intervention subgroup with severe obesity was followed for 12 months after receiving either bariatric surgery (BS, n = 34) or lifestyle intervention (LS, n = 37), with post-intervention histology to find MASLD responders and non-responders. Logistic regression assessed ADIPO-IR as a predictor of MASH and fibrosis at baseline, adjusted for age, gender and BMI.
Results: Subjects with MASH, No MASH or CT had comparable BMI (38.2–39.5 kg/m2) and SAT. But MASH and No MASH had higher waist/height and VAT compared to CT ($p < 0.05$). ADIPO-IR increased with the severity of steatosis, inflammation and fibrosis. After adjusting for age, sex, and BMI, ADIPO-IR independently predicted the presence of MASH (OR = 1.72, $p = 0.003$) and significant fibrosis (OR = 1.92, $p = 0.004$). PNPLA3 variant carriers had similar ADIPO-IR. Liver transcriptomic analysis revealed that ADIPO-IR was positively correlated with the enrichment of gene sets related to inflammatory and immune responses, including neutrophil degranulation and interferon-gamma signaling. Post-intervention, ADIPO-IR was significantly reduced ($p < 0.0001$) and reduction below the overall median (FU/baseline = 0.4877) was more prevalent in the BS group (67.6% vs. 32.4% for LS) and in MASLD responders (60.5% vs. 32.1% for non-responders). Regardless of the intervention, the change in waist/height predicted ($p < 0.05$) the change in ADIPO-IR.
Conclusion: ADIPO-IR is an independent predictor of MASH and fibrosis in MASLD. Its correlation with hepatic inflammatory gene expression combined with its significant reduction following histological improvement, highlights ADIPO-IR as a key marker & driver of MASH.

FRI-151
Which comes first: GLP-1 RA vs resmetirom in MASH real world practice

Ana Maria Davila Morales[1], Amanda Rodriguez[1], Nancy S. Reau[1], Phoebe Lebeau[1]. [1]*Rush University, Chicago, United States*
Email: anamdavila95@gmail.com

Background and aims: Metabolic Dysfunction-Associated Steatotic Liver Disease (MASLD) is a spectrum of liver diseases ranging from steatosis to metabolic dysfunction-associated steatohepatitis (MASH). MASLD is associated with metabolic diseases such as obesity, hyperlipidemia, diabetes and hypertension. MASLD guidelines have not outlined which medication to start first and when to add a second agent. Resmetirom is used in patients with moderate to severe fibrosis without cirrhosis. Given the high prevalence of obesity and diabetes in this population, many are also treated with glucagon-like peptide-1 receptor agonists (GLP-1 RAs). These are indicated in patients with MASLD and those with dyslipidemia and cardiovascular disease may benefit from lipid-lowering effects, which is also a positive effect from resmetirom. Tailoring these medications in patients with multiple metabolic risk factors may prove beneficial. This study aims to provide insight into real-world treatment practices for the treatment of MASH.
Method: A retrospective study of patients currently on resmetirom for treatment of MASH with moderate to advanced liver fibrosis without cirrhosis at an academic medical center was conducted using Slicer Dicer. Concurrent use of GLP-1 RA medication was recorded. Data included BMI (body mass index) and presence of metabolic risk factors including obesity, dyslipidemia, hypertension and diabetes.
Results: 30 patients currently on resmetirom were identified. Of these, 50% were concurrently on a GLP-1 RA medication (n = 15). Of patients on single-agent treatment, one patient had 0 metabolic risk factors (6.6%), three had 1 risk factor (20%), seven had 2 risk factors (46.6%), three had 3 risk factors (20%), and one had 4 risk factors (6.6%). Of patients on dual-agent treatment, no patients had 0 or 1 metabolic risk factors, one patient had 2 risk factors (6.6%), ten had 3 risk factors (66.6%), and four patients had 4 risk factors (26.6%).
Conclusion: This study demonstrates that patients with MASH and 3 or more metabolic risk factors were more likely to be started on dual agent therapy with resmetirom and GLP-1 RA compared to single agent. This is the result of an approach targeted to address inflammation and fibrosis of the liver while also addressing underlying risk factors. The high prevalence of multiple risk factors present in patients with advanced MASH highlights the need for further studies to determine the effectiveness and benefits of dual agent therapy compared to single agent therapy.

FRI-152
Online case-based certified medical education improved clinical decision-making in the management of metabolic dysfunction-associated steatohepatitis

Shari Dermer[1], Julie Schrand[1], Jason Quinones[1], Roderick Smith[1], Jeffrey Lazarus[2]. [1]*Medscape Education, Newark, United States;* [2]*ISGlobal Barcelona Institute for Global Health, Barcelona, Spain*
Email: sdermer@medscape.net

Background and aims: Metabolic dysfunction-associated steatohepatitis (MASH) is a common, but often undertreated liver disease. Risk-stratification plays a critical role in determining an appropriate treatment approach for MASH. The objective of this study was to assess the effect of online case-based certified medical education (CME) on competence and confidence in managing MASH.
Method: Gastroenterologists/hepatologists (GI/Heps; n = 560) participated in a case-based activity that gauged clinical decision-making. Educational effect was assessed using a repeated-pair design. Pre/post-assessment was measured by 3 multiple choice questions and a paired samples t-test was conducted at the question level. Data are presented as % change pre to post-education for correct responses. A question rated by a 5-point Likert scale was used to determine confidence. Data were collected from May 8, 2025 to December 11, 2025.
Results: Risk-stratification using noninvasive tests (NITs) and imaging improved by 28% (57% to 85%; $p < .001$) following education. Interpretation of NITs improved by 46% (28% to 74%; $p < .001$). Selection of evidence-based MASH treatment improved by 48% (24% to 72%; $p < .001$) following education. Confidence in the ability to select patients with MASH for liver-directed therapy based on NITs increased following education with means of 2.83 pre to 3.33 post on a 5-point scale.
Conclusion: This study demonstrated that participation in case-based CME on MASH resulted in improved competence in assessing risk for MASH and in selection of evidence-based treatment. Moreover, there was increased confidence in the use of NITs to identify patients who are candidates for liver-directed MASH therapy. Based on competence and confidence prior to education, there are GI/Heps who would benefit from additional case-based education that allows for applying clinical decision-making.
Acknowledgement: Supported by an independent educational grant from Madrigal Pharmaceuticals.

Treatment with naltrexone/bupropion enhances lifestyle-induced improvements in hepatic steatosis in adults with overweight/obesity

Carmen Dietvorst[1,2], Willem Pieter Brouwer[3], Diederick Grobbee[4,5], Marco Alings[6], Maja Thiele[7,8], Jose Ordovas[9], Kirsten Berk[2], Robin Peeters[10], Manuel Castro Cabezas[1,5,10]. *[1]Department of Internal Medicine, Franciscus Gasthuis & Vlietland, Rotterdam, Netherlands; [2]Department of Internal Medicine, Division of Dietetics, Erasmus MC, Rotterdam, Netherlands; [3]Department of Gastroenterology and Hepatology, Erasmus MC, Rotterdam, Netherlands; [4]University Medical Center, Utrecht, Netherlands; [5]Julius Clinical, Zeist, Netherlands; [6]Department of Cardiology, Amphia hospital, Breda, Netherlands; [7]Center for Liver Research, Odense University Hospital, Odense, Denmark; [8]Evido Health, Copenhagen, Denmark; [9]USDA Human Nutrition Research Center on Aging, Tufts University, Boston, United States; [10]Department of Internal Medicine, Rotterdam, Netherlands*
Email: carmendietvorst@gmail.com

Background and aims: Metabolic dysfunction-associated steatotic liver disease (MASLD) is closely linked to overweight and obesity. Lifestyle modification is the cornerstone of therapy, but long-term weight reduction is challenging. Pharmacological agents such as naltrexone/bupropion (NB) may enhance weight loss and improve liver health. This study examined the impact of a 56-week lifestyle program with or without NB on hepatic markers and their association with weight change.
Method: The COR-BMOD trial enrolled adults with obesity or overweight plus hypertension or dyslipidaemia into a 56-week randomised, double-blind study combining an intensive lifestyle intervention with either placebo (LS) or NB in a 1:3 ratio. The program consisted of an energy-restricted diet (1200–1500 kcal/day), exercise guidance, and 28 group sessions targeting behavioural change. Weight, BMI, alanine aminotransferase (ALT), aspartate aminotransferase (AST), Hepatic Steatosis Index (HSI) and Metabolic Associated Fibrosis Score-5 (MAF-5) were assessed at baseline and after 56 weeks. (Non) parametric tests and regression analyses were performed.
Results: A total of 460 patients completed the study (mean age 46.8 ± 10.4 years; mean BMI 32.5 ± 5.0 kg/m^2; 88% female; LS n = 118, NB n = 342). After 56 weeks, both groups showed significant improvements in weight (LS −7.9, NB −11.7 kg; $p < 0.001$ for each), BMI (LS −2.8, NB − 4.7 kg/m^2; $p < 0.001$), ALT (LS −2.2 U/L, NB −2.8 U/L; $p < 0.05$), AST (LS −1.9 U/L, NB −1.5 U/L; $p < 0.05$), HSI (LS −3.5, NB −4.6; $p < 0.001$), and MAF-5 (LS −1.1, NB −1.2; $p < 0.001$). Improvements in BMI and HSI were significantly greater in the NB group compared with LS ($p < 0.05$). Regression analyses showed a moderate correlation between weight change and ALT in both groups. Weight loss was also strongly correlated with a decrease of MAF-5 and HSI.
Conclusion: NB treatment produced greater weight loss than lifestyle modification alone, with a more pronounced impact on liver steatosis than on liver fibrosis. These findings support NB as an effective adjunct to lifestyle intervention in overweight-related MASLD. The results reinforce that weight reduction remains the key determinant of improved liver health.

FRI-154

Timing and concordance of non-invasive treatment responses to Resmetirom in real-world practice

Winston Dunn[1], Rida Nadeem[2], Ashwani K. Singal[3], Amreen Dinani[4], Imad Asaad[5], Edward Mena[6], Colin Walsh[7], Sari Alothman[7], Sheel Patel[3], Jamil Abdo[3], Wamda Ahmed[8], Larissa Lushniak[4], Naim Alkhouri[7]. *[1]University of Kansas Medical Center, Pinnacle Clinical Research, Mission Hills, United States; [2]Arizona Liver Health, Chandler, United States; [3]University of Louisville, Louisville, United States; [4]Duke University, Durham, United States; [5]Firelands, Sandusky, United States; [6]California Liver Research Institute, Pasadena, United States; [7]Summit Clinical Research, San Antonio, United States; [8]University of Kansas, Kansas City, United States*
Email: naim.alkhouri@gmail.com

Background and aims: Current AASLD guidance recommends using changes in liver stiffness measurement (LSM), controlled attenuation parameter (CAP), and ALT to monitor treatment response to resmetirom. MAESTRO-NASH primarily assessed noninvasive responses at 12 months, and the timing and concordance of earlier time points (3, 6, and 9 months) remain poorly defined. Understanding the pattern of earlier treatment response in real-world practice is essential for avoiding premature classification of treatment failure. This study aimed to characterize the frequency and overlap of LSM, CAP, and ALT responses over the first year of therapy.
Method: We conducted a multicenter, real-world study of resmetirom-treated patients from five centers. Eligible patients met treatment criteria based on liver biopsy, ELF score, or LSM and had a baseline LSM with ≥1 follow-up LSM between 3 and 12 months. LSM response and worsening were defined as ≥25% reduction and increase from baseline; ALT response as ≥20% or 17 U/L reduction; and CAP response as ≥40-dB/m reduction. Partial response was defined as LSM response plus either ALT or CAP response, and complete response as concurrent LSM, ALT, and CAP responses.
Results: Among 2,236 treated patients, 220 with available baseline and follow-up LSM were included. At baseline, 55.7% had diabetes or impaired glucose tolerance, and 26.2% received concomitant GLP-1 therapy. Median baseline LSM was 11.0 kPa (IQR 8.9–12.0). LSM response occurred in 10.5%, 26.8%, 33.6%, and 38.6% of patients at 3, 6, 9, and 12 months, respectively. CAP response was observed in 12.3%, 35.5%, 42.5%, and 47.9%, while ALT response occurred in 19.5%, 31.8%, 35.5%, and 38.6% across the same time points. Partial response was present in 6.8%, 20.9%, 25.6%, and 29.7%, and complete response in 1.8%, 6.8%, 9.5%, and 11.4%, respectively. ALT response at 6 was associated with subsequent LSM response (odds ratio 2.38, 1.34–4.28; $p < 0.01$).
Conclusion: In real-world resmetirom-treated patients, non-invasive treatment responses accumulate gradually and show incomplete overlap across biochemical and elastographic domains. ALT response at 6 months shows moderate concordance with subsequent LSM response, supporting cautious interpretation of early biochemical improvement and reinforcing the need for integrated, longitudinal assessment across multiple non-invasive markers.

FRI-155

Efficacy of oral semaglutide in overweight- obese patients with metabolic dysfunction-associated steatotic liver disease (MASLD) related compensated advanced chronic liver disease (cACLD) - Results of first randomized controlled trial

Ajay Kumar Duseja[1], Prahlad Kumar[2], Arka De[3], Sunil Taneja[1], Naveen Kalra[4], Sanjay Bhadada[5], Suvradeep Mitra[6]. *[1]Department of Hepatology, Postgraduate Institute Of Medical Education And Research Chandigarh, Chandigarh, India; [2]Department of Internal Medicine, Postgraduate Institute Of Medical Education And Research Chandigarh, Chandigarh, India; [3]Department of Hepatology, Postgraduate Institute Of Medical Education And Research, Chandigarh, India, Chandigarh, India; [4]Department of Radiodiagnosis and Imaging, Postgraduate Institute Of Medical Education And Research Chandigarh, Chandigarh, India; [5]Department of Endocrinology, Postgraduate Institute Of Medical Education And Research Chandigarh, Chandigarh, India; [6]Department of Histopathology, Postgraduate Institute Of Medical Education And Research Chandigarh, Chandigarh, India*
Email: ajayduseja@yahoo.co.in

Background and aims: There are limited options for treating patients with advanced fibrosis in metabolic dysfunction-associated steatotic liver disease (MASLD) and no randomized data exists regarding the

efficacy of oral semaglutide in these patients. Aim of the present study was to assess the efficacy of oral semaglutide in improving hepatic steatosis and fibrosis in overweight/obese patients with MASLD related compensated advanced chronic liver disease (cACLD).
Method: In a prospective study, 52 MASLD-cACLD, overweight/obese patients (as per Asian criteria) with baseline weight –88.6 ± 15.8 kg vs 75.9 ± 6.6 kg, BMI- 31.99 ± 5.91 vs. 28.45 ± 2.33 kg/m^2, with or without diabetes mellitus matched for age (~53 years) and gender (~55% female) were randomised to lifestyle interventions plus oral semaglutide, 14 mg/day (29 patients) or lifestyle interventions alone (23 patients). MASLD was defined as per standard criteria and cACLD as LSM on VCTE ≥10 kPa (mean LSM- 20 kPa). Evaluation was done at 6 months for change in anthropometry, hepatic steatosis [controlled attenuation parameter (CAP), MRI-PDFF], at-risk MASH (FAST and MAST and hepatic fibrosis (LSM on VCTE, MRE, APRI, FIB-4, Agile 3+, Agile 4).
Results: Patients on oral semaglutide achieved significantly higher weight loss (~9%) at 6 months and in spite of having higher baseline value, there was significant reduction in in CAP (322.85 ± 39.32 to 292.42 ± 45.98; $p < 0.001$) in the semaglutide group in comparison to insignificant change in control group. Similarly, in spite of higher liver stiffness measurement (LSM) on VCTE at baseline, semaglutide led to a significant reduction in LSM (17.16 ± 10.79 kPa; $p < 0.001$) at 6 months, while the control group showed no change. Among 26 patients subjected to MR-PDFF, MAST and MRE at 6 months with comparable baseline values, there greater reduction in MR-PDFF ($p = 0.034$) and MRE ($p = 0.043$), in comparison to controls. The reduction in Agile 3+, Agile 4 scores were also significant in the semaglutide group, however the difference in the change of APRI, FIB-4, FAST and MAST scores was not significant among the two groups. Oral semaglutide was well tolerated except for minor GI side effects. There were no hepatic decompensation or development of HCC in either group.
Conclusion: In a first randomized controlled trial, oral semaglutide, administered for 6 months, achieved substantial weight loss and significant improvement in non-invasive hepatic steatosis and fibrosis indices in MASLD-related cACLD without safety concerns.

FRI-156
DR10624, a novel FGF21R/GCGR/GLP-1R triple agonist, significantly reduced liver fat and improved hepatic and metabolic biomarkers in a phase 2 study of patients with severe hypertriglyceridemia

Yongliang Fang[1], Yanting Fan[2], Long Zhang[3], Yan Zhang[3], Chaonan Zhu[2], Kaile Zhou[2], Yulong Gan[1], Jun Zhou[2], Ying Wang[1], Junfang Xu[2], Yanshan Huang[1], Jianping Li[3]. [1]*Zhejiang Doer Biologics Co., Ltd., Hangzhou, China;* [2]*Huadong Medicine Co., Ltd., Hangzhou, China;* [3]*Peking University First Hospital, Beijing, China*
Email: fyl323@gmail.com

Background and aims: Severe hypertriglyceridemia (SHTG) is frequently associated with hepatic steatosis, contributing to increased risk of metabolic dysfunction-associated steatotic liver disease (MASLD). DR10624 is a first-in-class long-acting triple agonist against FGF21R, GCGR, and GLP-1R. In a Phase 2 study in participants with SHTG, DR10624 demonstrated significant improvement in participants' lipid profile, liver function, and metabolic biomarkers.
Method: This Phase 2 trial was a 12-week randomized, double-blind, placebo-controlled, multi-center study in adults with SHTG (fasting triglycerides [TG] between 5.6 mmol/L [500 mg/dL] and 22.6 mmol/L [2000mg/dL]). Participants received weekly subcutaneous injection of DR10624 (12.5 mg, 25 mg, or 50 mg titration) or placebo for 12 weeks. Prespecified liver and metabolic-related biomarkers included liver fat content (LFC), assessed by MRI-PDFF; alanine aminotransferase (ALT); aspartate aminotransferase (AST); alkaline phosphatase (ALP); Fibrosis-4 (FIB-4); and adiponectin.
Results: A total of 79 participants were included (mean age: 46.0, 70.0% male), with baseline TG (median 9.4 mmol/L [800 mg/dL]). At week 12, the median relative reduction from baseline in LFC was significantly greater with DR10624 (–63.2%, –53.7%, and –67.0% in the 12.5 mg, 25 mg, and 50 mg titration, respectively) than with placebo (–8.4%). After treatment with DR10624 at doses of 12.5 mg, 25 mg, and 50 mg titration, ≥50% relative reductions in LFC were achieved by 52.4%, 44.4%, and 71.3% of participants, respectively, compared with 5.7% in the placebo group, while normalized liver fat (LFC<5% by MRI-PDFF) was observed in 47.6%, of participants, respectively, versus 5.6% with placebo. DR10624 was associated with significant improvements in liver enzymes, particularly in the higher-dose group, including reductions in ALT (–10.0 U/L in 25 mg, $P = 0.0458$), AST (–10.0 U/L, – 5.4U/L in 25 mg, 50 mg titration, $P = 0.0012$, 0.0135, respectively), and ALP (–7.0 U/L in 50 mg titration, $P = 0.0439$). DR10624 led to significantly increased adiponectin levels by 1.9 mg/dL, 2.6 mg/dL, and 3.1 mg/dL in 12.5 mg, 25 mg, and 50 mg titration, respectively. DR10624 also decreased FIB-4 by –0.19 in the 50 mg titration.
Conclusion: In patients with SHTG, treatment with DR10624 produced robust reductions in triglyceride levels and was associated with significant improvements in liver steatosis, hepatic function, and metabolic biomarkers. Collectively, these findings support DR10624 as a promising therapy for MASLD.

FRI-157-YI
Habitual aspirin use and MRI-derived liver fat and fibroinflammation

Qi Feng[1], Pinelopi Manousou[1], Chioma Izzi-Engbeaya[1], Mark Woodward[1]. [1]*Imperial College London, London, United Kingdom*
Email: ermadake@gmail.com

Background and aims: Steatotic liver disease is the most prevalent chronic liver condition, affecting one-third of the adult population. Habitual aspirin use is common among older adults. This study aimed to investigate the relationship between aspirin use and liver fat accumulation and fibroinflammation.
Method: We used UK Biobank imaging cohort data. Aspirin use was self-reported at baseline and imaging assessment, and the main exposures were aspirin use at imaging assessment and longitudinal aspirin use patterns (never users, initiators, discontinuers, vs. persistent users). Outcomes were MRI-derived liver fat (%) and cT1 (ms, a measure for fibroinflammation). Multivariable adjustment analyses and inverse probability of treatment weighting (IPTW) analyses were performed, accounting for demographic, lifestyle and clinical factors.
Results: We included 36413 participants (age 64.6 years, 51.4% female). Aspirin use at imaging assessment was associated with lower liver fat (–0.35 (95% CI: –0.51, –0.20)) and slightly higher cT1 (5.13 (95% CI: 3.23, 7.03)). Analyses on longitudinal aspirin use pattern showed that compared to never users, initiators and persistent users showed lower liver fat (–0.48 (–0.69, –0.28) and (–0.24 (–0.45, –0.02)) and higher cT1 (2.94 (0.38, 5.49) and 8.31 (5.65, 10.97)). IPTW analyses showed consistent results.
Conclusion: In this large population-based cohort, aspirin use was linked to reduced liver fat, but a small, clinically insignificant (i.e. <80 ms) increase in cT1. These findings suggest aspirin may mitigate steatosis through metabolic pathways but does not necessarily rapidly reverse fibroinflammatory injury.

FRI-158-YI

Additive associations of the mediterranean diet, physical activity, and coffee consumption with reduced risk of liver fibrosis in metabolic dysfunction-associated steatotic liver disease

Meng-Lun Hsieh[1], Yen-Chun Peng[1,2], Vivian Chia-Rong Hsieh[3].
[1]*Taichung Veterans General Hospital, Taichung, Taiwan;* [2]*School of Medicine, National Yang Ming Chiao Tung University, Beitou District, Taiwan;* [3]*China Medical University, Beitun District, Taiwan*
Email: morganpolo@gmail.com

Background and aims: Mediterranean diet (MD), physical activity (PA), and coffee intake are key non-pharmacological strategies recommended by practice guidelines for improving outcomes in patients with metabolic dysfunction-associated steatotic liver disease (MASLD). This study aims to explore the combined association of these lifestyle factors with liver fibrosis in this population.
Method: Data from the National Health and Nutrition Examination Survey 2017-March 2020 were analyzed in this cross-sectional study. MASLD was defined by the latest criteria, using controlled attenuation parameter (CAP) ≥275 dB/m for steatosis. MD adherence, PA, and coffee consumption were derived from questionnaire data. Participants were categorized into tertiles of MD adherence (low, moderate, high by alternate MD index), PA groups (<600 vs. ≥600 MET-min/week), and coffee consumption groups (0, 0–2, ≥2 cups/day). Significant liver fibrosis was defined as liver stiffness measurement (LSM) ≥8 kPa. Multivariate logistic regression was performed with sample weights to compare fibrosis risk across various lifestyle groups, adjusting for age, sex, smoking, alcohol intake, diabetes, and hypertension.
Results: A total of 2,672 participants with MASLD were identified who had complete dietary, PA, LSM and CAP data. Higher proportions of DM (38.1% vs. 21.2%), hypertension (66.5% vs. 52.7%) and higher CAP (343.9 vs. 319.7 dB/m) were observed among those with significant fibrosis compared to those without. MD adherence, coffee consumption and PA were each independently and inversely associated with the risk of significant fibrosis in multivariate analysis (high vs. low MD adherence, aOR: 0.67, $p < 0.01$; coffee ≥2 vs. 0 cups/day, aOR: 0.48, $p < 0.01$; PA ≥ 600 vs. <600 MET-minutes/week, aOR: 0.76, $p < 0.01$). Combined analysis revealed an additive, dose-dependent protective association between three lifestyle factors and significant fibrosis. For example, in participants with low PA, the risk of significant fibrosis decreased with increasing coffee consumption and MD adherence (low PA/≥ 2 cups coffee/high MD vs. low PA/0 cup coffee/low MD, aOR: 0.316, 95% CI: 0.314–0.318). Lowest risk (aOR: 0.194, 95% CI: 0.192–0.195) was observed in individuals with the highest adherence to all three behaviors.
Conclusion: An additive association of MD adherence, coffee consumption, and PA with significant liver fibrosis was observed among MASLD individuals. Our findings support guideline-recommended adherence to these lifestyle patterns.

FRI-159

Dose-dependent efficacy and renal safety of pemafibrate in patients with MASLD: a multicenter randomized controlled trial

Email: michihirokeidai@yahoo.co.jp

Background and aims: The prevalence of metabolic dysfunction–associated steatotic liver disease (MASLD) is rapidly increasing worldwide, yet effective pharmacologic options remain limited. Pemafibrate, a selective PPARα modulator (SPPARMα), has stronger activity and selectivity than conventional PPARα agonists and may improve liver function. This study evaluated the efficacy and safety of pemafibrate in patients with MASLD.
Method: This multicenter, open-label, randomized controlled trial enrolled 360 patients with MASLD and hypertriglyceridemia at 29 sites in Japan. Participants were randomized to high-dose pemafibrate 0.4 mg/day (PEM-H), low-dose pemafibrate 0.2 mg/day (PEM-L), or fenofibrate 53.3–106.6 mg/day (FENO). The primary endpoint was the change in ALT at Week 24. Secondary endpoints included liver fibrosis markers, renal parameters, and MR elastography (MRE) at Week 48.
Results: At Week 24, both pemafibrate groups achieved significantly greater ALT reductions than fenofibrate (Mean: −24.0 U/L in PEM-H, −14.8 U/L in PEM-L, −4.22 U/L in FENO; PEM-H vs FENO $p < 0.001$; PEM-L vs FENO $p = 0.018$). PEM-H also showed greater improvement than PEM-L ($p = 0.018$), indicating clear dose dependency. At Week 48, Mac-2 binding protein glycosylation isomer decreased markedly in PEM-H (−21.6%) and PEM-L (−17.8%) but only modestly with FENO (−3.2%). Type IV collagen 7 s and Enhanced Liver Fibrosis score showed no statistically significant differences among the three groups. Liver stiffness by MRE improved in PEM-H (−9.2 ± 14.0%) and PEM-L (−8.4 ± 9.9%), whereas it increased in FENO (+3.6 ± 21.4%), demonstrating a significant benefit with pemafibrate. Renal parameters were significantly more favorable with pemafibrate compared with fenofibrate. Treatment-related adverse events occurred less frequently with pemafibrate (n = 8 in PEM-H; n = 8 in PEM-L) than with FENO (n = 18), including 15 muscle-related events in the FENO group. Hepatobiliary disorders occurred only with FENO (n = 5). No treatment-related serious adverse events were reported in either pemafibrate group.
Conclusion: Pemafibrate produced significantly greater ALT improvement than fenofibrate, with a clear dose–response relationship and a more favorable renal and safety profile. Reductions in M2BPGi and MRE-based liver stiffness suggest potential anti-inflammatory and anti-fibrotic effects. These results support pemafibrate as a promising therapeutic option for patients with MASLD and hypertriglyceridemia, and further histology-based studies are warranted.

FRI-163

Cost-effectiveness of resmetirom treatment, aligned with practice guidance, for suspected 'At-Risk MASH' identified by transient elastography without histologic confirmation

Jeong-Yeon Cho[1], Dae Won Jun[2], Eileen Yoon[2], Jihyun An[2], Ha Il Kim[2], Chul-min Lee[3], Mimi Kim[3], Bo-Kyeong Kang[3], Eun Chul Jang[4], Sang Bong Ahn[5], Joo Hyun Oh[6], Hyo Young Lee[2], Hye-Lin Kim[7], Nathorn Chaiyakunapruk[1]. [1]*Department of Pharmacotherapy, University of Utah College of Pharmacy, Salt Lake, United States;* [2]*Department of Internal Medicine, Hanyang University College of Medicine, Seoul, Korea, Rep. of South;* [3]*Department of Radiology, Hanyang University College of Medicine, Seoul, Korea, Rep. of South;*

[4]Department of Occupational and Environmental Medicine, College of Medicine, Soonchunhyang University, Chunan, Korea, Rep. of South; [5]Department of Internal Medicine, Nowon Eulji Medical Center, Eulji University, Seoul, Korea, Rep. of South; [6]Department of Internal Medicine, CHA University College of Medicine, Seongnam, Korea, Rep. of South; [7]College of Pharmacy, Sahmyook University, Seoul, Korea, Rep. of South
Email: noshin@hanyang.ac.kr

Background and aims: Resmetirom can be prescribed in clinical practice based on noninvasive tests (NITs) without liver biopsy for patients with suspected at-risk metabolic dysfunction–associated steatohepatitis (MASH). However, NITs–based selection may include false positives (e.g., F0–F1 hepatic fibrosis) cases, creating uncertainty regarding the cost-effectiveness of NITs oriented, guidance-aligned treatment.
Method: We conducted a cost-utility analysis from the US healthcare payer perspective to evaluate resmetirom treatment for suspicious at risk MASH based on NITs versus no treatment. A decision-analytic Markov model simulated fibrosis progression/regression and liver- and cardiovascular-related outcomes; costs and quality-adjusted life-years (QALYs) were discounted at 3% annually. Treatment effects on fibrosis progression and regression were based on MAESTRO-NASH relative risks, and cardiovascular benefit was conservatively modeled via LDL-cholesterol–mediated risk reduction. Base-case analyses assumed a cohort of 100,000 patients starting at age 40 years, with willingness-to-pay set at $150,000/QALY.
Results: In the base case, resmetirom treatment yielded 1.00 incremental QALYs and 1.06 incremental life-years at an incremental cost of $137,151 per patient, resulting in an incremental cost-effectiveness ratio (ICER) of $137,361/QALY. Although VCTE-based eligibility included 19% F0–F1 and 28% F4 at baseline, resmetirom remained cost-effective compared with no treatment, largely driven by reductions in liver-related complications and cardiovascular events that partially offset medication costs. In one-way sensitivity analyses, resmetirom price was the dominant driver: a 50% price reduction lowered the ICER to $106,525/QALY, and a semaglutide-level price scenario lowered it to $41,119/QALY. Lower assumed treatment effectiveness in F4 (50% of F2–F3 effect) increased the ICER to $153,883/QALY, slightly above the willingness-to-pay threshold. In probabilistic sensitivity analysis, the probability that resmetirom was cost-effective was 65% at $150,000/QALY, with cost-effectiveness becoming more likely than no treatment at approximately $130,000/QALY.
Conclusion: NITs based resmetirom treatment guidance is likely to be cost-effective in US practice, despite inclusion of considerable without histologic F2–F3.

FRI-164

Safety and efficacy of Lactobacillus delbrueckii subsp. lactis CKDB001 in patients with metabolic-associated steatotic liver disease: a randomized, double-blind, placebo-controlled phase II clinical trial

Jung Hee Kim[1], Ki Tae Suk[1]. [1]Hallym Medical Center, Chuncheon, Korea, Rep. of South
Email: mazyyang5@gmail.com

Background and aims: *Lactobacillus delbrueckii* subsp. *lactis* CKDB001 is a probiotic derived from raw milk fermentation with hepatoprotective and metabolic effects mediated through bile acid metabolism, lipid handling, and gut–liver axis signaling. This study evaluated its safety, clinical efficacy, and gut microbiome–metabolome modulation in patients with metabolic dysfunction–associated steatotic liver disease (MASLD).
Method: In this randomized, double-blind, placebo-controlled trial, patients with MASLD received CKDB001 (5.0×10^9 CFU/day, one capsule twice daily; n = 46) or placebo (n = 43) for 12 weeks. Primary outcomes were changes in serum AST and ALT. Secondary outcomes included liver function markers, lipid and glucose metabolism parameters, and fatigue. Exploratory outcomes assessed anthropometry, hepatic steatosis and stiffness by transient elastography, and gut microbiome and metabolome profiles using an integrative multi-omics.
Results: Eighty-nine participants (mean age 44.7 years; mean BMI 29.9 kg/m^2) were included, with comparable baseline characteristics between groups and no withdrawals. CKDB001 was well tolerated, with no differences in adverse events or aminotransferase levels compared with placebo. Favorable trends were observed in insulin resistance and hepatic steatosis. Significant reductions in waist and hip circumference were observed exclusively in the intervention group (all $p < 0.005$). Multi-omics analyses revealed stable microbial diversity but intervention-specific shifts in microbial taxa and metabolites at Week 12. Treatment-by-time interactions were identified for 8 taxa and 12 metabolites, including increases in *L. delbrueckii* and the butyrate-producing *Faecalibacterium duncaniae* (all $p < 0.001$). Lipid-related and bioactive metabolites involved in inflammation and host signaling were significantly altered. Correlation analyses linked *L. delbrueckii* with indole-3-butyric acid and 17α-hydroxyprogesterone, and *F. duncaniae* with arachidonic acid–related metabolites, indicating coordinated microbe–metabolite modulation.
Conclusion: CKDB001 supplementation modulated key metabolites and lipid mediators associated with gut–liver axis signaling in patients with MASLD. These findings suggest a mechanistic basis for its metabolic benefits and support further large-scale studies to evaluate its potential as a therapeutic target for MASLD.

FRI-165

Real-world effectiveness of one year of Resmetirom treatment in at-risk metabolic dysfunction–associated steatohepatitis

Rida Nadeem[1], Anita Kohli[1], Ann Moore[2], Savannah Nelson[1], Himanshi Kapoor[1], Noor El-Gendy[1], Erfan Asadipour[1], Noor El-Gendy[1], Sean Macaraeg[1], Phuong Nguyen[1,3], Richard Manch[1], Justin Reynolds[2], Jessica Omana Castaneda[1]. [1]Arizona Liver Health, Chandler, United States; [2]Arizona Liver Health, Peoria, United States; [3]Abrazo Health Network, Glendale, United States
Email: rnadeem@azclinicaltrials.com

Background and aims: Resmetirom, a selective thyroid hormone receptor-β agonist, has demonstrated histologic efficacy in the treatment of metabolic dysfunction–associated steatohepatitis (MASH). However, real-world data evaluating treatment response is limited. We aimed to assess hepatic and metabolic responses to resmetirom in a real-world MASH population treated for a minimum of one year using changes in NITs.
Method: We conducted a retrospective real-world study of adults with presumptive F2 or F3 MASH (at-risk MASH) treated with resmetirom in an outpatient hepatology practice. A total of 599 patients were prescribed resmetirom between March 2024 and July 2025, with 331 patients having completed at least 52 weeks of resmiterom. Patients on GLP-1 or GIP analog therapies (n = 268) were excluded from analysis given potential confounding. Liver disease activity and fibrosis were assessed at baseline and follow-up using NITs including serum aminotransferases, fibrosis scores (e.g., FIB-4, FAST), and vibration-controlled transient elastography (VCTE). Treatment response was defined as improvement in liver enzymes and percent changes in hepatic steatosis and fibrosis NITs. Secondary outcomes included changes in lipid parameters and resmiterom tolerability.
Results: 204 patients who completed atleast 52 weeks of resmiterom were included (mean age 55 years; 42% male; mean BMI 37.7 kg/m^2). 49.5% of patients had T2DM, 33.8% dyslipidemia, and 54.9% hypertension. After 52 weeks of treatment, 62.7% of patients had a one stage or greater reduction in liver fibrosis by VTCE. Mean reduction in VCTE kpa was 32.2%. Mean reduction in hepatic steatosis as measured by VCTE CAP was 21.1%. Decrease in hepatic inflammation at 52 weeks seen with mean reduction of AST and ALT 12.5 IU/L

and 22.44 IU/L respectively. Total cholesterol reduced by a mean of 24.36 mg/dL, LDL-cholesterol by 26.19 mg/dL, triglycerides by 68.6 mg/dL, and HDL increased by a 5.5 mg/dL after 52 weeks. 8% of patients discontinued therapy due to adverse events.
Conclusion: In a real-world clinical setting, 52 weeks of resmetirom treatment was associated with significant improvements in hepatic fibrosis and steatosis, as well as multiple biochemical and cardiometabolic parameters in patients with at-risk MASH. Therapy was safe and well tolerated across a diverse patient population with multiple comorbidities. These findings support the effectiveness of resmetirom in a real world patient population where NITs are routinely used to intiate and guide therapy.

FRI-166-YI
Improvement of liver steatosis after bariatric surgery in severe obesity is associated to weight reduction and type of surgery
Laura Konings[1,2], Carmen Dietvorst[1,2], Willy Theel[2], Jan Apers[1], Susan ter Borg[1], Tessa Noordermeer[1], Manuel Castro Cabezas[1,2].
[1]Franciscus Gasthuis, Rotterdam, Netherlands; [2]Erasmus University Medical Center, Rotterdam, Netherlands
Email: l.konings@franciscus.nl

Background and aims: Metabolic dysfunction-associated steatotic liver disease (MASLD) affects many patients with severe obesity. Weight reduction following bariatric surgery has been associated with improvement of MASLD. Vibration-controlled transient elastography (VCTE) is a non-invasive and reliable method to estimate liver steatosis (by controlled attenuation parameter, CAP) and fibrosis (by liver stiffness measurement, LSM). The aim of this study was to evaluate changes in liver steatosis and fibrosis after gastric sleeve resection (GS) or gastric bypass (GB).
Method: The Franciscus Obesity NASH Study (FONS) is a single centre cohort study including patients undergoing bariatric surgery. VCTE was done at baseline and at least one year after surgery. Anthropometric characteristics and laboratory data were also collected.
Results: Of the 229 subjects who underwent bariatric surgery, 170 subjects underwent VCTE at baseline and after one year. Overall, there was a significant decrease in weight, BMI, CAP and LSM. There were no baseline differences between GB (n = 77) and GS (n = 93) regarding age, weight, BMI, CAP or LSM. Before surgery, liver steatosis (CAP ≥ 275 dB/m) was present in 69% of patients in the GB group and 60% of patients in the GS group. At one-year follow-up, steatosis prevalence decreased to 5% in the GB group and 11% in the GS group. Liver fibrosis (LSM ≥ 8 kPa) was observed preoperatively in 51% of GB patients and 46% of GS patients, decreasing postoperatively to 3% and 9%, respectively. Although CAP normalised in both groups, the GB group had a greater decrease in CAP of – 98 ± 49 dB/m compared to – 65 ± 57 dB/m ($p < 0.001$). Patients in the GB group showed slightly greater improvements in BMI and weight, but not in LSM. Reductions in CAP were significantly associated with decreases in BMI, waist circumference and weight. In contrast, no such associations were observed for changes in LSM. In multivariable linear regression analyses, improvement in CAP was strongly associated with weight loss and type of surgery, whereas improvement in LSM was not associated with either.
Conclusion: Bariatric surgery leads to significant improvements in both liver steatosis and fibrosis. Improvement in liver steatosis was associated with reductions in BMI and was more pronounced following gastric bypass. In contrast, improvements in liver fibrosis were not dependent on the type of surgery or BMI.

FRI-167
First-in-human phase 1 study to evaluate the safety, tolerability, pharmacokinetics and pharmacodynamics of HP515, a selective THR beta agonist, in healthy participants
Fei Lan[1], Yangming Guo[1], Xiaolan Yong[2], Xiuqin Jia[1], Ling Chen[1], Yuanyuan Xv[1], Fei Luo[1], Yao Zhang[1], Zheng Yao[1], Simon Li[1], Yuanwei Chen[1], Xinghai Li[1]. *[1]Chengdu, China; [2]Chengdu Xinhua Hospital, Chengdu, China*
Email: flan@hinovapharma.com

Background and aims: HP515 is an oral small-molecule selective thyroid hormone receptor beta (THR beta) agonist developed to improve hepatic lipid metabolism while minimal systemic thyroid effects. Preclinical studies showed robust THR beta engagement with marked reductions in hepatic steatosis and improvements in metabolic dysfunction-associated steatohepatitis-related histologic features, alongside a wide safety margin. This study aimed to assess safety, tolerability, pharmacokinetics (PK), and pharmacodynamics (PD) of HP515 in healthy participants.
Method: This was a randomized, double-blind, placebo-controlled Phase 1 study including single ascending dose (SAD) and multiple ascending dose (MAD) cohorts. Participants in SAD cohorts received a single oral dose at 10, 20, 40, 80, 120, 160, or 200 milligrams (mg), while participants in MAD cohorts received 40, 60, or 80 mg, po, once daily for 14 days. Safety assessments included adverse events, clinical laboratory tests, vital signs, and electrocardiograms. PK parameters were calculated for single and repeated dosing. PD biomarkers included total cholesterol, low-density lipoprotein cholesterol, apolipoprotein B, small dense low-density lipoprotein cholesterol, and sex hormone binding globulin (SHBG).
Results: HP515 was safe and well tolerated at all doses. No serious adverse events or dose-limiting toxicities (DLT) occurred. Similar to the observation reported with other THR beta agonists, transient, asymptomatic alanine aminotransferase and aspartate aminotransferase elevations occurred in one subject in 60 mg cohort and one in 80 mg cohort in MAD part, which were normalized without intervention. PK exposure increased approximately dose-proportionally from 10 to 80 mg and greater than dose-proportionally from 80 to 200 mg. Following repeated dosing, the time to HP515 maximum concentration was approximately 2 to 4.5 hours, and the elimination half-life was 3 to 3.6 hours, supporting once-daily administration. Dose-dependent PD effects included reductions in lipid parameters and increases in SHBG at 40–80 mg, consistent with THR beta activation.
Conclusion: HP515 demonstrated a favorable safety profile, predictable PK, and dose-dependent PD activity in healthy participants. These results support ongoing Phase 2a dose-finding study in patients with metabolic dysfunction-associated steatotic liver disease.

FRI-168
Treatment effects of survodutide, a glucagon/glucagon-like peptide-1 receptor dual agonist, on hepatic biomarkers in patients with compensated and decompensated cirrhosis
Eric Lawitz[1], Yesilda Balavarca[2], Naim Alkhouri[3], Wiebke K. Fenske[4], István Takács[5], Daniel F. Mazo[6], Luiza Borowska[6], Corinna Schoelch[7].
[1]Texas Liver Institute, University of Texas Health San Antonio, San Antonio, United States; [2]Staburo GmbH, München, Germany; [3]Summit Clinical Research, Clinical Research Institute of Ohio, San Antonio, United States; [4]University Hospital Bonn, Bonn, Germany; [5]Semmelweis University, Budapest, Hungary; [6]Boehringer Ingelheim International GmbH, Ingelheim, Germany; [7]Boehringer Ingelheim Pharma GmbH & Co. KG, Biberach, Germany
Email: lawitz@txliver.com

Background and aims: Survodutide is a glucagon/glucagon-like peptide-1 receptor dual agonist under investigation in phase 3 trials for metabolic dysfunction-associated steatohepatitis (MASH) and obesity. In a phase 1 trial investigating safety, survodutide was

associated with improvements in liver-related non-invasive tests in patients with advanced liver disease (NCT05296733). We report a longitudinal analysis of survodutide effects on fibrosis and inflammation biomarkers in patients with cirrhosis.

Method: This was a multinational, non-randomized, open-label phase 1 clinical trial in patients with overweight/obesity, with or without cirrhosis by Child-Pugh criteria. Once-weekly subcutaneous doses of survodutide were escalated from 0.3 mg to 6.0 mg over 24 weeks then maintained for 4 weeks. Exploratory serological biomarkers measured longitudinally from baseline (BL) to Week 28 (W28) included Enhanced Liver Fibrosis (ELF)™ score and its components (hyaluronic acid [HA], tissue inhibitor of matrix metalloproteinase 1 [TIMP-1], and pro-collagen III amino-terminal peptide [PIIINP]); N-terminal type III collagen propeptide (PRO-C3); cytokeratin 18 (CK18-M30/CK18-M65); and glucagon. Descriptive statistics are reported.

Results: This analysis included 41 patients: 17 without cirrhosis, 16 with compensated cirrhosis, and 8 with decompensated cirrhosis, mostly due to MASH. Biomarker levels were elevated at BL in patients with cirrhosis vs those without. After 28 weeks of survodutide treatment, those without cirrhosis and those with compensated or decompensated cirrhosis exhibited reductions in mean ELF™ scores (value at BL: 8.65, 11.21, 11.53; W28: 8.46, 10.75, 10.80) and geometric means (gMean) for HA (value at BL: 22.66, 230.38, 289.88; W28: 21.89, 177.90, 152.83 ug/L), PIIINP (BL: 8.24, 15.37, 17.45; W28: 6.89, 11.35, 13.56 ug/L), PRO-C3 (BL: 30.72, 50.51, 48.61; W28: 19.63, 35.49, 36.23 ug/L), CK18-M30 (BL: 98.8, 265.5, 238.6; W28: 65.6, 156.7, 203.0 U/L), CK18-M65 (BL: 161.6, 433.9, 442.3; W28: 111.4, 313.7, 371.4 U/L), and glucagon (BL: 64.83, 68.23, 105.71; W28: 44.47, 49.11, 71.27 pmol/L), respectively. No consistent change in gMean was observed for TIMP-1 (BL: 223.11, 301.44, 326.89; W28: 209.26, 295.66, 328.10 ug/L).

Conclusion: Survodutide improved hepatic biomarkers of fibrosis and inflammation in both compensated and decompensated cirrhosis. These findings suggest potential disease-modifying effects in MASH-related cirrhosis; a large phase 3 trial in compensated MASH cirrhosis is ongoing (NCT06632457).

FRI-169

Phase 2a single doses of GSK4532990 produce sustained HSD17B13 suppression and liver biochemical improvement in patients with metabolic dysfunction-associated steatohepatitis

Eric Lawitz[1], Itziar Irurzun[2], Nitendra Agarwal[3], Nomita Kim[4], Raj Vuppalanchi[5], Kathy-Ann Cadogan[6], Hardik Chandasana[6], Marc Goldfinger[7], Chronis Kemos[8], Andrea Ribeiro[2], Brandon Swift[9], MeeJ Kim[10]. *[1]Texas Liver Institute, University of Texas Health and University of Texas Health Science Center, San Antonio, TX, United States; [2]GSK, Madrid, Spain; [3]ERG Clinical, San Antonio, TX, United States; [4]IMA Clinical Research, Austin, TX, United States; [5]Indiana University School of Medicine, Indianapolis, IN, United States; [6]GSK (At the time of the study), Collegeville, PA, United States; [7]GSK, London, United Kingdom; [8]GSK, Stevenage, Hertfordshire, United Kingdom; [9]GSK, Durham, NC, United States; [10]GSK, Rockville, MD, United States*
Email: lawitz@txliver.com

Background and aims: Loss-of-function (LOF) gene mutations in *hydroxysteroid 17-beta-dehydrogenase-13* (*HSD17B13*) are associated with reduced risk of liver disease (metabolic dysfunction-associated steatohepatitis [MASH] and alcohol-related liver disease [ALD]). GSK4532990, an N-acetylgalactosamine conjugated siRNA, selectively targets *HSD17B13* in hepatocytes to mimic the LOF mutation. This dose exploration study investigated hepatic target engagement of single doses of GSK4532990 in patients with MASH.

Method: This Phase 2a (NCT06104319), open-label, multi-center study assessed pharmacokinetics (PK), pharmacodynamics, safety and tolerability of GSK4532990. The 61 eligible adults enrolled had a diagnosis of MASH or suspected MASH (defined per protocol). Paired liver biopsies were collected pre- and post-dose (8, 12 or 28 weeks) after a single dose of 25, 200, 400 or 800 mg, administered by subcutaneous injection. Hepatic HSD17B13 mRNA and protein levels, PK and safety (laboratory tests, adverse events [AEs], vital signs, ECGs) were assessed.

Results: Mean (SD) percent change from baseline in hepatic HSD17B13 mRNA and protein after 12 weeks for the 25 mg, 200 mg, 400 mg doses were: −53.1 (15.7), −88.6 (4.4), −90.0 (2.7) and −44.7 (7.9), −80.9 (6.4), −85.4 (1.5), respectively; for the 800 mg dose knockdown was −80.4 (17.0) and −70.1 (18.5) at Week 28. Across the four doses, mean (SD) GSK4532990 maximum plasma concentration was 47.4 (18.3), 455 (203), 1060 (595), 3340 (1990) ng/mL; half-life ($t_{1/2}$) was 8.7 (3.2), 6.0 (2.8), 5.7 (2.4), 5.4 (1.8) hours. Mean (SD) change from baseline in alanine aminotransferase U/L, at Week 12, was: −16.8 (32.8), −26.3 (33.5), −45.0 (37.1), −26.1 (19.2), with similar trends of reduction for aspartate aminotransferase and gamma glutamyl transferase. Treatment-emergent AEs occurred in 25 participants and were mainly mild–moderate, including three non-drug-related serious AEs in two participants; no liver AEs were considered GSK4532990-related.

Conclusion: Robust and sustained dose-dependent knockdown of hepatic HSD17B13 was observed after a single dose of GSK4532990 with continued suppression observed with 800 mg at 28 weeks despite a short $t_{1/2}$. mRNA and protein levels demonstrated strong concordance, associated with liver biochemical improvements. GSK4532990 was well tolerated, with a mild–moderate AE profile, consistent with Phase 1/2a study results. These data support the continued development of GSK4532990 in MASH and ALD.

FRI-170

Results from two phase I trials evaluating the safety, pharmacokinetics, and efficacy of BI 3006337, a dual fibroblast growth factor 21/glucagon-like peptide-1 agonist, in healthy volunteers and people with overweight/obesity and hepatic steatosis

Rizwana Mohseni[1], Nitendra Agarwal[2], Salvador Augustin[3], Sridhar Guduri[4], Dr. Jens Klaus[5], Claudia Lange[3], Maximilian T. Lobmeyer[3], Scott J. Overcash[6], Mangesh Pagadala[7], Bruce Rankin[8], William Sanchez[9], Corinna Schoelch[5], William Smith[10], Eric Lawitz[11]. *[1]Catalina Research Institute, LLC, Montclair, CA, United States; [2]Endeavor Clinical Trials, San Antonio, TX, United States; [3]Boehringer Ingelheim Pharma GmbH & Co. Email: lawitz@txliver.com

Background and aims: Two Phase I trials assessed the tolerability and efficacy of BI 3006337, a dual fibroblast growth factor 21/glucagon-like peptide-1 agonist.

Method: Two randomised, Phase I trials evaluated subcutaneous BI 3006337. The Phase Ia single-rising dose (SRD) trial (NCT05076422) included healthy male volunteers aged 18–55 years with body mass index (BMI) 20–<32 kg/m^2. Participants (pts) received a single dose of BI 3006337 (0.2–150 mg) or placebo. The primary endpoint was the incidence of treatment-related adverse events (TRAEs). Secondary pharmacokinetic (PK) endpoints included area under the serum concentration–time curve from zero to infinity ($AUC_{0-\infty}$) and maximum serum concentration (C_{max}). The Phase Ib multiple-rising dose (MRD) trial (NCT05970640) included pts with overweight or obesity (BMI 25–<40 kg/m^2) and liver steatosis (liver fat ≥8% [measured by magnetic resonance imaging-proton density fat fraction [MRI-PDFF]). Pts were randomised to weekly BI 3006337 (50 mg, 100 mg, or 150 mg), or placebo for 12 weeks. The primary

endpoint was TRAEs. Secondary endpoints included relative change in liver steatosis (via MRI-PDFF) from baseline to week 12 and PK parameters.
Results: Overall, 80 pts were evaluable in the Phase Ia SRD trial (BI 3006337 dose groups [DGs]: n = 61; placebo: n = 19). TRAEs occurred in 7 pts (11.5%) receiving BI 3006337 vs none with placebo. No severe AEs, drug-induced liver injury, AEs leading to discontinuation or serious AEs were reported. BI 3006337 exhibited linear PK inter-individual variability in C_{max} and $AUC_{0-\infty}$ that was high (geometric coefficient of variation [gCV%] >50%) and moderate (gCV% 30–50%), respectively. In the Phase Ib MRD trial, 63 randomised pts were evaluable (BI 3006337: 50 mg, n = 11; 100 mg, n = 10; 150 mg, n = 23; placebo, n = 19). At week 12, the largest mean percentage reduction in liver fat was seen in the 150 mg group (– 40.5% reduction [standard deviation: 14.8%]) vs a 5.7% [36.3%] increase with placebo). TRAEs occurred in 31/44 BI 3006337-treated pts (70.5%) vs 5/19 receiving placebo (26.3%). There were no severe or serious events; discontinuation rate due to gastrointestinal effects was low (4.5%).
Conclusion: BI 3006337 demonstrated a manageable tolerability in healthy volunteers and individuals with overweight/obesity and hepatic steatosis up to a weekly dose of 150 mg. Preliminary efficacy data demonstrated a dose-dependent reduction in hepatic steatosis reaching the greatest magnitude at 150 mg.

FRI-171
First-in-class oral, once-monthly IKKalpha/beta inhibitor targeting steatosis, inflammation, and fibrosis in MASH: results from a phase 1 trial
Belle Wang[1], Yongmei Li[1], Nathan Li[1], Qisheng Li[1]. [1]*Hepanova Inc., Gaithersburg, United States*
Email: frank.li@hepanova.com

Background and aims: Metabolic dysfunction–associated steatohepatitis (MASH) with fibrosis is a leading cause of cirrhosis and hepatocellular carcinoma (HCC). While recently approved or late-stage therapies primarily target steatosis, none adequately address the critical drivers of inflammation and fibrosis. HPN-01 is a first-in-class, orally administered, highly selective dual IKKalpha/beta inhibitor that directly modulates the entire pathogenic triad – steatosis, inflammation, and fibrosis. Preclinical studies demonstrated robust efficacy across MASH and fibrosis models, as well as suppression of HCC progression through inhibition of IKKalpha-driven inflammatory, fibrotic, and oncogenic pathways.
Method: A randomized, placebo-controlled, ascending dose Phase 1 trial (HPN-01-US-101) enrolled healthy adults (25–150 mg; n = 8 per cohort). Extended pharmacokinetic (PK) sampling to 720 hours was performed at the highest dose. Safety endpoints included adverse events (AEs), labs, ECGs, and vitals. PK and population PK modeling characterized systemic disposition, terminal half-life, and informed dose scheduling.
Results: HPN-01 was well tolerated at all doses, with no treatment-related serious AEs, dose-limiting toxicities, or discontinuations. AEs were mild, transient, and not dose-related; no clinically meaningful laboratory or ECG abnormalities were observed. Exposure increased approximately dose-proportionally up to 150 mg. Extended PK confirmed a terminal half-life of 23 days with stable systemic exposure, reducing the risk of toxic peak inhibition and enabling controlled target modulation. Modeling projected therapeutic exposures achievable with once-weekly or once-monthly oral dosing.
Conclusion: HPN-01 demonstrated excellent safety, predictable PK, and prolonged persistence in its first-in-human trial, enabling infrequent oral dosing including once-monthly regimens. By uniquely tackling inflammation and fibrosis, gaps left by other agents, HPN-01 is differentiated as both an oral monotherapy for advanced MASH/fibrosis and a rational backbone in combination regimens (e.g., with GLP-1 agonists, THR-beta agonists, or FGF21 analogs). Its integrated mechanism, oral convenience, and strong safety profile highlight its potential as a patient-friendly therapy for advanced MASH and a strategy to reduce progression to HCC.

FRI-172
Imaging of Fibroblast Activation Protein: AZD2389 demonstrates liver target occupancy in participants with advanced chronic liver disease
Mathias Liljeblad[1,2,3], Zsolt Cselény[4], David Janzén[1], Mohammad Niazi[1], Magnus Schou[4], Andrea Varrone[5], Karin Westberg[1], Malin Aurell[1], Mahssa Karimi[1], Aurelija Jucaite[4], Hannes Hagström[5], Vian Azzu[6]. Email: mathias.liljeblad@astrazeneca.com

Background and aims: In patients with chronic liver disease (CLD), elevated expression of hepatic fibroblast activation protein (FAP) can be imaged by positron emission tomography (PET). Preclinical work also indicates that FAP is involved in the progression of fibrosis. AZD2389 is a small molecule FAP inhibitor in development for the treatment of advanced chronic liver disease (ACLD), that has been shown to be well tolerated with proven plasma target engagement in both healthy volunteers and patients with CLD. PECHORA is a Phase I, open-label, PET trial in male and female patients with ACLD to assess hepatic target (FAP) occupancy by AZD2389.
Method: The PECHORA study (EU Trial no.2024-517605-91-00) design included three consecutive PET examinations using radioligand [^{68}Ga]Ga-FAPI-46 separated by about one week. The first two PET examinations served as baseline (test, PET1) and reproducibility (retest, PET2) evaluation of the radioligand, followed by an imaging session at 22 h after a single oral dose of AZD2389 (target occupancy, PET3). The study planned to investigate three dose levels of AZD2389, with a maximum of 2 participants at each level. Quantitative analysis of the PET images consisted of calculation of total radioligand binding (V_T) parametric images using a wavelet-aided parametric imaging (WAPI) method employing the multilinear variant of Logan's linear graphical analysis to estimate V_T with a metabolite-corrected arterial input function. Test-retest variability (TRV) was calculated on the voxel level and organ level V_T estimates from PET1 and PET2. The voxel-wise V_T parameters from PET1 and PET3 were used to estimate liver FAP occupancy following drug administration using Lassen's graphical approach.
Results: Radioligand [^{68}Ga]Ga-FAPI-46 showed favourable PET-kinetics, low metabolism (<30% metabolised at 60 min post injection) and median TRV at <10%. Single doses of AZD2389 administered over a 7-fold dose range resulted in dose-dependent hepatic target occupancies of 14% to 86% measured at trough.
Conclusion: Radioligand [^{68}Ga]Ga-FAPI-46 demonstrated suitable kinetics and test-retest reliability for assessment of hepatic FAP. Single-dose AZD2389 produced measurable hepatic FAP occupancy at trough, confirming target engagement and supporting dose selection for early clinical development.

S. Middleton VA, Madison, WI, United States; [4]University of California San Diego, La Jolla, United States; [5]Regeneron Pharmaceuticals, Sleepy Hollow, United States
Email: jennifer.linge@amramedical.com

Background and aims: Metabolic dysfunction-steatotic liver disease (MASLD) overlaps with obesity and is associated with frailty and sarcopenia. Weight loss may improve MASLD but can cause muscle mass loss. Our aim was to describe changes in muscle composition (quantity and quality) with magnetic resonance imaging (MRI) following metabolic surgery (MBS, bypass or sleeve) in patients with low vs high liver proton density fat fraction (PDFF, LLF vs HLF).
Method: Adults with BMI ≥ 35 kg/m^2 were scanned neck to knee using MRI at 5 visits: 2–4 weeks before MBS, 0–4 days before MBS (pre-MBS) following a low-calorie diet (LCD), and week 12, 26, 52 after MBS at University of Wisconsin-Madison & University of California San Diego (UCSD). Thigh muscle volume (MV, liters), a sex- height- weight- and BMI-invariant MV z-score (z-MV), muscle fat infiltration (MFI, %), and intramuscular fat volume (IMF, liters) were quantified by AMRA Researcher. Liver PDFF (%) was analyzed at UCSD. Differences in muscle composition changes for LLF (≤ 6.7% [baseline median]) vs HLF were tested by mixed-effects linear modelling adjusted for sex, site, surgery type, and baseline age, weight, and value of the response variable with pre-MBS as referent. Significant differences ($p < 0.05$) are indicated by *.
Results: At study end n = 58/96 patients (88% women) included had complete muscle composition data (n = 8/11/13/7 missing data at n = 1/2/3/4 visits). Baseline, mean (SD), age, weight and BMI were 46.3 (8.8) years, 133.5 (20.6) kg and 47.6 (6.4) kg/m^2. Mean weight loss with LLF/HLF after LCD was −3.4%/−4.0% and similar with LLF/HLF from pre-MBS to week 12, 26, 52 (−13.0%/−13.5%, −19.4%/-19.9%, −23.2%/−23.7%). Mean muscle mass loss after LCD was −3.6%/−4.3% (Δz-MV: −0.25/−0.34) and larger with HLF from pre-MBS to week 12, 26, 52 (−8.7%/11.1%, −9.0%/−11.8%*, −9.2%/−12.7%*; Δz-MV: −0.43/−0.72*, −0.20/−0.58*, −0.02/−0.49*). Muscle fat decreased after surgery with significantly larger reductions at week 52 with LLF (MFI −1.56/−0.94* percentage points; IMF −0.04/−0.04 liters, −25.5%/−22.2%).
Conclusion: MBS was associated with reductions in MV and MFI, indicating decreased quantity but increased quality. Almost all muscle mass loss (MV and z-MV) occurred within 12 weeks after surgery and was significantly higher with HLF. At week 52, z-MV had recovered to pre-MBS level with LLF but was still reduced with HLF. Results indicate patients with MASLD experience larger muscle mass loss with MBS; potential implications should be further investigated.

FRI-174

Synergistic effects of SGLT2 inhibitors and HCV eradication on long-term MASLD improvement in patients with chronic hepatitis C and type 2 diabetes: a 3-year follow-up study

Ching-Chu Lo[1], Jow-Jyh Hwang[1], Chien-Hung Lin[1], Hsu-sheng Cheng[1], Yee-Tam Liao[1], Po-Yen Hsiao[1], Mei-Tsu Chen[1], Chen-Yu Lo[1]. [1]*Saint Martin De Porres Hospital, East District, Chiayi, Taiwan*
Email: locc0320@gmail.com

Background and aims: Direct-acting antivirals (DAAs) achieve sustained virologic response (SVR) in nearly all patients with chronic hepatitis C (HCV). However, patients with concomitant type 2 diabetes (T2D) are at increased risk of developing metabolic dysfunction–associated steatotic liver disease (MASLD). While HCV eradication and sodium-glucose cotransporter-2 (SGLT2) inhibitors improve metabolic control, long-term data regarding their combined effects on hepatic steatosis and fibrosis remain limited. This study aimed to evaluate longitudinal changes in MASLD following SVR and SGLT2 therapy over a three-year follow-up period.
Method: This prospective cohort study enrolled patients with chronic HCV infection and T2D who received DAA therapy between January 25, 2020 and January 22, 2021 at St. Martin De Porres Hospital. SVR was defined as undetectable HCV RNA 12 weeks after treatment completion. SGLT2 inhibitors were prescribed according to standard diabetic care. Hepatic steatosis was assessed using attenuation imaging (ATI, Canon), and liver fibrosis was evaluated by liver stiffness measurement (LSM) using transient elastography (FibroScan). Changes in ATI and LSM values from baseline through 1- 2- and 3-year follow-up were analyzed using repeated-measures ANOVA.
Results: A total of 250 patients were enrolled, of whom 245 (98%) achieved SVR. The mean age was 68 years. Patients were categorized into two groups: HCV without T2D (Group 1, n = 186) and HCV with T2D (Group 2, n = 59). In Group 1, mean LSM values (kPa) declined from 7.28 at baseline to 7.29, 6.72, and 6.60 at years 1, 2, and 3, respectively ($P < 0.001$). ATI values decreased from 0.705 to 0.705, 0.657, and 0.652 dB/cm/MHz over the same period ($P < 0.001$). Improvements in steatosis and fibrosis became significant after the second year following SVR. In Group 2, mean LSM values decreased from 8.86 at baseline to 7.73, 7.47, and 7.40 at years 1, 2, and 3, respectively ($P < 0.001$). ATI values declined from 0.852 to 0.753, 0.739, and 0.717 ($P < 0.001$). Notably, significant improvements in both steatosis and fibrosis were observed as early as the first year and persisted throughout the three-year follow-up.
Conclusion: HCV eradication leads to gradual MASLD improvement, while concomitant SGLT2 inhibitor therapy in patients with T2D is associated with earlier and sustained reductions in hepatic steatosis and fibrosis (MASLD). These findings support an integrated antiviral and metabolic treatment strategy for HCV patients with T2D.

Email: barry.crittenden@gilead.com

Background and aims: Liver noninvasive tests (NITs) show promise for the detection of cirrhosis in patients (pts) with metabolic dysfunction-associated steatohepatitis (MASH). This *post hoc* analysis evaluated the effects of semaglutide (SEMA), cilofexor (CILO)/firsocostat (FIR) and SEMA + CILO/FIR on liver NITs, and liver NIT-determined cirrhosis (Agile 4 score) in pts with cirrhotic MASH from the placebo (PBO)-controlled, phase 2 WAYFIND study (NCT04971785).
Method: Pts who received SEMA 2.4 mg weekly + CILO 30 mg/FIR 20 mg daily, SEMA 2.4 mg weekly, CILO 30 mg/FIR 20 mg daily or PBO for 72 weeks (W), and had non-missing data for each outcome, were included. Least squares (LS) mean differences (nominal p values) in liver NITs between treatment groups were estimated using analysis of covariance models.
Results: In total, 453 randomized pts took ≥ 1 dose of study drug (SEMA + CILO/FIR: N = 124; SEMA: N = 122; CILO/FIR: N = 123; PBO: N = 84). Nominally significant LS mean differences versus PBO were observed at W72 with SEMA + CILO/FIR, SEMA, and CILO/FIR treatment, respectively, for percent change from baseline in alanine transaminase (ALT U/L: −54.5, −31.4 and −25.8; all $p < 0.0001$), aspartate aminotransferase (AST U/L: −47.7, −32.8 and −22.0; all $p < 0.0001$) and liver stiffness (FibroScan kPa: −29.7, −30.7 and −30.3; all $p < 0.05$), and for absolute change from baseline in Enhanced Liver Fibrosis (ELF score: −1.01, −0.82 and −0.56; all $p < 0.0001$) and Fibrosis-4 (FIB-4 score: −0.88, −0.80 and −0.58; all $p < 0.0001$). The proportion of pts with an Agile 4 score ruling in cirrhosis (≥ 0.565) decreased from baseline to W72 with SEMA + CILO/FIR (from 43.5% [50/115] to 22.9% [19/83]), SEMA (41.1% [46/112] to 28.8% [21/73]) and CILO/FIR (40.0% [44/110] to 25.4% [18/71]), and increased with PBO (42.3% [33/78] to 51.8% [29/56]). In parallel, the proportion of pts with an Agile 4 score ruling out cirrhosis (< 0.251) increased from baseline to W72 with SEMA + CILO/FIR (from 22.6% [26/115] to 38.6% [32/83]), SEMA (22.3% [25/112] to 41.1% [30/73]) and CILO/FIR (24.5% [27/110] to 39.4% [28/71]), but stayed similar with PBO (23.1% [18/78] to 26.8% [15/56]); remaining pts had indeterminate Agile 4 scores (0.251 to <0.565).
Conclusion: SEMA, CILO/FIR and their combination reduced liver NIT levels/scores (ALT, AST, ELF, FIB-4 and liver stiffness) versus PBO in pts with cirrhotic MASH, and likely reduced proportions of pts with liver NIT-determined cirrhosis.

FRI-179

Early and Week 52 biomarker (MRI-PDFF, ALT, MRE and PRO-C3) responses to resmetirom predict improvements in MASH and liver fibrosis

Rohit Loomba[1], Rebecca Taub[2], Krishna Padmanabhan[2], Dominic Labriola[2], Mazen Noureddin[3], Naim Alkhouri[3]. [1]*San Diego School of Medicine, San Diego, United States;* [2]*Madrigal Pharmaceuticals, Conshohocken, United States;* [3]*Pinnacle, San Antonio, United States*
Email: rebeccataub@yahoo.com

Background and aims: MAESTRO-NASH (NCT03900429) is an ongoing 54-month, randomized, double-blind, placebo (PBO)-controlled Phase 3 trial evaluating the efficacy of resmetirom (RES) in patients with MASH and F2/F3 fibrosis. The 52-week histologic endpoints demonstratted resolution of MASH (MR) and fibrosis improvement (FI) with RES 80 mg and 100 mg leading to approval. We report early non-invasive biomarkers of change and their correlation with Week (W) 52 biopsy responses, as well as the odds of achieving an early biomarker response with treatment.
Method: To assess relationships between early biomarker responses and W52 liver biopsy outcomes, changes in ALT, MRE, MRI-PDFF, at W12,24 52 following initiation of RES or PBO were analyzed for correlation with biopsy-defined MR and FI. Odds of achieving early improvement in these biomarkers were evaluated as a function of treatment. PRO-C3 change was a measure of response.
Results: ≥20% reduction in ALT at w12, 24, 52 was associated with higher odds (OR) of W52 MR/FI. With RES, ALT response showed an OR of 2.0, 2.2, 2.6 repectively at W12, 24, 52; $p < 0.002$). RES OR of achieving an FI response at w12, 24 and 52, compared to PBO: ORs of 2.2, 2.7, 3.6 respectively. All $p < 0.001$. MR was similar. ≥15% reduction in MRE at W16, 52 was associated with higher OR of Week 52 FI/MR. With RES, MRE response ORs FI, 2.6 and 2.3 at W16, 52, respectively, $p \leq 0.02$, less association in PBO. MR was similar. RES compared with PBO stat sig. odds of achieving an MRE response, at W52 (OR = 1.71) but not at (W16 OR = 1.31). A ≥30% reduction in MRI-PDFF from baseline at W16 and 52 was strongly associated with higher odds of FI and MR. With RES, MRI-PDFF response was associated with increased odds of FI (ORs 1.9 and 2.95 at w16 and 52, respectively; $p \leq 0.02$) and MR at Week 52 (OR ~ 6.5). RES was associated with significantly higher odds of achieving an PDFF response compared with PBO at W16, 52 (ORs 12.4 and 6.7; both $p < 0.0001$). For Pro-C3, change and % change n PRO-C3 at Weeks 24 and 52 in F3 showed a relationship to FI in all treatment groups, w52: 80 mg, −7%, −23%; 100 mg, −14%, −20%; PBO, 0%, −20% FI nonresponders and responders, respectively with far more responders in RES, regression currve $p = 0.0017$ RES, $p = 0.04$ PBO.
Conclusion: Early and W52 responses to RES, particularly reduction in PDFF at W16 and W52, correlate with FI and MR responses on liver biopsy. Reduction in ALT, MRE and PRO-C3 (≤W24 and W52) showed a significant correlation with FI on biopsy with RES treatment.

Email: andmel@rm.dk

Background and aims: Carbohydrate-reduced high-proten (CRHP) diets have shown promising results in the management of metabolic disease, but direct effects on liver fat content and lipid and glucose metabolism are unclear. Here, we assess the effects of a CRHP diet supplemented with whey protein isolate (WPI) or micellar casein isolate (MCI) compared to a conventional diet (CD) on metabolic-dysfunction associated steatotic liver disease (MASLD).
Method: Non-diabetic participants with MASLD and a BMI ≥ 27.5 kg/m2 were randomly allocated (1:1:1) to a 4-week isocaloric period followed by a 20-week hypocaloric period with either CRHP with WPI or MCI, or CD in an open-label design. Participants received dietary counselling bi-weekly to facilitate weight maintenance in the isocaloric phase and a weight loss target of 5% after the hypocaloric phase. Liver fat content was measured by MR-spectroscopy. Glucose, palmitate, and VLDL-triglyceride (TG) kinetics were evaluated during basal conditions and during a hyperinsulinemic, euglycemic clamp using radioisotope tracers.
Results: 45 participants were enrolled. CRHP with WPI reduced liver fat content after the isocaloric phase compared to CD (mean

difference: −8.9%-points [95% CI: −14.6 to −3.2]) without changes in body weight or composition. After the hypocaloric phase, all diets reduced liver fat content (mean: −6.8%-points [95% CI: −9.6 to −3.9]) and body weight (mean: −3.7 kg [95% CI: −4.6 to −2.9]) equally. Basal and insulin-mediated palmitate and VLDL-TG secretion rates and endogenous glucose production were unchanged by CRHP intake and weight loss.

Conclusion: CRHP with WPI reduced liver fat content compared to a CD in overweight patients with MASLD after 4 weeks of isocaloric intake without concurrent weight changes. CRHP did not augment the beneficial effects of weight loss. The depletion of liver fat and mild weight loss were not associated with changes in free fatty acid or VLDL-TG turnover.

FRI-181

Efficacy and safety of semaglutide 2.4 mg in the Japanese subgroup of the ESSENCE study

Sanyal[8]. *[1]Department of Gastroenterology and Hepatology, International University of Health and Welfare, Narita, Japan; [2]IUHW atami hospital, Atami, Japan; [3]Department of Gastroenterology and Hepatology, Saiseikai Suita Hospital, Osaka, Japan; [4]Department of Gastroenterology and Metabology, Ehime University Graduate School of Medicine, Toon, Japan; [5]Division of Metabolism and Endocrinology, Saga University Faculty of Medicine Graduate School of Medical Sciences, Saga, Japan; [6]Novo Nordisk A/S, Copenhagen, Denmark; [7]Novo Nordisk Pharma Ltd, Tokyo, Japan; [8]Stravitz-Sanyal Institute for Liver Disease and Metabolic Health, VCU School of Medicine, Richmond, VA, United States*
Email: nakajima-tky@umin.ac.jp

Background and aims: The ESSENCE trial (NCT04166773) is a Phase 3 study evaluating the efficacy and safety of Semaglutide 2.4 mg (Sema), a GLP-1 receptor agonist, in patients with MASH and liver fibrosis stages F2 or F3 (Sanyal et al., NEJM, 2025). This study aimed to evaluate the efficacy and safety of Semaglutide in the Japanese population.

Method: This trial was an international multicenter, double-blind, randomized, placebo-controlled Phase 3 study. A total of 1,197 subjects were randomized, of whom first 800 subjects (116 Japanese) were included in the efficacy analysis for the interim analysis of Part 1. The safety analysis at the interim analysis included 1,195 subjects who received treatment (141 Japanese). The primary endpoints were the resolution of steatohepatitis without worsening of fibrosis (MASH resolution) and reduction in liver fibrosis without worsening of steatohepatitis (fibrosis reduction) after 72 weeks of weekly administration of Sema or placebo.

Results: Demographics and baseline characteristics were generally comparable between the Japanese population and the overall population, except for age group and body weight/BMI. Less subjects were aged ≥ 45 to < 65 and more subjects were aged ≥ 65 years in the Japanese population. Mean body weight/BMI was lower in Japanese population (77.8 kg/29.8 kg/m^2) than in entire population (96.1 kg/34.6 kg/m^2). In Japanese population, the proportion of patients achieving MASH resolution was 63.1% for Sema and 36.8% for placebo. In addition, the proportion of patients achieving fibrosis reduction was 36.5% for Sema and 28.5% for placebo. Further, the proportion who achieved MASH resolution with fibrosis reduction was 33.3% for Sema and 21.1% for placebo. These results suggested that the responder proportions were similar for Japanese population and overall population, both in favor of Sema. Body weight was reduced by up to 11.4% with Sema and 2.6% in placebo. Liver enzymes and liver stiffness decreased, and serum biomarkers of liver fibrosis, ELF, improved in the Sema groups vs. placebo. No apparent difference in the safety profile was seen between the Japanese population and the entire trial population.

Conclusion: These results suggested that efficacy and safety of Sema in the Japanese population are expected to be similar to those in the overall population.

FRI-182

Semaglutide shows favourable safety across subgroups and a positive hepatic safety profile: findings from ESSENCE part 1

Email: philip.newsome@kcl.ac.uk

Background and aims: The ESSENCE trial assesses semaglutide 2.4 mg in metabolic dysfunction-associated steatohepatitis (MASH). In non-clinical studies, semaglutide has not shown liver toxicity. This post hoc analysis of ESSENCE evaluated general and liver-specific safety of semaglutide in participants (pts) with biopsy-defined MASH and liver fibrosis stage 2 or 3 (F2–F3).

Method: Pts were randomised 2:1 to semaglutide or placebo. Safety analyses were on all pts who took at least 1 dose of semaglutide (N = 1195); efficacy evaluations were at week 72 on the first 800 randomised pts.

Results: Adverse event (AE) and gastrointestinal (GI) AE reporting increased with age and was higher in women than men. Pts with type 2 diabetes (T2D) and non-T2D reporting AEs with semaglutide were comparable (87% and 85%): GI AEs were numerically higher in the non-T2D semaglutide group. AEs and GI AEs were higher in semaglutide F2 vs F3, with a higher proportion in F2 reporting serious AEs (SAEs). GI AEs were more frequent with semaglutide than placebo; mainly nausea, diarrhoea, constipation, and vomiting; generally mild/moderate, non-serious, and most occurring during dose escalation. Discontinuation due to GI AEs was comparable between groups (1.6% vs 0.5%). Most hepatic AEs were mild/moderate and non-serious; none led to premature treatment discontinuation in the semaglutide group. Hepatic SAEs occurred in 1 semaglutide pt and 3 placebo pts.

Baseline alanine aminotransferase (ALT) and aspartate aminotransferase (AST) elevations were common (ALT: 31.1% vs 33.1%; AST: 42.9% vs 43.6% for semaglutide vs placebo). Week 72 elevations in ALT and AST were lower with semaglutide vs placebo in pts with elevated baseline levels (ALT: 7.3% vs 16.9%, AST: 11.2% vs 26.7%) and normal

baseline levels (ALT: 2.4% vs 14.7%, AST: 4.7% vs 21.4%). All cases meeting prespecified criteria for potential drug-induced liver injury (DILI) were adjudicated, with none confirmed. Gallbladder AEs were mostly mild/non-serious; none led to discontinuation, cholelithiasis was most frequent, one SAE occurred in each group. Acute pancreatitis occurred in 3 semaglutide pts (2 SAEs) and 2 placebo (1 SAE).
Conclusion: Semaglutide demonstrated a favourable safety profile in F2–F3 MASH regardless of age, sex, T2D, or fibrosis stage. Hepatic AEs were mild/moderate with SAEs uncommon; no confirmed DILI, and liver enzymes improved vs placebo. Gallbladder events were mild/non-serious, with no safety signal for pancreatitis.

FRI-183
Ontamalimab reduces fibroinflammatory biomarkers and liver injury signals in metabolic dysfunction associated steatohepatitis
Mazen Noureddin[1], Eric Lawitz[2], Naim Alkhouri[3], Madhavi Rudraraju[4], Zeid Kayali[5], Gary Reiss[6], Michael Chen[7], Jay Tang[7], Wendi Lichtenberger[7], Jie Feng[7], Vandana Gupta[7], Talakad G. Lohith[7], Aaron Huang[7], Haakan Wennbo[7], Paresh Thakker[7], Zoltan Derdak[7]. *[1]Houston Research Institute and Houston Methodist Hospital, Houston, Houston, TX, United States; [2]Texas Liver Institute, San Antonio, United States; [3]Summit Clinical Research, San Antonio, TX, United States; [4]Pinnacle Clinical Research, San Antonio, TX, United States; [5]Inland Empire Clinical Trials, Rialto, CA, United States; [6]Tandem Clinical Research, Marrero, LA, United States; [7]Takeda Development Center Americas, Inc., Cambridge, MA, United States*
Email: zoltan.derdak@takeda.com

Background and aims: Mucosal addressin cell adhesion molecule 1 (MAdCAM-1) mediates gut–liver lymphocyte trafficking and contributes to fibroinflammation in the liver. Ontamalimab is a monoclonal antibody targeting MAdCAM-1. This phase 1b study assessed safety and biomarker effects in participants with metabolic dysfunction-associated steatohepatitis (MASH).
Method: Adults with biopsy-confirmed MASH and fibrosis stages F1 to F4 received ontamalimab 75 mg subcutaneously every 4 weeks for 24 weeks. Primary endpoints focused on safety and tolerability, while key secondary endpoints assessed the percent change from baseline in N-terminal propeptide of type III collagen (PRO-C3), the Enhanced Liver Fibrosis (ELF) score, and iron-corrected T1 at (MRI *c*T1) at week 24. Exploratory endpoints included alanine aminotransferase (ALT), aspartate aminotransferase (AST), liver stiffness assessed by vibration-controlled transient elastography (VCTE), FibroScan-AST (FAST) and Fibrosis-4 (FIB-4) scores, and inflammatory biomarkers including interleukin 8 (IL-8) and thrombospondin 2 (TSP-2).
Results: Eleven biopsy-proven MASH participants were treated (mean age 49 years, 64% female). Ontamalimab was well tolerated with no deaths, serious adverse events, or treatment-related discontinuations. At week 24, mean percent changes from baseline were −14.904% for PRO-C3, −0.82% for ELF, and −3.2% for MRI *c*T1. 5 out of 7 participants with end of study PRO-C3 values achieved more than 10% Pro-C3 reduction. ALT and AST declined from baseline at week 24 with reduction of 23.4 U/L and 14.2 U/L, respectively ($p = 0.002$ and $p = 0.001$). Mean VCTE decreased from 15.09 ± 1.643 kPa to 11.36 ± 1.712 kPa (n.s.) by the end of treatment. There was a statistically significant decrease in FAST score (0.66 ± 0.047 vs 0.4563 ± 0.069, $p = 0.03$) and FIB 4 scores trended downward. IL-8 showed modest reductions, and TSP-2 declined directionally in line with other fibroinflammatory markers.
Conclusion: Ontamalimab demonstrated a favorable safety profile and produced coherent improvements across markers of fibrogenesis, liver injury, inflammation, liver stiffness, and quantitative magnetic resonance imaging.

FRI-184
Effects of SGLT-2 inhibitors on clinical outcomes in patients with MASLD and type 2 diabetes mellitus: a nested case-control study using LIFE study data
Eiichi Ogawa[1], Yurina Akeno[2], Nobuyuki Shimono[1], Haruhisa Fukuda[3]. *[1]Department of General Internal Medicine, Kyushu University Hospital, Fukuoka, Japan; [2]Department of Health Sciences, Graduate School of Medical Sciences, Kyushu University, Fukuoka, Japan; [3]Department of Health Care Administration and Management, Graduate School of Medical Sciences, Kyushu University, Fukuoka, Japan*
Email: e.ogawa.a65@m.kyushu-u.ac.jp

Background and aims: Disordered glucose metabolism is a major driver of disease progression in metabolic dysfunction-associated steatotic liver disease (MASLD). Sodium-glucose cotransporter-2 (SGLT-2) inhibitors and dipeptidyl peptidase-4 (DPP-4) inhibitors are widely used for type 2 diabetes mellitus (T2DM). However, whether these agents reduce the incidence of liver-related or extrahepatic events in patients with MASLD and T2DM has not been fully elucidated. This study aimed to estimate the preventive effects of SGLT-2 inhibitors and DPP-4 inhibitors in patients with MASLD and T2DM.
Method: We conducted a nested case-control study using administrative claims data in Japan, covering a population of 2.56 million. Patients newly diagnosed with steatotic liver disease (SLD) and T2DM within the first three years of data availability were identified. Patients without SLD or those who had already initiated antidiabetic therapy were excluded. Cases were defined as patients who developed at least one major outcome-hepatocellular carcinoma (HCC), extrahepatic malignancy, major adverse cardiovascular events (MACE), or death-after three years from cohort entry. Controls were selected from non-case individuals and matched 1:1 by age and sex. Associations between new prescriptions and outcomes were evaluated using conditional logistic regression.
Results: A total of 10,338 patients were included in the final analysis. During a follow-up period of 25–42 months, 65 patients developed HCC, 1,082 developed extrahepatic malignancies, 753 experienced MACE, and 219 died. Although the number of SGLT-2 inhibitor users was limited in the HCC analysis, six patients in the non-HCC group received SGLT-2 inhibitors, whereas none in the HCC group did, resulting in a significantly lower prescription frequency among HCC cases ($P = 0.037$). Using SGLT-2 inhibitor as the reference, the adjusted odds ratio for extrahepatic malignancy was 0.588 (95% CI: 0.374–0.925; $P = 0.022$) after adjustment for the Charlson comorbidity index. No significant association was observed for DPP-4 inhibitors ($P = 0.29$). For MACE, neither SGLT-2 inhibitors nor DPP-4 inhibitors showed significant differences. Similarly, no significant associations were observed for mortality.
Conclusion: In patients with MASLD complicated by T2DM, SGLT-2 inhibitors may be associated with a reduced risk of not only HCC but also extrahepatic malignancies. These findings suggest a potential event-preventive benefit of SGLT-2 inhibitors beyond glycemic control in this population.

FRI-185
Roux-en-Y gastric bypass is associated with higher risk of major adverse liver outcomes compared with sleeve gastrectomy
Ilias Papadimopoulos[1], Laurens A. van Kleef[2], Filippos Anagnostakis[3], Michail Kokkorakis[4,5]. *[1]Alma Mater Studiorum-Medicine and Surgery, University of Bologna, Bologna, Italy; [2]Departments of Gastroenterology and Hepatology, Erasmus MC University Medical Center, Rotterdam, Netherlands; [3]Artificial Intelligence in Biomedical Imaging Laboratory (AIBIL), Center for AI and Data Science for Integrated Diagnostics (AI2D), Perelman School of Medicine, University of Pennsylvania, Philadelphia, United States; [4]Section of Digestive Diseases, Department of Internal Medicine, Yale School of Medicine, New Haven, CT, United States;*

[5]*Department of Clinical Pharmacy and Pharmacology, University of Groningen, University Medical Center Groningen, Groningen, Netherlands*
Email: ilias.papadimopoulos@studio.unibo.it

Background and aims: Bariatric surgery reduces obesity-related complications, including major adverse liver outcomes (MALO). However, the comparative long-term risk of MALO between Roux-en-Y gastric bypass (RYGB) and sleeve gastrectomy (SG) remains unclear. We aimed to compare the incidence of MALO following RYGB versus SG in adults with severe obesity.
Method: We conducted a retrospective cohort study using de-identified electronic health records from the TriNetX Research Network, encompassing over 100 million patients across 67 North American healthcare organizations. Adults with body mass index (BMI) greater than or equal to 35 kg/m^2 who underwent RYGB or SG between 2011 and 2021 were included. Patients with pre-existing liver disease were excluded. Propensity score matching (1:1) balanced baseline demographics, comorbidities, laboratory values, and medications. MALO was defined as a composite of incident ascites, cirrhosis, portal hypertension, varices, hepatic encephalopathy, or liver cancer. Hazard ratios (HR) and 95% confidence intervals (CI) were estimated using Cox proportional hazards models.
Results: After matching, 19,529 patients were included in each group (19% male, median age 45 years). Over a median follow-up of 6.7 years, 1,755 MALO events occurred. RYGB was associated with a significantly higher risk of MALO compared with SG (HR 1.58, 95% CI 1.44–1.74; $p < 0.001$). This elevated risk was consistent across individual MALO components: ascites (HR 2.08, 95% CI 1.82–2.38), cirrhosis (HR 1.29, 95% CI 1.06–1.58), portal hypertension (HR 1.75, 95% CI 1.24–2.47), and hepatic encephalopathy (HR 1.40, 95% CI 1.19–1.64). The association was strongest in the early postoperative period (90 days to 2 years: HR 2.06, 95% CI 1.76–2.42) and attenuated beyond 5 years (HR 1.11, 95% CI 0.94–1.31). Results were consistent across sex, metabolic dysfunction-associated steatotic liver disease, type 2 diabetes, and hypertension subgroups.
Conclusion: In this large propensity-score matched cohort, RYGB was associated with significantly higher long-term risk of MALO compared with SG, driven primarily by liver decompensation events. When considering bariatric surgery, SG may be the safer option for high-risk individuals, such as those with compensated cirrhosis.

FRI-186

Twelve-month changes in liver function enzymes and lipids in patients receiving resmetirom

Christina Parrinello[1], Sean Stern[2], Setareh Williams[2], Yestle Kim[1], John O'Donnell[1], Anthony Martinez[3]. [1]*Madrigal Pharmaceuticals, Inc., West Conshohocken, United States;* [2]*Star Biopharma Consulting, LLC, Malvern, United States;* [3]*University at Buffalo, Buffalo, United States*
Email: cparrinello@madrigalpharma.com

Background and aims: Resmetirom (Rezdiffra™) is a thyroid hormone receptor β-selective agonist, conditionally approved in the United States (US) in March 2024 for the treatment of adults with noncirrhotic metabolic dysfunction-associated steatohepatitis (MASH) and moderate-to-advanced fibrosis. Real-world evidence on resmetirom effectiveness remains limited. This study reports 12-month changes in lab measures.
Method: This retrospective cohort study used Truveta deidentified electronic health record data from US health systems linked to third-party medication dispensing data. Patients aged ≥18 years were indexed at first resmetirom fill on or after March 14, 2024 and followed through October 17, 2025. In the 2-year baseline period, patients had ≥2 healthcare encounters, no evidence of other causes of liver disease (e.g., alcohol use) or advanced liver disease (e.g., cirrhosis). Means (and standard deviations [SDs]) were calculated at index (−90 to +45 days) and 12 months (±90 days) for alanine transaminase (ALT), aspartate aminotransferase (AST) and low-density lipoprotein cholesterol (LDL-C), with mean change and *p*-values from paired *t*-tests. Analyses were stratified by type 2 diabetes (T2D) status and GLP-1 use.
Results: A total of 728 patients received resmetirom and had follow-up for 12-month assessment (mean 58 [SD 13] years, 36% male, 77% White, 64% obese, 52% T2D, 80% dyslipidemia, 62% hypertension, 30% GLP-1 use). In 222 patients (30%) with baseline and 12-month ALT and AST, means (SD) decreased (64.5 U/L [47.5] to 43.1 [32.0], −21.5 U/L and 50.1 U/L [35.5] to 35.4 [20.4], −14.7 U/L, respectively, both $p < 0.01$). Mean LDL-C (in 85 patients) decreased (93.9 mg/dL [33.4] to 85.4 [34.1], −8.5 mg/dL, $p < 0.05$). ALT and AST results were similar among patients, regardless of baseline T2D status or GLP-1 use. Decreases in LDL-C were similar between T2D and non-T2D (−7.9 and −9.4 mg/dL, respectively), and smaller in patients with than without baseline GLP-1 use (−1.0 and −11.9 mg/dL, respectively). However, numbers were small in LDL-C subgroup analyses.
Conclusion: In this descriptive study of patients treated with resmetirom, mean liver function test results decreased over 12 months, irrespective of T2D status or GLP-1 use. LDL-C decreased overall and irrespective of T2D, with smaller reductions observed in the smaller subgroup of baseline GLP-1 users. Future research will evaluate additional non-invasive measures and longer-term clinical outcomes with extended follow-up.

FRI-187

Long-term real-life experience of semaglutide in a monocentric cohort with type 2 diabetes and metabolic dysfuction-associated steatotic liver disease (MASLD)

Giovanni Petralli[1,2], Antonio Salvati[2], Simone Cappelli[1], Lidia Surace[2], Laura De Rosa[3], Francesco Damone[1], Maurizia Brunetto[1,2].
[1]*Department of Clinical and Experimental Medicine, Pisa, Italy;*
[2]*Hepatology Unit, Reference Center of the Tuscany Region for Chronic Liver Disease and Cancer, University Hospital of Pisa, Pisa, Italy;*
[3]*Institute of Clinical Physiology, National Research Council, Pisa, Italy*
Email: g.petralli94@gmail.com

Background and aims: MASLD is the liver manifestation of a multifaceted metabolic disorder, strongly associated with type 2 diabetes (T2D). Subcutaneous semaglutide, highly effective in T2D treatment, has recently been shown to induce resolution of steatohepatitis, albeit at the higher 2.4 mg weekly dose. We longitudinally evaluated a T2D-MASLD cohort following the introduction of semaglutide 1 mg weekly for diabetes optimization, aiming to assess its long-term effects on liver disease activity.
Method: 90 patients (age 60.7 ± 9.9 years; 38% female; T2D-duration 5[1–8] years) were evaluated non-invasively through anthropometry, biochemical profiling, and transient elastography (FibroScan®) at baseline (t0), 6 months (t1, 5–8 months), and 24 months (t2, 21–31 months, n = 67). Variations (Δ) in ALT, controlled attenuation parameter (CAP), and liver stiffness measurement (LSM) were used as proxies of liver disease burden. The PNPLA3 I148M polymorphism was also assessed. Ultrasound evidence of irregular liver margins, left-lobe hypertrophy, and nodular echo-pattern defined compensated cirrhosis.
Results: After treatment, significant reductions ($p < 0.01$) were observed in BMI (t0 32.6 ± 5.7 kg/m^2; Δ_{t1-t0} −6 ± 1%, Δ_{t2-t0} −6 ± 1%), glycated hemoglobin (HbA_{1c}; t0 53 ± 13 mmol/mol; Δ_{t1-t0} −17 ± 2%, Δ_{t2-t0} −13 ± 2%), ALT [t0 35 (22–54) U/L; Δ_{t1-t0} −22 ± 5%, Δ_{t2-t0} −20 ± 5%], CAP [t0 339 (288–372) dB/m; Δ_{t1-t0} −3 ± 3%, Δ_{t2-t0} −6 ± 4%], and LSM [t0 8.2 (5.5–11.0) kPa; Δ_{t1-t0} −25 ± 4%, Δ_{t2-t0} −11 ± 5%]. No significant differences were detected between t1 and t2, except for a mild HbA_{1c} increase (+2.4 ± 0.8 mmol/mol; $p = 0.006$). At t1, a ≥17 U/L ALT reduction occurred in 36% of patients, while ≥30% reductions in CAP and LSM were observed in 14% and 39% of patients, respectively, comparable to t2–t0 changes. Variations in ALT, CAP, and LSM were not influenced by PNPLA3 polymorphisms, baseline BMI, or HbA_{1c}. Compared with the patients without cirrhosis (n = 77), those with cirrhosis (n = 13) exhibited numerical subgroup differences in ALT

(Δ_{t1-t0} −18 ± 5% vs −42 ± 12%; Δ_{t2-t0} −19 ± 6% vs −32 ± 15%) and LSM (Δ_{t1-t0} −24 ± 5% vs −32 ± 12%; Δ_{t2-t0} −10 ± 5% vs −22 ± 14%).
Conclusion: Semaglutide at a 1 mg weekly dose effectively reduces steatotic and fibro-inflammatory liver involvement in diabetic MASLD, with early improvements at 6 months that persist over time without further enhancement. Baseline anthropometric parameters, glycemic control, and PNPLA3 genotype do not modify the hepatic response to semaglutide. Notably, steatohepatitis improvement was maintained even in cirrhotic patients.

FRI-188-YI
Evaluating non-invasive eligibility criteria for resmetirom in metabolic dysfunction-associated steatotic liver disease (MASLD): real-world data from an italian multicentric cohort
Nicola Pugliese[1], Davide Polverini[1], Arianna Bertazzoni[1], Federica Cerini[2], Rosa Lombardi[2], Grazia Pennisi[3], Stella De Nicola[1], Valerio Gullace[1], Anna Ludovica Fracanzani[2], Mauro Viganò[4], Salvatore Petta[3], Alessio Aghemo[1]. *[1]Humanitas University, Rozzano (Milano), Italy; [2]Università di Milano, Milano, Italy; [3]università di palermo, palermo, Italy; [4]Azienda Ospedaliera Papa Giovanni XXIII, Bergamo, Italy*
Email: nicola.pugliese@live.com

Background and aims: Resmetirom is approved for non-cirrhotic metabolic dysfunction–associated steatohepatitis (MASH) and moderate-to-advanced fibrosis (F2-F3). In clinical practice, eligibility largely depends on non-invasive tests (NITs). We aimed to quantify resmetirom eligibility in a real-world italian MASLD cohort according to AASLD Practice Guidance and Noureddin Expert Panel frameworks, and to evaluate concordance, clinical/biopsy accuracy and predictors of eligibility.
Method: We retrospectively included 908 consecutive MASLD adults from four Italian tertiary centres. Demographic, clinical, laboratory and vibration-controlled transient elastography (VCTE) data were retrieved from electronic records; 175 patients (19.3%) also had liver biopsy. Eligibility definitions mirrored clinical guidance: AASLD (VCTE 8–15 kPa, absence of cirrhosis/portal hypertension) and Noureddin (VCTE 10–19.9 kPa, platelets $\geq 140 \times 10^9$/L, no cirrhosis). Agreement was assessed with Cohen's κ and McNemar's test; multivariable logistic regression identified independent predictors.
Results: Median age was 62 years, 57% male. Median BMI was 29.4 kg/m^2; obesity and type 2 diabetes (T2D) affected 45.5% and 35.8%, respectively. Median VCTE was 6.3 kPa; 23.7% had LSM >10 kPa. In biopsied patients, fibrosis stages were F0–F1 41.1%, F2–F3 41.7%, F4 17.1%. Overall, 22.6% (205/908) met AASLD and 12.9% (117/908) met Noureddin criteria. Eligible patients presented more frequently with obesity (AASLD 56.6% vs 46.1%; Noureddin 60.7% vs 46.7%) and T2D (AASLD 52.7% vs 30.9%; Noureddin 57.3% vs 32.6%) ($p < 0.01$). Among biopsy-proven F2–F3 ($n = 73$), 52.1% were AASLD-eligible and 32.9% Noureddin-eligible; most missed cases had VCTE values below entry thresholds. Agreement between frameworks was 84.3% ($\kappa = 0.468$) with significant directional discordance (McNemar $p < 0.0001$): 116 patients were eligible only by AASLD, and 27 only by Noureddin. In multivariable models, age ($p = 0.0146$), BMI ($p = 0.0161$) and T2D ($p < 0.0001$) independently predicted eligibility for both frameworks, while FIB-4 was inversely associated with Noureddin eligibility ($p = 0.0348$).
Conclusion: AASLD and Noureddin frameworks select overlapping yet non-interchangeable populations. AASLD criteria are broader, while Noureddin's are more selective but may miss up to two-thirds of biopsy-confirmed F2–F3 patients. Integrated clinical–NIT approaches may optimize resmetirom allocation in real-world settings.

FRI-189
Lanifibranor-induced improvements in histological parameters and cardiometabolic markers in MASH are independent of weight change and closely associated with adiponectin induction
Mary E. Rinella[1], Guillaume Wettstein[2], Philippe Huot-Marchand[2], Jason Campagna[3], Sven Francque[4], Manal F. Abdelmalek[5]. *[1]Division of Gastroenterology, Hepatology and Nutrition, University of Chicago, Pritzker School of Medicine, Chicago, United States; [2]Inventiva, Daix, France; [3]Inventiva Inc, Boston, United States; [4]Department of Gastroenterology and Hepatology Antwerp University Hospital, Antwerp, Belgium; [5]Division of Gastroenterology and Hepatology, Mayo Clinic, Rochester, United States*
Email: mrinella@bsd.uchicago.edu

Background and aims: In the phase 2 NATIVE study, lanifibranor, a pan-PPAR agonist, demonstrated significant efficacy on improvement of steatohepatitis and fibrosis and markers of cardiometabolic health (CMH) in patients with metabolic dysfunction–associated steatohepatitis (MASH). Adiponectin (ADP), a pleiotropic adipokine downstream of PPARγ activation, improves insulin sensitivity, lipid metabolism, and inflammatory and fibrotic pathways. The modest weight gain of PPARγ agonists may be attributable to the expansion of metabolically favourable subcutaneous adipose tissue. This analysis examined relationships between ADP induction, weight change, and histological and CMH outcomes following lanifibranor treatment.
Method: In NATIVE, 247 patients with non-cirrhotic MASH were randomized to lanifibranor 800 mg, 1200 mg, or placebo for 24 weeks. Circulating ADP levels were measured at baseline (BL) and end of treatment (EOT) in 211 patients; weight-based CMH analyses were performed in 217 completers. Patients were stratified by BL ADP level (< 5, 5–10, > 10 µg/mL) and by fold-change at EOT (< 1.5×, 1.5–4×, > 4×) and weight change (≤ 2.5%, 2.5–5% and > 5%). Glycemic, lipid, liver, and inflammatory markers, and hepatic steatosis (CAP and NASH-CRN) were compared across strata.
Results: Despite modest weight gain with lanifibranor (2.6–3.1% for 800 mg and 1200 mg), improvements in histologic parameters and CMH markers were consistent across weight change categories. ADP levels increased across all weight-change groups, with no correlation between ADP fold-change and magnitude of weight gain, indicating independence of these PPARγ-associated effects. In contrast, placebo-treated patients with > 2.5% weight gain showed no improvement in ADP or CMH markers and worsening hepatic steatosis by CAP. Lanifibranor induced a dose-dependent rise in ADP level associated with improvements in histology and CMH markers independent of body-weight change.
Conclusion: Unlike life-style related weight gain, lanifibranor associated weight gain correlates with increases in ADP and improvements in liver histology. ADP may serve as a biomarker of therapeutic response with lanifibranor. The association between ADP induction and markers of CMH supports improved adipose-tissue health and insulin sensitivity as key mechanisms underlying lanifibranor efficacy in MASH.

Email: geert.robaeys@uhasselt.be

Background and aims: To reduce the process of Metabolic Dysfunction-Associated Steatotic Liver Disease (MASLD), new guidance methods, such as lifestyle coaching and mobile health (m-health), should be investigated. Therefore, we studied the outcome of these guidance methods on steatosis, steatohepatitis and fibrosis in MASLD patients.
Method: In a monocentric, 12-month, randomised controlled trial, participants were randomised into three arms: (1) minimal intervention therapy (MIT), (2) lifestyle coaching, and (3) m-health (Happi app) with real time diet, based on image recognition, and exercise self-monitoring. The outcome on steatosis, steatohepatitis, and fibrosis were measured using the controlled-attenuation parameter (CAP^{TM}), hepatic steatosis index (HSI); aspartate transaminase (AST), Fibroscan-AST (FAST) and vibration-controlled transient elastography (VCTE^{TM}).
Results: The guidance by Happi app (n = 98) was superior to MIT (n = 102) and coaching (n = 97) with respect to reduction of the mean serum AST levels (−2.8 U/l, 95% CI [−5.1;−0.6], p = 0.014) and also caused a small but significant decrease in the FAST score (−0.03, 95% CI [−0.05;−0.02], p = 0.018). In addition, m-health induced, similar to coaching and MIT, a significant reduction in steatosis over the 12-month study period, measured by CAP^{TM} (-22 dB/m, 95% CI [−35.8; −8.1], p = 0.002), as well as by HSI (−1.1, 95% CI [−1.8;−0.4], p = 0.002) but no significant change in fibrosis as measured by VCTE^{T}M.
Conclusion: This well-documented study shows that m-health has a more pronounced effect on steatohepatitis-related features than coaching or the MIT. M-health reduces liver steatosis to the same extent as MIT or coaching, but does not improve liver stiffness after one year of intervention. M-health guidance is hence a useful and potentially superior tool to conventional care and should be preferred in MASLD management, being it as a stand-alone approach or to complement anti-MASLD therapy.

Efruxifermin improved digital pathology and noninvasive fibrosis measures in participants with MASH and advanced fibrosis or compensated cirrhosis: analysis of the HARMONY and SYMMETRY phase 2b trials

Jörn M. Schattenberg[1], Mary E. Rinella[2], Vlad Ratziu[3], Elaine Chng[4], Julian Lee[4], Yukti Choudhury[4], Doreen Chan[5], Erik Tillman[6], Dean Tai[4], Kitty Yale[6], Tim Rolph[6], Mazen Noureddin[7]. [1]Department of Internal Medicine II, Saarland University Medical Center, Homburg, Germany; [2]University of Chicago, Chicago, United States; [3]Sorbonne Université, Hôpital Pitié-Salpêtrière, Paris, France; [4]HistoIndex Pte Ltd, Singapore, Singapore; [5]Akero Therapeutics - a Novo Nordisk company, Austin, United States; [6]Akero Therapeutics - a Novo Nordisk company, South San Francisco, United States; [7]Houston Methodist Hospital, Houston Research Institute, Houston, United States
Email: joern.schattenberg@uks.eu

Background and aims: Individuals with MASH and advanced fibrosis (F3) or cirrhosis (F4) are at high risk of disease progression. Efruxifermin improved categorical fibrosis stages (NASH CRN) in phase 2b trials in participants with MASH and biopsy-confirmed stage F2/3 or compensated cirrhosis (F4c). The effects of efruxifermin on continuous fibrosis measures were evaluated by digital pathology and noninvasive tests in the phase 2b trials.
Method: This post hoc analysis included participants with MASH and F3 or F4c from the HARMONY (NCT04767529) and SYMMETRY (NCT05039450) randomized placebo-controlled trials. Changes from baseline at Week 96 in digital pathology and noninvasive measures (liver stiffness by transient elastography [LSM] and Enhanced Liver Fibrosis [ELF] test) for efruxifermin (pooled 28/50-mg) vs placebo were evaluated. Digital pathology was evaluated in unstained liver biopsies by second harmonic generation (SHG)/two-photon excitation fluorescence microscopy, and included measures applicable to F3/4 fibrosis: qFibrosis (continuous), relative collagen amount (%) in biopsy tissue area detected by SHG signal, and septa area (qSepta).
Results: The analysis included 53 participants with F3 fibrosis (efruxifermin N = 33, placebo N = 20): 59% female, 79% T2D, mean age 56 years, 37 kg/m^2 BMI, LSM 15 kPa, ELF 9.9; and 130 with F4c fibrosis (efruxifermin N = 86, placebo N = 44): 72% female, 79% T2D, mean age 60 years, 36 kg/m^2 BMI, LSM 25 kPa, ELF 10.6. Digital pathology measures in F3 were: mean qFibrosis value 2.9, SHG 7%, median septa area: 1.33×10^5 μm^2, and were more severe in F4c: mean qFibrosis value 4.0, SHG 14%, median septa area: 2.95×10^5 μm^2. At Week 96, mean change in LSM was greater for efruxifermin vs placebo (F3: – 36% [-6.6 kPa] vs 0% [−0.4 kPa], p < 0.001 and F4c: −39% [−28.8 kPa] vs −28% [−17.3 kPa], p = 0.05). There was also a greater reduction in ELF with efruxifermin than placebo (F3:−0.9 vs −0.1, p < 0.01 and F4c: −0.6 vs 0.2, p < 0.001). Relative change in qFibrosis value was greater with efruxifermin vs placebo (F3: −16% vs 0.6%, p = 0.006; F4c: −15% vs −2%, p = 0.03). Many improvements with efruxifermin were observed early and continued through Week 96.
Conclusion: In this post hoc analysis of participants with MASH at high risk of disease progression (F3 or F4c), efruxifermin was associated with improvements in continuous fibrosis measures assessed by digital pathology and noninvasive tests. Phase 3 trials of efruxifermin in MASH are ongoing.

FRI-195-YI

A machine learning model for predicting endpoint achievement in pharmacological trials for metabolic dysfunction-associated liver disease

Seyed Sahab Aarabi[1,2], Farbod Semnani[1,2], Kiavash Semnani[3], Shirin Esmaeili[1], Ehsaneh Taheri[4], Armita Mahdavi-Gorabi[3], Mohsen Rajabnia[3], Shirin Djalalinia[5], Amir Kasaeian[4], Mohammad Shadab Siddiqui[6], Mostafa Qorbani[3,7]. Email: kiavashsemnani@gmail.com

Background and aims: Despite recent successes, drug development for metabolic dysfunction-associated steatotic liver disease (MASLD) faces major challenges – with many agents failing to meet efficacy endpoints in later stages of development. We evaluated non-drug influences on trial endpoint achievement to elucidate trial design factors associated with success and patient subgroups likely to benefit from tried treatment strategies.
Method: This is an exploratory analysis from a large-scale systematic review on the safety and efficacy of pharmacological interventions for MASLD. Data from 172 randomized controlled trials with pre-

specified efficacy endpoints was analyzed after screening records from MEDLINE, Web of Science, Scopus, CENTRAL, ICTRP, and ClinicalTrials.gov up to September 4, 2025. We developed a gradient-boosting machine learning (XGBoost) model. The model was trained – with 5-fold cross validation – on trial (duration, phase, diagnostic criteria [histological vs other], comparator [placebo vs lifestyle vs older agents], publication date, sponsor, and endpoint choice [e.g. MASH resolution, fibrosis improvement, etc.]) and patient characteristics (age, sex, diabetes status, BMI, ALT, hepatic fat fraction [PDFF], NAFLD Activity Score [NAS], and disease severity). Performance was evaluated via Receiver Operating Characteristic analysis. Feature importance was assessed via Shapley Additive Global importance (SAGE).

Results: The model showed robust capability (AUC = 0.83, 95% CI: 0.76 to 0.90; 0.82 F1 score; 0.87 sensitivity; 0.73 specificity; and 0.80 accuracy). Recency (SAGE: 0.40); shorter follow-up (SAGE: 0.18); evaluations of off-label therapy (SAGE: 0.04); enrolment of younger patients (SAGE: 0.66) with higher BMI (SAGE: 0.15); higher proportion of male patients (SAGE: 0.15); lower ALT (SAGE: 0.49); available/higher PDFF (SAGE: 0.43) or NAS (SAGE: 0.12) values at baseline; and absence of steatohepatitis (SAGE: 0.07) were associated with endpoint achievement. Proportion of patients with diabetes; diagnostic methodology; comparator type; endpoint definition; and pharmacological targets showed minimal importance.

Conclusion: Our model demonstrated strong performance in predicting MASLD trial successes. These findings highlight important associations between patient demographics; metabolic profile (obesity); and trial design parameters with judgements of efficacy for appraisal of evidence and future trial design.

FRI-196

Safety of resmetirom in MASLD: a propensity score–matched real-world cohort analysis

Abdullah Sohail[1], Sayed Tauseef Ahmad Jan[1], Antonio Sanchez[1], Sara Naimimohasses[1]. [1]*The University of Iowa, Iowa City, United States*
Email: sara-naimimohasses@uiowa.edu

Background and aims: Resmetirom is approved for metabolic dysfunction–associated steatotic liver disease with moderate to advanced fibrosis, yet real-world hepatic safety data remain limited. This study evaluated early and intermediate-term hepatic outcomes among adults with MASLD treated with Resmetirom compared with matched untreated controls.

Method: Using the TriNetX Research Network, adults with MASLD were identified. Exclusions included liver transplantation, hepatocellular carcinoma, viral hepatitis, significant alcohol-related liver disease, pregnancy, and cholestatic autoimmune disorders. Propensity score matching incorporated demographics, MELD laboratory components, metabolic comorbidities, and concurrent medications to ensure comparable baseline liver disease severity. The Resmetirom cohort (n = 2,981) was matched 1:1 with untreated MASLD controls, yielding 2,056 patients per group. Outcomes at 90 and 180 days included new cirrhosis, liver enzyme elevation, and biliary complications.

Results: At 90 days, Resmetirom users had a significantly lower risk of developing new cirrhosis (2.8% vs 15.7%; odds ratio, 0.153; 95% CI, 0.115–0.204; $p < 0.0001$). Liver enzyme elevation occurred less frequently with Resmetirom (5.5% vs 13.4%; odds ratio 0.379, 95% CI 0.302–0.475; $p = 0.000$). Biliary complications were also reduced (0.7% vs 4.7%; odds ratio 0.148, 95% CI 0.086–0.257; $p = 0.000$).

At 180 days, the benefit persisted. New cirrhosis occurred in 4.6% of Resmetirom users versus 18.5% of controls (odds ratio 0.214, 95% CI 0.169–0.270; $p = 0.000$). Liver enzyme elevation remained lower in the Resmetirom group (7.6% vs 15.6%; odds ratio 0.449, 95% CI 0.367–0.549; $p = 0.000$). Biliary complications were similarly reduced (1.5% vs 6.1%; odds ratio 0.236, 95% CI 0.159–0.352; $p = 0.000$). Kaplan–Meier analyses demonstrated significantly higher event-free survival across all outcomes with Resmetirom at both time intervals.

Conclusion: Across 90 and 180 days, Resmetirom demonstrated a favorable hepatic and biliary safety profile, with significantly lower odds of new cirrhosis, liver enzyme elevation, and biliary complications compared with matched MASLD controls. These findings support the early safety and clinical benefit of Resmetirom in routine practice. Longer-term follow-up is necessary to assess the sustained effects on fibrosis progression and hepatic outcomes.

Email: nicole.sytang@outlook.com

Background and aims: Metabolic dysfunction–associated steatohepatitis (MASH) has an expanding drug pipeline but no comparative hierarchy of efficacy.

Method: We performed a systematic review and network meta-analysis of phase 2–3 randomized controlled trials enrolling adults with non-cirrhotic MASH. Primary endpoints were histologic MASH resolution without fibrosis worsening, ≥1-stage fibrosis improvement without MASH worsening, and ≥30% steatosis reduction in MRI-PDFF.
Results: Sixty-four trials were included. Metabolic and insulin-sensitizing agents provided the largest benefits versus placebo (odds ratios 2.5–7.1) and the lowest failure rates, yet absolute histologic response rates remained modest and variable. At the class and medication levels, FGF21 analogues and incretin-based multi-agonists ranked highest, yet 35–70% of treated patients failed to reach histologic targets, and placebo responses reached 11–18%.
Conclusion: These findings support potent metabolic agents as a pharmacologic backbone and highlight the need for durable, combination strategies that can more robustly distinguish true drug effects from placebo effects.

FRI-198
Protective potential of minimally processed, plant-derived foods against steatotic liver disease in early adulthood
Yasmina Tashkent[1,2,3], Jocelyn Choo[1,2], Steven Taylor[1,2], Therese O'Sullivan[4], Dujinthan Jayabalan[5,6], Sophie Miller[1,2], Richard Woodman[1], Luis Calzadilla Bertot[5,6], Oyekoya Ayonrinde[6,7,8], Lawrence Beilin[6], Trevor Mori[6], John Olynyk[7,8], Alan Wigg[1,3], Kate Muller[1,3], Leon Adams[5,6], Geraint Rogers[1,2]. *[1]Flinders Health and Medical Research Institute, College of Medicine and Public Health, Flinders University, Bedford Park, Australia; [2]Microbiome and Host Health Program, South Australian Health and Medical Research Institute, Adelaide, Australia; [3]South Australian Hepatology and Transplant Medicine Unit, Southern Adelaide Local Health Network, Bedford Park, Australia; [4]Nutrition and Health Innovation Research Institute, The School of Medical and Health Sciences, Edith Cowan University, Joondalup, Australia; [5]Department of Hepatology, Sir Charles Gairdner Hospital, Nedlands, Australia; [6]Medical School, The University of Western Australia, Perth, Australia; [7]Department of Gastroenterology and Hepatology, Fiona Stanley Hospital, Murdoch, Australia; [8]Curtin Medical Research Institute, Curtin University, Bentley, Australia*
Email: yasmina.tashkent@gmail.com

Background and aims: The incidence of steatotic liver disease (SLD) among younger adults is increasing globally. While poor diet is a recognised risk factor, the impact of specific dietary components is unclear. We investigated associations between dietary patterns and SLD markers in younger adults.
Method: Analysis involved 887 members of the Raine Study Generation 2 cohort, assessed at age 27. SLD was defined using a validated MRI volumetric liver fat fraction equation. Dietary intake, assessed by food frequency questionnaires, was summarised using a modified Overall Diet Score (ODS) that classified foods as "healthy" or "unhealthy." Associations between diet and SLD were evaluated by logistic regression, adjusting for waist circumference, sex, alcohol intake and physical activity.
Results: SLD was identified in 142 participants (16%). Higher consumption of vegetables, nuts, fish/seafood, coffee (all $P < 0.001$), tea ($P = 0.003$), and legumes ($P = 0.024$) was associated with reduced odds of SLD. Conversely, higher intake of fruit juice, processed animal products, processed meats (all $P < 0.001$), and sweets/desserts ($P = 0.029$) was associated with increased odds. Greater healthy food consumption (overall median [IQR] = 23 [19–27]) was inversely associated with SLD (adjusted OR = 0.949 per unit, 95% CI 0.909–0.992; $P = 0.021$). This association remained statistically significant only in males after adjustment ($P = 0.007$). The ODS and unhealthy food intake were not significantly associated with SLD following adjustment.
Conclusion: A higher intake of unprocessed or minimally processed plant-based foods is associated with lower SLD risk in younger adults, independent of central adiposity. These findings underscore the protective potential of plant-rich dietary patterns against SLD in early adulthood.

FRI-199
Effect of utreglutide on cardio-metabolic and non-invasive fibrotic biomarkers in participants with metabolic-dysfunction associated steatotic liver disease
Rajamannar Thennati[1], Vinod Burade[1], Muthukumaran Natarajan[1], Pradeep Shahi[1], Ravishankara Nagaraja[1], Bernard Thorens[2], Richard E Pratley[3], John Olynyk[4], Rohit Loomba[5]. *[1]High Impact Innovations – Sustainable Health Solutions (HISHS), Sun Pharmaceutical Industries Limited, Vadodara, Gujarat, India; [2]Center for Integrative Genomics, University of Lausanne, Lausanne, Switzerland; [3]AdventHealth Translational Research Institute, Orlando, United States, [4]Professor, Curtin Medical Research Institute, Curtin University and Fiona Stanley Hospital, West Australia, Australia; [5]Chief, Division of Gastroenterology and Hepatology, Professor of Medicine, University of California, San Diego, United States*
Email: rajamannarthennati@yahoo.com

Background and aims: Utreglutide (UTG, GL0034) is a potent glucagon-like peptide-1 receptor agonist. Here, we present safety and efficacy data of stratified participants on treatment with enhanced liver fibrosis (ELF) score reduction of ≥ 0.25 units and age ≥ 40 years; for placebo age ≥ 40 years from a Phase 1b/2a study.
Method: The study enrolled 48 subjects (BMI ≥ 30 kg/m^2, liver fat content ≥ 10 percent by magnetic resonance imaging-proton density fat fraction (MRI-PDFF), randomized (3:1) to once-weekly subcutaneous UTG with dose titration (0.4 to 1.6 mg over 10 weeks) followed by a fixed dose of 2.4 mg for 3 weeks, or placebo for 13 weeks. Data from stratified participants on UTG, n = 8 and placebo (PBO) n = 9, are presented.
Results: UTG treatment was well-tolerated, and the most common adverse events were mild to moderate gastrointestinal. The mean (SD) BMI (kg/m^2) at baseline was 40.3 (4.57) for PBO and 39.5 (4.38) UTG. The mean change in each of BMI and body weight (BW) at W14 was −9.9% ($p < 0.001$) and −10.1% ($p < 0.001$) respectively, which sustained till W17. Glycated hemoglobin mean reduction was 0.6% at W14 ($p < 0.001$) and 0.7% ($p < 0.001$) at W17 from BL of 6.1 (0.62). Non-invasive tests (NITs) revealed; a relative mean percent change of MRI-PDFF −34.1% ($p < 0.001$), BL of 22.7% (7.41); ELF score of −0.7 ($p < 0.001$), BL of 9.4 (0.75); percent subjects achieved reduction in MRI-PDFF and ELF score of ≥ 30% and > 0.5 units were 50% and 62.5% respectively, and no change in PBO; N-terminal propeptide of type III collagen (PRO-C3) (ng/mL) of −31.5 ($p < 0.05$), BL of 109.3 (46.97); and controlled attenuated parameter (CAP) mean (dB/m) of −67.9 ($p < 0.01$), BL of 350.9 (21.94)]. Alanine transaminase (U/L) decreased by 16.7% ($p < 0.05$) from a BL value of 40.0 (21.17). Lipid levels (mmol/L) at W14 showed reduction of 15.4% ($p < 0.05$) for cholesterol from BL of 4.9 (1.17) and 15.2% ($p < 0.01$) for LDL from a BL of 2.8 (0.98). High sensitivity C-reactive protein (mg/L) reduction was 44.8% ($p < 0.05$) from BL of 7.0 (6.23). Changes in PBO group were significant only for BMI and BW at W 14 ($p < 0.05$).
Conclusion: Utreglutide well tolerated; robust and sustained reductions in BW and BMI were observed. Clinically meaningful changes in cardiometabolic biomarkers and NITs associated with metabolic liver disease were noted. Collectively, these findings highlight the potential of utreglutide as a therapeutic option for metabolic dysfunction-associated steatohepatitis (MASLD) and other obesity-related disorders.

FRI-200
The impact of nutritional intervention on the echographic regression of metabolic dysfunction-associated steatotic liver disease in a cohort of postmenopausal women
Valerie Tikhonoff [1], Arianna Cocco[2], Pamela Paganini[1], Dario Cattelan[1], Giancarlo Bombonato[2]. *[1]Unit of dietetic and clinical nutrition, Department of medicine - Dimed, University of Padova,*

Padova, Italy; [2]Unit of internal medicine and hepatology, Department of medicine - Dimed, University and hospital of Padova, Padova, Italy
Email: valerie.tikhonoff@unipd.it

Background and aims: Menopause is associated with metabolic changes, secondary to estrogen decline, including increased visceral fat and impaired insulin sensitivity, resulting in an increased cardiovascular (CV) risk. In this context, metabolic dysfunction-associated liver disease (MASLD) shows a higher prevalence. Aim of this study is to evaluate the effect of a hypocaloric dietary intervention on the regression of MASLD in a cohort of postmenopausal women (PMW).
Method: 75 PMW were enrolled with BMI between 24 and 39 kg/m^2 and with at least one other CV risk factor. Complete clinical and biochemical data were acquired at the enrolment visit and at the six-month follow-up. Anthropometric, plicometric and bioimpedance measurements were performed. All participants underwent hepatosplanchnic ultrasound to evaluate hepatic steatosis via attenuation index (ATI) with a Canon Aplio i800 Ultrasonography System (Canon Medical Systems S.R.L., Roma). Each woman followed a balanced hypocaloric diet plan. Data analysis is based on paired t-test and ANOVA for repeated measures.
Results: After 6 months of dietary intervention, a significant reduction in ATI value was observed [$\Delta = -0.07$ dB/cm/MHz, (95% CI −0.09, −0.44) $p < 0.0001$], with complete regression of steatosis in 52.5% of PMW. Significant reductions in body weight (4.7%), BMI (5.6%), waist circumference (4.2%), and abdominal obesity prevalence (from 80% to 58%) were observed as well as in fat mass (10.6%) without change in fat-free mass. From a metabolic perspective, significant reductions in insulin resistance indices (HOMA-index and Metabolic Score for Insulin Resistance) and the visceral adiposity index (Metabolic Score for Visceral Fat) were observed. These positive results were achieved through a qualitative modification of dietary intake, with a reduction in daily lipid intake, particularly those of animal origin and thus saturated fatty acids, a reduction in animal protein intake, and an increase in plant proteins and total fiber.
Conclusion: The results provide evidence on the effectiveness of a targeted nutritional intervention on the regression of MASLD in PMW. The adopted approach, focused on reducing saturated fat intake and increasing plant proteins and fiber, has proven effective in promoting weight loss, improving body composition, and reducing insulin resistance, crucial factors for the regression of MASLD. These findings underscore the importance of adequate nutritional education in PMW.

FRI-201
Effect of pemvidutide on cardiovascular risk factors in patients with metabolic dysfunction-associated steatohepatitis: 48-week results from the phase 2b, IMPACT trial

John Suschak[1], Shaheen Tomah[1], Julio Gutierrez[1], M. Scot Roberts[1], Rachel Garner[1], Sarah Browne[1], M. Scott Harris[1], Christophe Arbet-Engels[1]. *[1]Altimmune, Inc, Gaithersburg, MD, United States*
Email: jsuschak@altimmune.com

Background and aims: Obesity is a primary driver of metabolic dysfunction-associated steatohepatitis (MASH), and the most common cause of mortality in patients with non-cirrhotic MASH is cardiovascular disease. Weight loss is central to the treatment of MASH as weight loss is associated with both MASH resolution and improvement in hepatic fibrosis. Beyond obesity, waist circumference, a measure of visceral adiposity, elevated serum lipids, and high blood pressure can be risk factors for cardiovascular disease. Pemvidutide is a balanced 1:1 glucagon/GLP-1 dual receptor agonist in development for the treatment of MASH. IMPACT was a phase 2b, randomized, placebo-controlled, double-blind trial in patients with biopsy-confirmed MASH and fibrosis stage F2 or F3 (NCT05989711).
Method: 212 patients were randomized 1:2:2 to receive once-weekly subcutaneous pemvidutide (1.2 mg or 1.8 mg) administered without dose titration, or placebo. The primary endpoints were MASH resolution and fibrosis improvement at 24 weeks. Secondary endpoints of the trial included reductions in body weight, waist circumference, and serum lipids at 48-weeks. Blood pressure was followed for safety.
Results: The mean age was 53 years, the mean body mass index (BMI) was 39 kg/m^2, 58% were female, and 43% had type 2 diabetes (T2D). At 48 weeks, pemvidutide treatment resulted in significant reductions in body weight of up to 7.5% ($p < 0.0001$) in the 1.8 mg group, versus 0.2% in the placebo group. Importantly, the 1.8 mg weight loss curve did not plateau at 48 weeks, suggesting continued weight loss with continued treatment. Treatment with 1.8 mg pemvidutide also yielded an absolute reduction in waist circumference of 5.3 cm ($p = 0.0026$) versus 1.9 cm in placebo. Significant reductions in elevated triglycerides with a baseline > 150 mg/dL [1.8 mg (−23.7%; $p = 0.026$) versus placebo (−3.3%)] and elevated total cholesterol with a baseline > 200 mg/dL [1.8 mg (−15.4%; $p = 0.046$) versus placebo (−5.1%)] were observed in the 1.8 mg group. Lastly, significant reductions in systolic and diastolic blood pressure were observed in the 1.8 mg group.
Conclusion: Pemvidutide treatment resulted in reductions in key cardiovascular risk factors. Significant reductions in body weight, waist circumference, serum lipids, and blood pressure may be indicative of broad improvements in cardiovascular disease.

FRI-202
Semaglutide improves hepatic and cardiometabolic outcomes in paediatric metabolic dysfunction-associated steatotic liver disease: a prospective observational study

Andrea Tou[1], Brandon Perumpail[1], Nathan Smyk[1], Michael Kallan[2,3], Nikhil Pai[1,2,3], Jennifer Panganiban[1,2,3]. *[1]Children's Hospital of Philadelphia, Division of Pediatric Gastroenterology, Hepatology, and Nutrition, Philadelphia, United States; [2]University of Pennsylvania, Philadelphia, United States; [3]Perelman School of Medicine, Philadelphia, United States*
Email: touandrea@gmail.com

Background and aims: Paediatric metabolic dysfunction-associated steatotic liver disease (MASLD) is increasingly prevalent and lacks approved pharmacologic therapies. While growing evidence demonstrates that glucagon-like peptide-1 receptor agonists (GLP-1RAs), particularly semaglutide, are associated with histological improvements in steatohepatitis in adults, paediatric data remain lacking. We aimed to evaluate the real-world impact of semaglutide on hepatic and cardiometabolic outcomes in children and adolescents with MASLD.
Method: This single-centre prospective observational study enrolled patients ≤ 18 years with MASLD initiating semaglutide for type 2 diabetes mellitus (T2DM) or obesity. Anthropometrics, laboratory values, transient elastography via FibroScan, demographics, and treatment course were collected at baseline, 3 months, and 6 months. The primary outcome was change in alanine aminotransferase (ALT). Secondary outcomes included changes in body mass index (BMI), BMI percentile, waist circumference, aspartate aminotransferase (AST), gamma-glutamyl transpeptidase (GGT), glycated haemoglobin (HbA1c), lipid profile, and FibroScan-derived controlled attenuation parameter (CAP) and liver stiffness measurement (LSM). Longitudinal changes were analysed using mixed linear models.
Results: 12 patients (mean age 16 years, 92% male, 50% White) had follow-up data at 3 months, and 10 at 6 months. Semaglutide was initiated for obesity in 83% and T2DM in 17%. ALT declined at 3 months (−33, $p = 0.07$), with a significant reduction by 6 months (−69, $p = 0.001$). FibroScan CAP (dB/m) (−33, $p = 0.013$ at 3 months; −36, $p = 0.013$ at 6 months), BMI (kg/m^2) (−1.1, $p = 0.028$ at 3 months; −2.8, $p < 0.001$ at 6 months) and HbA1c (%) (−0.2, $p = 0.046$ at 3 months; −0.4, $p = 0.003$ at 6 months) significantly improved at both timepoints; whereas BMI percentile, weight, waist circumference,

AST, GGT, and total cholesterol showed significant reductions at 6 months.
Conclusion: This is the first prospective study on semaglutide use in paediatric MASLD. Semaglutide was associated with clinically meaningful improvements in surrogate markers of MASLD disease activity, including ALT and GGT, as well as reduced FibroScan CAP values reflecting improved hepatic steatosis within 6 months. Anthropometric indices and glycaemic control also significantly improved, consistent with existing literature. This supports semaglutide as a promising adjuvant therapy in paediatric MASLD and underscores the need for longer-term and controlled studies.

FRI-203-YI
Roux-en-Y gastric bypass versus sleeve gastrectomy in MASH advanced fibrosis resolution: comparable outcomes
Ana Luiza Gomes Reis[1], Isabel Veloso Alves Pereira[1], Marcella Motta Lucindo Duarte[1], Patricia Momoyo Zitelli[1], Renato Altikes[1], Daniel Szor[2], Danilo Mardegam Razente[2], Miller Barreto[2], Denis Pajecki[2], Marco Aurelio Santo[2], Mário Pessoa[1], Claudia Pinto Oliveira[1]. Email: anagreismed@hotmail.com

Background and aims: MASH is highly prevalent in individuals with obesity, and bariatric surgery is a key therapeutic option to improve metabolic health and liver steatosis. Roux-en-Y gastric bypass (RYGB) and sleeve gastrectomy (SG) are the most common procedures, each inducing weight loss through distinct anatomical and hormonal mechanisms. Although both improve MASH, evidence in advanced fibrosis remains limited and inconclusive regarding procedural superiority. We aimed to compare RYGB and SG in a biopsy-proven MASH cohort with advanced fibrosis (F3–F4) using non-invasive assessments.
Method: We conducted a retrospective analysis of twenty-six biopsy-proven MASH patients with advanced fibrosis (stage F3–F4) who underwent bariatric surgery (7 RYGB and 19 SG). Demographic variables, clinical parameters, and laboratory markers were collected. MASH resolution was evaluated after at least one year post-surgery using Vibration-Controlled Transient Elastography (VCTE) risk categories (<10 kPa low risk; 10–14.9 kPa intermediate risk; ≥15 kPa high risk), and AGILE 3+ (rule out <0.45) score.
Results: Baseline demographic and clinical characteristics were similar between groups, including age (51.3 ± 8.6 vs. 54.6 ± 13.7 years; p = 0.32), sex (86% vs. 80% female; p = 0.70), preoperative weight (116 vs. 105 kg; p = 0.48) and BMI (45.0 vs. 39.3 kg/m^2; p = 0.68). Hypertension (86% vs. 79%; p = 0.70), diabetes and dyslipidemia (100% vs. 95%; p = 0.54), fibrosis F4 (14% vs. 37%; p = 0.27) and NAS ≥5 (57% vs. 68%; p = 0.59) did not differ. Postoperative weight-related outcomes were similar (76 vs. 77 kg; p = 0.87), BMI (29.8 vs. 29.7 kg/m^2; p = 0.87) and total weight loss (32% vs. 30%; p = 0.27). Laboratory markers before and after surgery showed no significant differences. Comorbidity improvement was also similar. MASH resolution did not differ between RYGB and SG. VCTE risk categories were comparable (low: 57% vs. 63%; medium: 14% vs. 16%; high: 29% vs. 21%; p = 0.92). AGILE 3+ rule-out improvement occurred in 60% (4/7) vs. 40% (7/19), likely reflecting the higher baseline F4 prevalence in SG; only one F4 patient achieved rule-out.
Conclusion: RYGB and SG showed comparable metabolic and hepatic benefits in patients with biopsy-proven MASH and advanced fibrosis. No significant differences were observed across non-invasive liver markers, fibrosis risk categories, or metabolic improvements, indicating that both procedures offer similar effectiveness for MASH resolution in this high-risk population.

FRI-204
FB7033: A novel siRNA dual-targeting Hydroxysteroid 17-beta Dehydrogenase 13 (HSD17β13) and cell death-inducing DFF45-like effector B (CIDEB) exhibits potential for treatment of metabolic dysfunction-associated steatohepatitis (MASH)
Michael Wang[1,2,3], Jieting Zhang[1], Siwen Tang[1], Jundong Han[4], Lilei Guo[1], Xia Liu[1], Min Hu[1], Peizhuo Zhang[4], Dong Xie[1]. [1]*Frontier Biotechnologies, Inc., Nanjing, China;* [2]*Frontier Biotechnologies, Inc., R&D, N, China;* [3]*Frontier Biotechnologies, Inc, Nanjing, China;* [4]*Suzhou GenePharma Co. Ltd., Suzhou, China*
Email: wangzhiyan@frontierbiotech.com

Background and aims: MASH is characterized by hepatocellular steatosis, inflammation, and fibrosis, potentially progressing to cirrhosis and hepatocellular carcinoma. Current therapies for MASH are limited by safety, efficacy, and adherence issues. HSD17β13 and CIDEB contribute to MASH progression through distinct mechanisms. HSD17β13 exacerbates hepatic lipid metabolism dysfunction, inflammation, and fibrosis, while CIDEB primarily mediates lipid droplet dynamics and storage. Here we report the discovery and development of FB7033, a novel dual-targeting siRNA on HSD17β13 and CIDEB mRNA, as a promising therapeutic candidate for treatment of MASH.
Method: The HepG2, Hep3B cells, humanized HSD17β13 or CIDEB transgenic mice, and cynomolgus macaques were used to evaluate the efficacy of FB-7033 on HSD17β13 or CIDEB mRNA knockdown both *in vitro* and *in vivo*. A previously validated cynomolgus monkey MASH model, which was induced by high-fat diet, was used to assess efficacy. FB7033 was administrated by SC injections at 3, 6, 12 mg/kg (Q4Wx3). ARO-HSD (GSK4532990) (3 mg/kg, SC, Q4Wx3) and resmetirom (5 mg/kg, PO, QD) were used as positive controls. The MRI Proton Density Fat Fraction (MRI-PDFF) and NAFLD Activity Score (NAS) were measured for assessment of MASH progression for a duration of 12 weeks. The safety profile of FB7033 was assessed by *in vitro* and *in vivo* studies.
Results: FB7033 effectively knock-down HSD17β13 (IC_{50} = 5 pM) and CIDEB (IC_{50} = 3 pM) mRNA *in vitro*. A single subcutaneous injection of FB7033 led to simultaneous and significant suppression of both target mRNAs expression, with the maximal knock-down of 94% in monkeys. In the NHP MASH model, FB7033 reduced the expression of both target mRNAs in liver in a dose-dependent manner. More importantly, FB7033 significantly reduced hepatic fat (MRI-PDFF) and NAS Scoring, exhibiting superior efficacy of MASH remission, to those of ARO-HSD and resmetirom. FB7033 showed good safety profile in off-target, immunotoxicity, and repeat-dose toxicology study in rats.
Conclusion: FB7033 robustly inhibits the expression of HSD17β13 and CIDEB, conferring superior treatment potential against MASH progression, which indicates potential synergistic effect of the dual-targeting siRNA strategy. The pharmacodynamic profile of FB7033 may support a once every 1–3 months dosing regimen in human, addressing both efficacy and dosing challenges in current treatment regimens. Further clinical evaluation of FB7033 in MASH patients is warranted.

FRI-205-YI
Sodium-glucose co-transporter-2 inhibitors and risk of major adverse liver outcomes in patients with chronic liver disease and type 2 diabetes
Axel Wester[1], Ying Shang[1], Emilie Toresson Grip[1], Daniel Andersson[1], Camila Olarte Parra[1], Hannes Hagström[1]. [1]*Karolinska institutet, Stockholm, Sweden*
Email: axel.wester@ki.se

Background and aims: Small randomized trials suggest sodium-glucose co-transporter-2 (SGLT2) inhibitors may improve surrogate markers for major adverse liver outcomes (MALO), but whether SGLT2 inhibitors affect the risk of MALO is unknown. Large randomized trials to assess the effect of SGLT2 inhibitors on rare

hard clinical outcomes such as MALO would however likely be challenging to conduct. Therefore, we designed a hypothetical randomized trial that would estimate the causal effect of SGLT2 inhibitors on the risk of MALO in patients with any chronic liver disease and type 2 diabetes and then emulated this target trial using observational data.
Method: We used observational data from Swedish healthcare registers 2016–2022 to emulate a target trial of SGLT2 inhibitors in eligible patients with chronic liver disease and type 2 diabetes. We used an inverse-probability weighted marginal structural model to compare the 5-year risk of MALO (decompensated cirrhosis, hepatocellular carcinoma, liver transplantation, or liver-related death) in initiators of SGLT2 inhibitors versus non-initiators. The model was adjusted for age, sex, calendar year, socioeconomic parameters, markers for diabetes and liver disease severity, comorbidities, and medications that may affect both the exposure and the outcome.
Results: We included 37,503 patients with a median age of 65 years (interquartile range 56–73) of whom 22,159 (59%) were men and 7,007 (18.7%) had compensated cirrhosis at baseline. Baseline characteristics were well balanced between treatment groups after inverse-probability weighting. Initiators of SGLT2 inhibitors had a 5-year risk of MALO at 6.8% (143/4,160) versus 7.2% in non-initiators (1,922/33,343) in intention-to-treat analysis (risk ratio [RR] = 0.94, 95% confidence interval [CI] = 0.75–1.13). The corresponding 5-year per-protocol risk estimates were 5.2% (69/4,160) and 6.6% (1,807/33,343), respectively (RR = 0.78, 95% CI = 0.32–1.24). Risk estimates in subgroups based on sex, cirrhosis status at baseline (compensated cirrhosis, or no cirrhosis), and liver disease etiology (metabolic dysfunction-associated steatotic liver disease, or other) were consistent with the main results.
Conclusion: In patients with chronic liver disease and type 2 diabetes, initiation of an SGLT2 inhibitor did not affect the risk of MALO. Other antidiabetic treatment options may therefore be preferred in patients with concomitant chronic liver disease.

FRI-206
RNA editing of PNPLA3 I148M decreases hepatocyte fat content
Hsiu-Chiung Yang[1], Chikdu Shivalila[1], Pachamuthu Kandasamy[1], Stearne Briem[1], Michael Byrne[1], Alyse Faraone[1], Naoki Iwamoto[1], Tomomi Kawamoto[1], Richard Looby[1], Frank Favaloro[1], Stephany Standley[1], Suma Veermachineni[1], Hailin Yang[1], Benny Yin[1], Hui Yu[1], Genliang Lu[1], Chandra Vargeese[1], Erik Ingelsson[1]. [1]*Wave Life Sciences, Cambridge, United States*
Email: cshivalila@wavelifesci.com

Background and aims: The *PNPLA3 I148M* variant disrupts PNPLA3 function and hepatic lipid homeostasis and retinol metabolism and is associated with substantially increased risk of liver-related deaths, including from MASH and alcohol associated liver diseases. We have developed RNA editing oligonucleotides, or AIMers, that are designed to edit the base sequence of *PNPLA3 I148M* transcripts to restore functional protein. Emerging evidence showing that PNPLA3 plays an important role in hepatic lipid metabolism suggests that an RNA editing approach that restores PNPLA3 enzymatic function may be preferable to silencing *PNPLA3*, which causes a loss of function, for the treatment of liver disease.
Method: We synthesized GalNAc-conjugated chemically modified AIMers to edit the I148M variant using endogenous adenosine deaminase acting on RNA (ADAR) enzymes. GalNAc-AIMer editing efficiency was quantified by Sanger sequencing in concentration-response experiments in human primary hepatocytes. The impact of editing or silencing (with GalNAc-siRNA) on intracellular lipid droplet density was evaluated using the human HEPATOPAC system and in long-term primary human hepatocyte monolayer cultures. Mice were dosed subcutaneously with GalNAc-AIMers, and tissue concentrations of PNPLA3 AIMer in liver were quantified by ELISA after one week.
Results: We evaluated PNPLA3 GalNAc-AIMers in human homozygous *PNPLA3 I148M* primary hepatocytes from multiple donors. The most effective AIMers directed potent (EC_{50} 12 nM) and efficient (~70%) editing of *PNPLA3* transcripts. In a human HEPATOPAC system with homozygous I148M hepatocytes, PNPLA3 GalNAc-AIMers significantly decreased lipid droplet density compared to mock treatment ($p < 0.0001$), whereas GalNAc-siRNA designed to silence expression of *PNPLA3* did not have a significant effect. In long-term cultures of human homozygous *PNPLA3 I148M* primary hepatocytes, PNPLA3 transcript editing of ~50% corresponded with a substantial lowering of lipid droplet density. In mice expressing wild-type *Pnpla3*, GalNAc-AIMers dosed subcutaneously reached 500–1,000 µg/g in liver, concentrations expected to yield substantial RNA editing based on in vitro experiments in hepatocytes.
Conclusion: These data demonstrate that AIMers supporting *PNPLA3 I148M* editing to restore functional PNPLA3 protein decrease fat content in hepatocytes, and outperform *PNPLA3* silencing in lowering lipid density. Overall, these data support continued advancement of AIMers for the treatment of *PNPLA3 I148M* liver disease.

TOP-535-YI
Barriers and facilitators in alcohol-related care pathways: findings from a qualitative interview study
Stine Munk Larsen[1], Mette Lauridsen[1], Lea Ladegaard Grønkjær[1]. [1]*University Hospital of Southern Denmark, Esbjerg, Denmark*
Email: lea.ladegaard.gronkjaer@rsyd.dk

Background and aims: Alcohol-related liver disease (ALD) remains a leading cause of morbidity and mortality. Although effective treatments for alcohol use disorder exist, engagement in treatment and sustained abstinence remain inconsistent. Patients with ALD often navigate fragmented care pathways between hospital-based services and municipal alcohol treatment, where motivational, relational, and organisational factors may influence outcomes. This study aims to explore barriers and facilitators in alcohol-related care pathways from the perspectives of both patients and healthcare professionals.
Method: Between September and December 2025, semi-structured interviews were conducted with six patients with alcohol-related liver disease and six healthcare professionals from a hospital liver unit and a municipal alcohol treatment service. Patients were purposively sampled to include individuals with both sustained abstinence and ongoing alcohol use. Interviews explored experiences of care pathways, treatment engagement, motivation, patient-healthcare professional interactions, and perceived gaps in care. Data were analysed thematically using Braun and Clarke's six-phase framework.
Results: Four themes emerged: (1) motivational readiness and self-recognition as prerequisites for sustained change; (2) relational trust and communication, where non-moralising interactions promoted openness, while perceived judgement led to disengagement; (3) the value of peer-based and intensive support, particularly residential treatment and peer communities; and (4) fragmentation and transition gaps between hospital and municipal services associated with relapse risk. Healthcare professionals described challenges initiating motivational conversations in time-limited settings.
Conclusion: Alcohol-related care pathways are shaped by a complex interplay of individual motivation, relational factors, and organisational structures. Findings suggest that effective care for patients with ALD requires timely, trust-based conversations, improved continuity across sectors, and integration of peer-based support. Interventions

targeting motivational readiness and cross-sector collaboration may enhance engagement and reduce relapse. Further research should explore implementation strategies to strengthen coordinated, patient-centred alcohol care in liver disease services.

THU-527-YI

Social nurse interventions may reduce mortality in patients with acute decompensated liver cirrhosis

Palle Bager[1], Jonatan Petersen[1], Tine Dideriksen[1], Lotte Eriksen[1], Marie Storgaard[1], Karen Louise Thomsen[1]. [1]*Aarhus University Hospital, Hepatology and Gastroenterology, Aarhus, Denmark*
Email: pallbage@rm.dk

Background and aims: Social nurse (SN) functions are well-established in a number of somatic hospitals. SNs work with patients facing social vulnerability and they aim to minimise the impact of problematic behaviors that could influence health. Patients with acute decompensated (AD) liver cirrhosis may benefit from the care given by SNs. We aimed to investigate if contact to a SN were associated with readmission and mortality in patients with AD cirrhosis.
Method: A historical cohort study included all patients with AD cirrhosis, admitted to Aarhus University Hospital, Denmark between Jan. 2019 and Jan. 2024. Patients were identified via the electronic patient record. Demographic- and clinical data were extracted as well as data on contact to a SN during admission, readmissions, and mortality. The patients were grouped into: i) the SN group, who had contact to the SN, and ii) the NSN group, who did not have contact to a SN. Group comparisons were conducted using the Student's t-test or the χ^2-test. Cox proportional hazards regression was used to evaluate the association between variables and mortality.
Results: Of 476 identified patients, we included 245 patients with a definite diagnosis of AD cirrhosis. Of these, 49 (20%) were in the SN group. Patients in the SN group were younger (mean age of 54 ± 10 years vs. 62 ± 10 years), $p < 0.005$. The predominant etiology of cirrhosis was alcohol, 190 (78%) across the whole cohort. The total median observation time was 203 days (IQR: 48–510). There was no difference in number of readmissions between the groups, 33 (67%) vs. 120 (61%), $p = 0.43$. The median time to first readmission was 34 days (IQR: 16–207) in the SN group vs. 67 days (IQR: 15–234) in the NSN group. During follow-up, 150 (61%) patients died: 24 (49%) in the SN group vs. 126 (64%) in the NSN group, $p < 0.05$. The one-year mortality rate was lower in the SN group compared to the NSN group, 13 (27%) vs. 87 (44%), $p < 0.05$, whereas there was no difference in the 90-day mortality rate, 9 (18%) in the SN group vs. 47 (24%) in the NSN group, $p = 0.40$.
Conclusion: Support provided by SNs to patients with AD cirrhosis was found to be associated with lower one-year mortality, however, having contact with a SN was also associated with sooner readmission to hospital. This observational study did not adjust for confounders so the described associations may have been affected by other factors than SNs.

THU-528-YI

Knowledge of filipino adults on metabolic dysfunction–associated steatotic liver disease (masld) and its relationship with sociodemographic factors, nutritional status, physical activity, food security, and diet quality: a cross-sectional study

Melvin Bernardino[1,2], Kristine Joy Sofia Cruz[1], Cassandra Abalos[1], Jeanne Carla Bruce[1]. [1]*Colegio de San Juan de Letran Manila, Manila, Philippines;* [2]*151 Muralla St, Nutrition and Dietetics, Manila, Philippines*
Email: melvin.bernardino@letran.edu.ph

Background and aims: Metabolic Dysfunction–Associated Steatotic Liver Disease (MASLD) is a major contributor to chronic liver disease worldwide. Awareness of MASLD is critical for early prevention and management, yet data on public knowledge in the Philippines remain limited. This study aimed to assess MASLD knowledge among Filipino adults and examine its relationship with sociodemographic factors, nutritional status, physical activity, food security, and diet quality.
Method: A cross-sectional study was conducted in Intramuros, Manila, with 172 adults aged 19–59 years. MASLD knowledge and source of information was assessed using a 25-item validated questionnaire. Sociodemographic data, body mass index (BMI), body fat%, physical activity (International Physical Activity Questionnaire–Short Form), diet quality (Diet Quality Questionnaire), and food security (Household Food Insecurity Access Scale) were collected. Spearman's rank correlation was used to examine associations, with significance set at $p < 0.05$.
Results: The majority of respondents were male (61.05%), and most participants were aged 30–49 years (45.35%). Overall, 72% of respondents reported no prior awareness of MASLD. Regarding sources of information about MASLD, 10.47% of respondents obtained information from family or friends, followed by the internet (8.14%), doctors (6.98%), television, radio, or public advertisements (6.40%), and health education in hospitals or communities (5.23%). Knowledge levels were highest for risk factors such as alcohol consumption (80%) and obesity (69%), but were low for disease reversibility (28%) and asymptomatic presentation (28%). Significant positive correlations were observed between MASLD knowledge and physical activity (Spearman's rho = 0.173, $p = 0.023$), diet quality (Spearman's rho = 0.161, $p = 0.035$), income (Spearman's rho = 0.215, $p = 0.005$), and educational attainment (Spearman's rho = 0.170, $p = 0.025$). No significant associations were identified with BMI, body fat percentage, sex, age, occupation, or food security.
Conclusion: To our knowledge, this is the first study to report MASLD awareness among Filipino adults. Awareness was low, with substantial gaps in knowledge regarding disease reversibility and asymptomatic presentation. Higher educational attainment, income, physical activity, and diet quality were associated with greater MASLD knowledge, underscoring the need for targeted public education and lifestyle-based and interventions to prevent disease progression in the Philippine population.

THU-537

Diagnostic performance of non-invasive fibrosis scores for detecting advanced fibrosis in a biopsy-proven indian MASLD cohort- a record based cross-sectional study

Ankit Bhardwaj[1], Ankur Jindal[1], Shiv Kumar Sarin[1]. [1]*Institute of Liver & Biliary Sciences, New Delhi, India*
Email: shivsarin@gmail.com

Background and aims: Non-invasive fibrosis tests are widely used to detect advanced fibrosis and cirrhosis in MASLD, but their performance varies across populations. Data correlating these tests with biopsy-proven fibrosis in Indian MASLD patients, especially in the intermediate fibrosis group, remain limited.
Method: All consecutive biopsy-proven MASLD patients, with and without advanced fibrosis (F3–F4), were included. The diagnostic performance of FIB-4, NFS, AGILE-3, AGILE-4, LSM, and APRI for detecting advanced fibrosis was compared using liver biopsy as the reference standard. Accuracy was assessed by AUROC, and optimal cohort-specific cut-offs were derived using the Youden Index.
Results: A total of 838 patients with biopsy-proven MASLD were included (mean age 50.8 ± 12.3 years; 70.2% male; 52.5% with diabetes). Advanced fibrosis (F3–F4) was present in 721/838 (86%), while 117/838 (14%) had F0–F2 disease. FIB-4 and NFS demonstrated good diagnostic accuracy for advanced fibrosis with AUROCs of 0.77 (95% CI 0.72–0.82) and 0.78 (0.72–0.83), respectively (both $p < 0.001$), outperforming APRI (AUROC 0.64, 95% CI 0.58–0.70). Mean NFS and FIB-4 values increased progressively with fibrosis stage. The intermediate FIB-4 zone (1.3–2.67) showed limited discriminatory ability for advanced fibrosis, with 75.2% sensitivity, 12.1% specificity, 12.3% PPV, and 74.8% NPV. AGILE-3 and AGILE-4 score showed good diagnostic accuracy for advanced liver fibrosis with AUROCs of 0.79 (95% CI 0.73–0.85) and 0.82 (0.77–0.88), respectively (both $p <$

0.001); at Youden-derived cut-offs (0.95 and 0.96), sensitivities exceeded 93% with modest specificities (39–43%). LSM demonstrated comparable performance (AUROC 0.80, 95% CI 0.74–0.86; p < 0.001), and at a cut-off of 15.56 kPa showed 94.6% sensitivity and 42.8% specificity. Using cohort-specific cut-offs, FIB-4 (2.71) and NFS (0.33) showed high sensitivity (>92%) but limited specificity, while APRI performed inferiorly. PPV were high across models, whereas negative predictive values remained modest.
Conclusion: In this large biopsy-proven MASLD cohort from India, non-invasive fibrosis tests demonstrated high sensitivity but limited specificity to detect advanced liver fibrosis, indicating better rule-out than rule-in ability. Our results support the use of AGILE models and LSM in sequential or combined non-invasive strategies for fibrosis risk stratification in MASLD. There is need for development of new models for more specific fibrosis assessment for Indian population.

THU-538-YI
Relationship between patient activation and e-health literacy levels and associated factors in patients with liver cirrhosis: a cross-sectional study
Ferya Celik[1], Hicran Bektas[1]. [1]*Akdeniz University Faculty of Nursing, Antalya, Türkiye*
Email: feryacelik@gmail.com

Background and aims: Effective medical management and nursing care of liver cirrhosis require active patient participation in care practices. Adequate e-Health literacy levels are essential for patients to learn and correctly implement these care practices.
This study was carried out to examine the relationship between patient activation and e-Health literacy, and to identify the factors associated with these variables in patients with liver cirrhosis.
Method: The study was conducted with 153 patients with liver cirrhosis who received treatment in a university hospital in Antalya, Turkey, between November 2024 and December 2025. A personal information form, the Patient Activation Measure and the e-Health Literacy Scale were used to collect the data. After evaluating the normality of the data, independent-samples t-test, one-way analysis of variance (ANOVA), and Pearson correlation were performed.
Results: The mean age of the participants was 59.04 ± 14.35 years. Of the patients, 58.8% were male, 43.8% had completed primary education, 30.7% had alcohol-related liver cirrhosis, and 64.0% had been diagnosed for 1–4 years. The Cronbach's alpha coefficient of the Patient Activation Measure was 0.97, with a mean score of 46.31 ± 11.44. Patient activation scores showed statistically significant differences according to age, educational level, duration of diagnosis, dietary adherence, regular medication use, body weight monitoring, and attendance at health check-ups (p < 0.05). The Cronbach's alpha coefficient of the e-Health Literacy Scale was 0.77, with a mean score of 23.76 ± 7.39. e-Health literacy scores showed statistically significant differences according to age, marital status, educational level, etiology of liver cirrhosis, duration of diagnosis, dietary adherence, regular medication use, body weight monitoring, health check-up attendance, and alcohol use. There was a strong, positive relationship between patient activation and e-Health literacy levels (r = 0.603, p < 0.001).
Conclusion: Patient activation was strongly and positively associated with e-Health literacy. Both constructs differed across key socio-demographic and clinical self-management characteristics, indicating that activation and digital health competencies may co-vary with real-world adherence behaviours. These findings support the need for targeted, nurse-led, digitally supported education and individualized follow-up to strengthen self-management capacity and potentially improve care engagement in this population.

THU-539-YI
Elafibranor tolerability and response in patients with primary biliary cholangitis previously treated with bezafibrate: a real-world single-centre experience
Fatema Jessa[1], Megan Morgan[1], Neil Halliday[1]. [1]*Royal Free Hospital, London, United Kingdom*
Email: fatema.jessa@nhs.net

Background and aims: Patients with primary biliary cholangitis (PBC) with inadequate biochemical response or intolerance to ursodeoxycholic acid (UDCA) may require second-line therapy, including bezafibrate (BZF), used off-licence in PBC. Elafibranor (ELA), a dual peroxisome proliferator-activated receptor (PPAR)-α/δ agonist, is a recently licensed treatment option. Given overlapping mechanisms of action, it is unclear whether prior response or intolerance to BZF is relevant to ELA tolerability or biochemical response. This study evaluated single centre experience of tolerability and response to ELA according to prior BZF exposure.
Method: All PBC patients initiated on ELA at the Royal Free London NHS Foundation Trust between January and November 2025 were identified using the electronic dispensing system (JAC). Clinical records were reviewed to determine prior BZF exposure and documented adverse events (AEs) to BZF and ELA.
Results: 38 patients commenced ELA; 95% female, median age 56years, 45% (17/38) were cirrhotic with median ALP 371 U/L on ELA initiation. 61% (23/38) had prior BZF exposure of which 57% (13/23) experienced AEs (54% muscle related events (MR), 38% liver biochemistry rise) leading to BZF discontinuation. 43% (10/23) switched to ELA due to non-response. AEs with ELA were reported in 91% (21/23) of BZF-exposed patients (48% gastrointestinal (GI), 35% MR). Among patients without prior BZF, 80% (12/15) reported AEs (53% MR, 47% GI). Overall, in evaluable patients, POISE response criteria were met in 45% (14/31) at week 4 and 46% (11/24) at week 12. Week 4 response differed by prior BZF status: 83% (10/12) in BZF-naïve patients, 27% (3/11) with prior BZF intolerance, and 13% (1/8) in BZF non-responders. However, among those who did not meet POISE criteria, 65% had ALP reduction >15% at week 4 and 54% at week 12. Improvement in pruritus was reported in 21%(8/38). 32%(12/38) discontinued ELA of which 50% (6/12) were BZF intolerant.
Conclusion: In this cohort, AEs with ELA were common regardless of prior BZF exposure but often did not lead to treatment discontinuation. While prior BZF intolerance accounted for half of ELA discontinuations, BZF intolerance did not uniformly preclude treatment with ELA. However, biochemical response to ELA appeared lower in patients previously non-responsive to BZF compared with BZF-naïve patients. These findings require confirmation in larger, multicentre studies and support an individualised approach to counselling, monitoring and treatment selection when initiating ELA.

Early UK experience with elafibranor in primary biliary cholangitis: a multicentre pharmacist-led review
Arron Jones[1], Robert Elliot-Cooke[2], Rachael Kamiri-Ngugi[3], Fiona Rees[4], Sarah Cripps[5], Kate Greener[6], Sital Shah[6], Alison Boyle[7]. [1]*Barts Health NHS Trust, London, United Kingdom;* [2]*University Hospitals Plymouth NHS Trust, Plymouth, United Kingdom;* [3]*Royal Surrey NHS Foundation Trust, Guildford, United Kingdom;* [4]*University Hospitals Sussex NHS Foundation Trust, Brighton, United Kingdom;* [5]*Oxford University Hospitals NHS Foundation Trust, Oxford, United Kingdom;* [6]*King's College Hospital NHS Foundation Trust, London, United Kingdom;* [7]*NHS Greater Glasgow & Clyde, Glasgow, United Kingdom*
Email: arron.jones@nhs.net

Background and aims: Elafibranor, a dual peroxisome proliferator-activated receptor (PPAR) alpha/delta agonist, is a treatment option for primary biliary cholangitis (PBC) in the UK. It was introduced recently as a second line option for patients with an inadequate response, or intolerance to, ursodeoxycholic acid (UDCA). In many liver centres, specialist hepatology pharmacists manage PBC patients

on second line therapies. This review reports on early real-world experience, clinical response, and safety of elafibranor.
Method: A retrospective review of patients prescribed elafibranor from November 2024 – December 2025 was undertaken across seven UK centres. Patient records were reviewed to determine demographics and clinical features, including liver stiffness measurements (LSM), liver biochemistry, and prior PBC treatments. Treatment experience with elafibranor, including clinical response, safety, and tolerability, was documented.
Results: 76 patients were initiated on elafibranor, 62 (82%) patients continued over 6 months. 14 (18%) patients discontinued elafibranor with 8 (11%) stopping prior to their first review. Follow up data is available for 45 patients (59%). 39 (87%) patients were AMA positive, 44 were female (98%). Mean age was 67 years (+/– 12) and mean LSM 9.9 kPa (+/– 6.4), with 10 (22%) cirrhotic patients. 34 (75.6%) patients had trialled obeticholic acid and/or bezafibrate before starting elafibranor. 26 (58%) patients experienced adverse effects, with gastrointestinal effects the most common (n = 13). 13 patients (29%) discontinued treatment due to adverse effects. 8 patients reported improvement in pruritus (18%) and 2 in fatigue (4%). 4 (9%) reported worsening pruritus, and 2 (4%) worsening fatigue. 1 patient developed decompensated cirrhosis; however, a causal relationship was not confirmed. 8 (18%) patients were not taking UDCA due to intolerance. 5 of these patients reported adverse effects with elafibranor. Mean ALT prior to elafibranor initiation was 67.1 (+/– 50.6), and ALP 379 (+/– 242.9). Post treatment liver biochemistry was available for 36 patients; mean ALT was 57.7 (+/– 41.3), and ALP 301.8 (+/– 175.6). Liver biochemistry was available for 15 patients after 6 months treatment, mean ALT was 55.3 (+/– 38.1) and ALP 196.7 (+/– 80.5).
Conclusion: Patients on elafibranor demonstrated a positive initial biochemical response to therapy. Adverse effects led to discontinuation in a number of patients. Additional real-world data is needed to better understand treatment response.

THU-541-YI
Exploring issues and challenges experienced by patients with ascites in a view to develop an innovative abdominal belt for early detection of ascites

K L Ajee[1], Arun Valsan[2], Jerlin Roy[1], R Helen[1]. [1]*Amrita College of Nursing, Amrita Vishwa Vidyapeetham, Health Sciences Campus, Kochi, Kerala, India 682041, Ernakulam, India;* [2]*Amrita Institute of Medical Science & Research Centre, Kanayannur, India*
Email: capt.ajee@gmail.com

Background and aims: Cirrhosis patients often develop ascites, causing extensive physical, psychosocial, and challenges. Ascites marks most common decompensation, with five-year mortality of 44% from complications such as spontaneous bacterial peritonitis and hepatorenal syndrome. Early detection in home setting may enforce diet control, fluid and medication adherence. This study aimed to explore lived in experiences of patients with ascites, and use those insights to design a sensor based abdominal belt for early onset of ascites at community level.
Method: A qualitative phenomenological approach with in-depth interviews were conducted for 11 adult patients with radiologically confirmed cirrhotic ascites and their primary caregivers admitted to a tertiary liver unit in South India. Patients with hepatic encephalopathy were excluded. Purposive sampling was used and data saturation determined sample size. Ethical clearance and written informed consent were obtained from institutional ethics committee and the participants respectively. A validated semi-structured questionnaire consisted of 10 open-ended questions explored physical symptoms, mobility and comfort, social issues, emotional concerns, and monitoring and management at home. Interviews were audio-recorded, transcribed, and analyzed thematically using MAXQDA.
Results: Seven major themes were identified:1) Physical discomfort including abdominal distension, dyspnoea, pain, and activity limitations. 2) Social challenges like altered body image, dependency, and employment and family role disruption. 3) Psychological distress like anger, anxiety, fear of deterioration, and repeated hospital visits. 4) Financial strain from hospital costs due to recurring visits and loss of occupation. 5) Altered coping strategies, including delayed decision-making and avoidance of familial interaction. 6) Caregiver burden arising from strict dietary restrictions and lifestyle modifications, leading to care giver occupational withdrawal.7) A strong desire for a comfortable user-friendly device to provide early alerts for tailored management to reduce frequent hospital visits.
Conclusion: A device to assess the early onset of ascites at home or community level can initiate or enhance self-care and reduce frequent hospitalization. This study is primarily in alignment with UN SDGs 3 (Good Health & Well-being) and 9 (Industry, innovation and infrastructure) by developing a sensor-based device for early detection of ascites.

THU-542
Clinical efficacy of 3 dose Hepatitis B vaccine on protective seroconversion among patients with cirrhosis of liver

K L Ajee[1], Arun Valsan[2], Lena Saji[1], M Monisha[1], G Nikhilamol[1], Niveditha Sunish[1]. [1]*Amrita College of Nursing, Amrita Vishwa Vidyapeetham, Health Sciences Campus, Kochi, Kerala, India 682041, Ernakulam, India;* [2]*Amrita Institute of Medical Science & Research Centre, Kanayannur, India*
Email: capt.ajee@gmail.com

Background and aims: CDC recommends vaccination against Hepatitis B in all patients with liver cirrhosis. However, development of protective vaccine in CLD and its optimization is not clear. Hence, we aimed to evaluate the clinical efficacy of a 3 dose Hepatitis B vaccination among patients with cirrhosis of liver and to identify the factors that influence the presence of hepatitis B antibody titre in patients with liver cirrhosis.
Method: A prospective observational analytical study with purposive sampling was conducted in a tertiary care hospital among 339 vaccine-naïve adult patients who were diagnosed to have cirrhosis of liver of varying severity as per the clinical, radiological, and pathological findings. The study was conducted from January 2024 to September 2025. We included all those who were seronegative for HBsAg, HIV and HCV and had given an accelerated regimen of 3 dose hepatitis B vaccine at intervals of 0, 1, and 2 months. Anti-HBs titre was checked 8 weeks after receiving the third dose of hepatitis B vaccination. We excluded patients with HCC and who were having severe coexisting medical conditions. Other than sample characteristics and clinical profile, sarcopenia was assessed using SARC-F. Anti-HBs antibody <10 IU/L was considered as non-reactive. Institutional ethical clearance and written informed consent were obtained. Chi-square, Mann-Whitney U, and logistic binary regression were done with SPSS 30.0.
Results: Majority (84%) were male and the median age was 48. Diabetes mellitus (27%) was the most common co-morbidity among those with comorbidities (59%). Overall seroconversion was found to be 60%, and median MELD and CTP score were 11 and class A, respectively. Among those who attained seroconversion, only 9% had a titre value >100. Patients who were less than 60 years of age had better response to the vaccine ($p < 0.001$). Anti-HBs titer was significantly high ($p < 0.01$) among patients with normal serum albumin. Patients with higher MELD and CTP had significantly lower odds (OR 0.42, $p < 0.01$) of achieving protective seroconversion. The seroconversion rate was significantly high ($p < 0.01$) among patients without comorbidities. However, nutritional status did not show any association with anti-HBs antibody titer.
Conclusion: Younger age groups with preserved liver function and who were not having any comorbidities were considered to have high seroconversion. Nurse-led counseling on adult vaccination may

improve the status. This study is in alignment with SDG 3.3, 3.4 and 3.8.

THU-543

Cost-effectiveness of screening for hepatitis C virus infection among people who use drugs in South Korea

Hye-Lin Kim[1], Kyung-Ah Kim[2], Gwang Hyeon Choi[3], Sook-Hyang Jeong[3]. *[1]Sahmyook University College of Pharmacy, Seoul, Korea, Rep. of South; [2]Inje University Ilsan Paik Hospital, Goyang, Korea, Rep. of South; [3]Seoul National University Bundang Hospital, Seongnam, Korea, Rep. of South*
Email: maristella76@tistory.com

Background and aims: To eliminate hepatitis C virus (HCV) infection, targeted screening and treatment of the established high risk group such as people who use drugs (PWUD) is essential. This study evaluated the cost-effectiveness of HCV screening and direct acting antiviral (DAA) treatment compared with no screening among PWUD who were detected drug offenders in South Korea.
Method: We conducted cost-utility analysis using a decision analytic model to estimated the expected costs and quality-adjusted life years (QALYs) between one-time HCV screening targeting PWUD and no screening. As screening algorithm, HCV RNA reflex testing which automatically tests for HCV RNA if the anti-HCV test is positive was applied. The hypothetical cohort of 45-year-old PWUD, and their prevalence of anti-HCV was estimated to be 31.3% was simulated over 30-year horizon. Key features in PWUD–such as HCV prevalence and treatment rates–were obtained from the Korea HCV-PWUD registry. The incremental cost-effectiveness ratio (ICER) between two strategies was calculated, and sensitivity analyses were also conducted to explore the impact of parameter and structural uncertainty on results.
Results: The HCV screening strategy yielded an ICER of $2,449/QALY, which was substantially lower than Korea's willingness-to-pay threshold (about $22,000/QALY), demonstrating that universal screening in PWUD was highly cost-effective compared with no screening. In sensitivity analyses, the most influential parameters were age (associated with HCV seroprevalence and fibrosis stage; ICER for patients in their 30s: $7,391/QALY) and HCV re-infection rate (rising to 10% for 10 years, then 6% for 20 years: $4,184/QALY). All ICERs from sensitivity analyses remained below the threshold. The long-term effectiveness of screening also demonstrated cost savings through the reduction of decompensation, hepatocellular carcinoma, and liver-related death cases.
Conclusion: The screening with HCV reflex testing and DAA treatment among PWUD in South Korea would be highly cost-effective from both healthcare system and societal perspectives. These findings support implementing universal HCV screening programs for PWUD as a public health strategy to reduce disease burden and healthcare costs while improving clinical outcomes in this high-risk population.

THU-544

Care competency skills and degree of distress among informal caregivers of patients with chronic liver disease

S Suja Kumari[1], Arun Valsan[2], Anju Roy[3], J Aparna[3], Angela Paulson[3], Anjana Lal[3], Sheela Pavithran[3]. *[1]Amrita College of Nursing, Ernakulam, India; [2]Amrita Institute of Medical Sciences, Kochi, Amrita Vishwa Vidyapeetham, Ernakulam, India; [3]Amrita College of Nursing, Amrita Vishwa Vidyapeetham, Kochi, India*
Email: sujaks@nursing.aims.amrita.edu

Background and aims: Chronic liver disease (CLD) is an imminent danger to global health and has emerged as one of the leading causes of death globally. Due to the rising occurrence of cases linked to metabolic dysfunction-associated steatotic liver disease (MASLD), steatotic liver disease (SLD) is expected to become a significant contributor to diseases and liver disease by 2040 worldwide. This study aimed to evaluate the knowledge, competency, and level of distress of informal carers.
Method: A descriptive quantitative study was conducted among 200 caregivers for CLD patients. Caregivers aged 18–60 years were included, whereas caregivers with comorbidities that need formal treatment were not included. A structured sociodemographic survey, Chronic Liver Disease Questionnaire (CLDQ), Carer Self-Assessment Questionnaire (CSAQ), and Care Competency Skill Questionnaire (CCSQ) inventories were used for data acquisition. Each scale had high reliability (Cronbach's alpha value ≥0.78).
Results: Caregivers were predominantly middle-aged females (75%), mostly spouses (66%), from urban nuclear families (60%), with 90% lacking formal caregiving training. Caregivers had average knowledge regarding general symptoms of CLD, specifically abdominal symptoms (mean score, 11.75) and fatigue symptoms (mean score, 20.57). Despite this, there was considerable variation in scores for overall symptoms and functioning (SD = 24.6), indicating considerable variation in knowledge and competence levels. There was a higher mean score on the distress scale for high-distress (21%) (M = 12.23, SD = 1.12) in comparison with that for low-distress (M = 3.56, SD = 2.04) caregivers. High distress was most common among caregivers of patients with alcohol-associated liver disease, the predominant aetiology (49.5%), while lower distress levels were observed in MASLD, viral hepatitis, genetic, and autoimmune liver diseases.
Conclusion: Informal carers of patients with CLD express considerable psychological distress and differ in their competency to offer care; most of these problems are associated with inadequate training in the past and a lack of experience providing care. These findings demonstrate the critical need for need-based carer education and psychological support programs to be included in routine CLD care to enhance patient outcomes by enhancing caregiving competence and reducing suffering.

THU-545-YI

Binge drinking as a key driver of steatotic liver disease: prevalence, predictors, and population impact in a large screening cohort

Ea Kyed[1,2], Stine Johansen[1,2], Helle Schnefeld[1,2], Johanne Kragh Hansen[1,2], Katrine Tholstrup Bech[1,2], Kathrine Sejer Sørensen[1], Anine Andersen[1,2], Katrine Thorhauge[1,2], Camilla Dalby Hansen[1,2], Mads Israelsen[1,2], Peter Andersen[1], Sönke Detlefsen[2,3], Maja Thiele[1,2], Aleksander Krag[1,2]. *[1]FLASH - Centre for Liver Research, Odense, Denmark; [2]SDU - University of Southern Denmark, Odense, Denmark; [3]Department of Pathology, Odense, Denmark*
Email: ea.ditte.stage.kyed@rsyd.dk

Background and aims: Alcohol is a major driver of liver-related morbidity, yet the impact of alcohol consumption patterns, particularly binge drinking, to liver disease severity is insufficiently described. Phosphatidylethanol (PEth) is an objective biomarker of recent alcohol intake and complements self-reported data. We aimed to examine the association between self-reported binge drinking behaviour and increased liver stiffness and correlations with sociodemographic and cardiometabolic factors.
Method: We screened participants from the general population and individuals at risk of steatotic liver disease in a large prospective cohort using vibration-controlled transient elastrography (VCTE). We defined possible significant liver fibrosis as VCTE ≥8 kPa. Participants reported alcohol consumption patterns using AUDIT-C. We defined frequent binge drinking as intake of ≥5 units per drinking episode at least once weekly and alcohol overuse ≥14/21 units per week for women/men for at ≥5 years. We used PEth ≥200 ng/mL as an indicator of high alcohol intake. Participants reported sociodemographics via questionnaires, and clinical assessment captured cardiometabolic risk factors. We applied multivariable logistic regression adjusting for sociodemographic and cardiometabolic factors, alcohol overuse, and PEth ≥200 ng/mL.
Results: We included 6,400 participants (mean age 57 years; 52% female; 37% obesity; 9% type 2 diabetes). Overall, 5.9% had VCTE

≥8 kPa, and 17% had PEth ≥200 ng/mL. Frequent binge drinking occurred in 1,092 participants; 71% were male and 81% reported alcohol overuse. Elevated liver stiffness occurred more frequently with binge drinking than without (10.3% vs. 4.7%, p < 0.001). PEth ≥200 ng/mL occurred in 60% with binge drinking compared with 8% without. Median PEth reached 253 ng/mL (IQR 118–494) versus 21 ng/mL (IQR 6–65), indicating concordance between binge drinking and high recent alcohol intake. In adjusted analyses, binge drinking associated independently with VCTE ≥8 kPa (OR 1.41, 95% CI 1.03–1.93, p = 0.031), independent of both self-reported alcohol overuse and PEth ≥200 mg/mL. Male sex strongly associated with binge drinking, whereas partnership and parenthood associated with lower odds. Hypertension remained independently associated with binge (OR 1.70, 95% CI 1.40–2.06).
Conclusion: Frequent binge drinking behaviour independently associates with increased liver stiffness. Beyond cumulative alcohol intake, binge drinking represents a clinically relevant determinant of liver disease risk.

THU-546-YI
LivR Well 2.0 - Nourishing a hungry liver: interim results
Sophie Page[1,2], Erin Russell[1], Anita Figredo[2], June Song[2], Patricia Anderson[3], Phillip George[2,4], Suong Le[3], Thomas Worland[3], Sally Bell[3,4], Natalie Ngu[3,4]. *[1]Nutrition and Dietetics, Monash Health, Melbourne, Australia; [2]Hospital in the Home, Monash Health, Melbourne, Australia; [3]Department of Gastroenterology and Hepatology, Monash Health, Melbourne, Australia; [4]Faculty of Medicine Nursing & Health Sciences, Monash University, Melbourne, Australia*
Email: sophie.page@monashhealth.org

Background and aims: Frailty and malnutrition are highly prevalent among individuals with decompensated chronic liver disease (CLD), contributing to adverse clinical outcomes and healthcare burden. Whilst nutritional optimisation has been shown to improve outcomes such as mortality and frailty, there is limited evidence to support home-based interventions. We evaluated the impact of LivR Well 2.0, a home-based, multidisciplinary program on frailty and nutritional status in patients with CLD.
Method: Adults presenting with an episode of decompensated CLD to a tertiary hospital network in Melbourne, Australia were enrolled from July 2025. The intensive nutritional program includes a 28-day admission to Hospital in the Home; with hepatology review, dietetics, pharmacy, addiction counselling, home nursing, and physiotherapy. Dietetic management includes education, home-delivered meals, oral nutrition supplements, and nasogastric tube (NGT) feeding if clinically indicated. Participants are followed for up to 24-weeks. The primary outcome of frailty was change in Liver Frailty Index (LFI). Secondary outcomes included nutritional status measured by Subjective Global Assessment (SGA) and percentage of Estimated Energy Requirements (EER) and Estimated Protein Requirements (EPR) met in accordance with European Association for the Study of the Liver guidelines.
Results: Twenty one participants were included in this interim analysis (61.9% alcohol-related CLD), median age 62.4 years [Interquartile Range (IQR): 56.9–69.8], 58% male, baseline body mass index 26.4 kg/m^2 [IQR: 24.1–30.3], and Model for End-stage Liver Disease score 15.5 [IQR: 10.7–19.6]. To date, seven participants have completed week 12; one required NGT. Median LFI improved from 4.6 [IQR: 4.0–5.3, Frail] to 3.99 [IQR: 3.4–4.4, Pre-Frail] (p = 0.08). % EER increased significantly from 65.2% [IQR: 49.1–78.9] to 92.8% [IQR: 78.9–95.6] (p = 0.02); and EPR improved from 70.4% [IQR: 54.5–101.1] to 88.4% [IQR: 85.9–111.6] (p = 0.26). At week 2, SGA classified 21.4% as A (well-nourished), 57.1% B (moderate malnutrition), 21.4% C (severe malnutrition); by week 12, 50% were A, 33.3% B, 16.7% C (p = 0.44).
Conclusion: Interim results from the LivR Well 2.0 program demonstrate promising improvements in nutritional adequacy and trends toward reduced frailty in patients with decompensated CLD. These findings support the feasibility and potential clinical benefit of integrated home-based care models in this population. Complete analysis will clarify long-term outcomes.

THU-547
Widespread misconceptions about analgesic safety drive undertreatment of pain in hepatocellular carcinoma
Jina Park[1], Jonggi Choi[1], Chaeyeon Lim[1], Sung Won Chung[1], Ji won Yang[1], Won-Mook Choi[1], Danbi Lee[1], Ju Hyun Shim[1], Kang Mo Kim[1], Young-Suk Lim[1], Han Chu Lee[1]. *[1]Asan Medical Center, Seoul, Korea, Rep. of South*
Email: jkchoi0803@gmail.com

Background and aims: Pain profoundly impacts quality of life in cancer patients yet remains inadequately managed. Hepatocellular carcinoma (HCC) presents unique challenges due to underlying liver disease, raising concerns about analgesic safety. This study comprehensively assessed pain prevalence, management practices, and patient perceptions in HCC, examining associations with clinical characteristics.
Method: We surveyed 200 HCC patients at a tertiary center using a comprehensive 30-item questionnaire assessing pain prevalence/intensity, management strategies, perceptions about analgesics and liver function, opioid attitudes, and educational needs. Clinical data included demographics, tumor characteristics, and liver function. Statistical analyses examined associations between patient characteristics and pain outcomes.
Results: Pain prevalence was 27.5% with moderate intensity (mean 3.6/10). Critically, 43.6% of pain patients were not using analgesics, with 30% simply waiting. Extrahepatic metastasis strongly predicted pain (33.6% vs 20.4%, p = 0.040; OR = 2.0), while liver function showed no association (p = 0.560). Paradoxically, hepatotoxicity concerns were universal and identical regardless of remnant liver function (all p > 0.6): 70% believed analgesics harm the liver, 50% hesitated due to liver concerns. Among analgesic users, 68% reported adequate control. Educational needs were high: 80% desired specialized counseling, 73% wanted side effect information. Patient characteristics showed minimal influence on perceptions, indicating universal educational gaps rather than disease-driven concerns.
Conclusion: Nearly half of HCC pain patients remain untreated due to widespread liver-related misconceptions paradoxically affecting patients with preserved liver function equally. Pain is driven by tumor metastasis, not liver dysfunction. Standardized education emphasizing analgesic safety in good liver function, combined with nurse-led programs, could substantially reduce unnecessary suffering in this population.

THU-548
Prevalence and risk factors of liver steatosis, fibrosis, and at-risk mash in mexican patients with recently diagnosed type 2 diabetes mellitus
Astrid Ruiz Margáin[1], Oscar M. Fierro-Angulo[1], Jose Gonzalez Regueiro[1], Ariana Pereira Garcia[1], Cristina Garcia Ulloa[1], Sergio Hernandez Jimenez[1,2], Naga Chalasani[3], Ricardo Macias-Rodriguez[1]. *[1]Instituto Nacional de Ciencias Médicas y Nutrición Salvador Zubirán, Ciudad de México, Mexico; [2]Instituto Nacional de Ciencias Médicas y Nutrición Salvador Zubirán, CAIPaDi, Ciudad de México; [3]Indiana University School of Medicine, Indianapolis, United States*
Email: ricardomacro@yahoo.com.mx

Background and aims: Metabolic associated steatotic liver disease (MASLD) is the most common cause of chronic liver disease and the leading cause of liver-related mortality. Long-standing type 2 diabetes mellitus (T2DM) is a significant risk factor for both liver steatosis and liver fibrosis. However, whether newly diagnosed T2DM also carries the same risk remains unclear. Moreover, only few studies have focused on Hispanic patients, who are known to have a faster

progression of liver disease compared to non-Hispanic races, but only few studies have focused in this specific population.
We aimed to assess the prevalence of MASLD and liver fibrosis in Mexican patients with a recent diagnosis of T2DM and identify the risk factors associated with worse liver disease.
Method: This cross-sectional study was conducted in Mexico City and it included individuals with T2DM less than 5 years since diagnosis and without any micro- or macrovascular complications. Clinical, biochemical, liver stiffness measurement (LSM), controlled attenuation parameter (CAP), and FAST score were evaluated.
Results: A total of 1,337 patients were included in the study. The majority of the patients were women (60.9%), median age was 55 (IQR: 49–63) years, and 78.2% were overweight or obese. Overall prevalence of MASLD (using the ³ 288 dB/m cutoff) was 41.4%, and 10.05% had clinically significant liver fibrosis (LSM. Moreover, 3% of the population had cirrhosis. In the multivariate analysis, higher BMI, HbA1C, triglycerides and ALT were independently associated with the presence of steatosis. Higher BMI, CAP, GGT, ALT and AST, were associated with fibrosis. According to the FAST score, 4.8% of the patients had at-risk MASH.
Conclusion: There is high burden of MASLD and clinically significant fibrosis in Mexican adults who are recently diagnosed with type2 diabetes. These data strongly indicate that Mexican adults with type2 diabetes should be systematically evaluated for the presence of MASLD and fibrosis.

THU-549-YI
Patient characteristics and treatment outcomes associated with the retreatment of Hepatitis C in patients previously treated with direct-acting antivirals
Shannyn Sheehan[1,2], Colm Bergin[1], Susan McKiernan[1], Suzanne Norris[1], Gail Melanophy[1], Michelle Lynch[1], Paul Gilvarry[1], Carlos Medina[2], Miriam Coghlan[1,2]. *[1]St. James's Hospital, Dublin, Ireland; [2]Trinity College Dublin, Dublin, Ireland*
Email: ssheehan@stjames.ie

Background and aims: Direct-acting antivirals (DAA) are the mainstay of Hepatitis C (HCV) treatment with sustained virological response 12 weeks after treatment (SVR12) achieved in over 95% of cases. However, retreatment is required if patients present with detectable HCV ribonucleic acid (RNA) following initial treatment. This study aims to evaluate the characteristics and treatment outcomes of patients retreated with DAAs due to reinfection, treatment failure or indeterminate outcomes.
Method: A retrospective cohort study was conducted including patients who received two or more DAA treatment courses. Clinical characteristics and HCV treatment outcomes of patients were collected.
Results: A total of 101 patients were included. Within the reinfection cohort, 60% reported active intravenous drug use (IVDU), 82% were prescribed opioid substitution therapy (OST) and 49% received retreatment in prison. Treatment failure appeared more associated with biological factors such as resistance-associated substitutions (RAS) and cirrhosis than social determinants such as adherence and accommodation. First line retreatment regimens were highly effective in both the reinfection and indeterminate treatment outcome cohorts. Retreatment counts within this cohort demonstrated a yearly increase, with those due to reinfection estimated to increase by 33% annually.
Conclusion: Elimination relies on effective DAA therapy and sustained efforts to prevent reinfection and treatment failure, including the need to strengthen harm reduction strategies. Reinfection reflects successful initial treatment, highlighting the strengths of current service delivery models. However, as retreatment due to reinfection is expected to increase, healthcare services should align resources with evolving epidemiology.

THU-553
Early health-related quality of life decline and hypoalbuminaemia predict outcomes in advanced hepatocellular carcinoma treated with atezolizumab–bevacizumab
Masako Shomura[1], Haruka Okabe[1], Maya Sakakibara[1], Emi Sato[2], Yusuke Mishima[2], Kota Tsuruya[2], Shunji Hirose[2], Yoshitaka Arase[2], Tatehiro Kagawa[2]. *[1]Faculty of Nursing, Tokai University School of Medicine, Japan, Division of Gastroenterology, Department of Internal Medicine, Tokai University School of Medicine, Japan, 143 Shimokasuya, Isehara-City, Kanagawa, Japan; [2]Division of Gastroenterology, Department of Internal Medicine, Tokai University School of Medicine, Japan, Isehara-City, Japan*
Email: s-masako@tokai.ac.jp

Background and aims: Patient-reported health-related quality of life (HRQoL) during atezolizumab–bevacizumab (Atezo+Bev) therapy for unresectable hepatocellular carcinoma (HCC), and its clinical utility in real-world practice, remain unclear. We characterised early HRQoL changes and evaluated if HRQoL and nutrition-related adverse events (AEs) predict response, treatment duration, and survival.
Method: Consecutive patients with advanced/unresectable HCC treated with Atezo+Bev at Tokai University Hospital (Nov 2020–Dec 2025; N = 110) were analysed. Response was assessed at weeks 6–9 by mRECIST, AEs by CTCAE v5.0, and monthly HRQoL by EORTC QLQ-C30 (0–100). Using a 3-month landmark for HRQoL/AEs, multivariable logistic regression (objective response; OS <1 year) and Cox regression (treatment duration; OS) were performed.
Results: Most patients were men (82%); 61% were aged >70 years; and 31% had HCV. Child–Pugh scores were 5/6/7/8 in 56/34/14/6 cases, respectively. Overall, 70% of patients had TNM stage IV; BCLC stage B1/B2/C, 14/57/39; 42% had AFP >100 ng/mL; and 46% had DCP >1000 ng/mL. Median treatment duration, progression-free survival, and OS were 7.3, 7.6, and 19 months; objective response and disease control rates were 26.2% and 79.6%, respectively. Common AEs included fatigue (84%), hypolabuminaemia (78%), and thrombocytopenia (57%); grade 3 fatigue occurred in 10 patients. HRQoL declined in the physical, role, cognitive, and global health domains; however, emotional and social functioning remained stable. Age ≥70 years and TNM IV predicted lower ORR. Grade ≥2 fatigue shortened treatment duration (HR: 1.80), whereas physical/general health ≥80 and grade ≥2 proteinuria prolonged it (HR: 0.46, 0.55, 0.30). OS was reduced with grade ≥2 hypolbuminaemia or DCP >1000 (HR: 3.20, 2.06) but longer with high physical/role functioning (HR: 0.48, 0.54). Tumour size ≥40 mm^2, DCP≥1000, and physical function <80 predicted OS <1 year (OR: 3.44, 2.70, 4.34). Serum albumin levels declined markedly during the first 4 months.
Conclusion: Early declines in physical/role functioning and hypoalbuminaemia can identify patients at risk for early discontinuation and poor survival during Atezo+Bev therapy. Routine HRQoL and nutritional monitoring, linked to timely multidisciplinary interventions (symptom control, rehabilitation, and dietetic support), may help address modifiable functional and nutritional deficits and improve treatment continuity and patient-centred outcomes.

THU-554-YI
Joint consultations during transition: perspectives of young adults with rare liver diseases
Janne Suykens[1,2], ERN Rare Liver Youth Panel[2], Kaat De Pourcq[3], Marcus Kenia[4], Kari Klein[2], Ansgar W. Lohse[2,4], Louisa Lund[2,4], Angel Westbrook[2], Karsten Vanden Wyngaert[1,2], Ruth de Bruyne[1,2]. *[1]Ghent University Hospital, Ghent, Belgium; [2]European Reference Network on Hepatological Diseases (ERN RARE-LIVER), Hamburg, Germany; [3]Ghent University, Ghent, Belgium; [4]University Medical Centre Hamburg-Eppendorf, Hamburg, Germany*
Email: janne.suykens@ugent.be

Background and aims: Transition from pediatric to adult care is a critical phase for adolescents and young adults with rare liver diseases. Joint consultations, where healthcare providers from both

services meet with the patient, are recommended to support continuity and patient-centered care. Yet the term is often invoked rather than clearly defined, and practices vary considerably, leading to differing expectations among participants. This study explores patient perspectives on joint consultations, based on a focus group held during the ERN Rare Liver Youth Panel workshop (Hamburg, July 2025), as part of a broader investigation that will also include parents and healthcare providers.

Method: A focus group session was conducted with thirteen members of the ERN Rare Liver Youth Panel during a two-day workshop. Nine participants attended on site and four joined online. Ages ranged from 20 to 28 years, and participants represented seven countries: Belgium, Germany, Portugal, France, the United Kingdom, Denmark, Cyprus, and Italy. Diagnoses included autoimmune hepatitis, biliary atresia, primary sclerosing cholangitis, and combinations of these conditions. Discussions were guided by a semi-structured interview guide addressing experiences, expectations, and perceived goals of joint consultations. Conversations were audio-recorded, transcribed verbatim, and analyzed using inductive thematic analysis with open coding to identify recurring themes.

Results: Most participants had never experienced a joint consultation but expressed strong interest in its potential benefits. Key themes included: 1) continuity and preparation, with clear transfer planning and gradual transition; 2) relationship-building, meeting the adult physician early to foster trust; 3) patient-centeredness, including private discussion without parents; 4) information exchange, ensuring pediatric and adult providers share medical history in the patient's presence; and 5) psychosocial support, emphasizing mental health and feelings of safety. Participants recommended multiple consultations, preferably in the adult clinic, with sufficient time for discussion, involvement of psychologists, and when appropriate, parents.

Conclusion: Young adults view joint consultations as essential for safe, structured transition. They advocate for flexible, patient-driven formats that prioritize preparation, continuity, and emotional well-being. These insights should inform guidelines for transition of healthcare in rare liver diseases.

THU-555-YI

Real-world nutritional management and outcomes in alcohol-associated hepatitis: a comparison of adherence to guidelines and short-term mortality between two centers

Erica Wajntraub Bakszt[1,2], Bonnie Bengtsson[1,2,3], Hannes Hagström[1,4], Catarina Lindqvist[1,5]. [1]*Gastroenterology and Nutrition Unit, Department of Medicine, Huddinge, Karolinska Institutet, Stockholm, Sweden;* [2]*Karolinska Institutet, Stockholm, Sweden;* [3]*Department of Clinical Science and Education, Södersjukhuset, Karolinska Institutet, Stockholm, Sweden;* [4]*Division of Hepatology, Department of Upper GI Diseases, Karolinska University Hospital, Stockholm, Sweden;* [5]*Section Clinical Nutrition, Karolinska University Hospital, Stockholm, Sweden*
Email: erica.wajntraub-bakszt@regionstockholm.se

Background and aims: Alcohol-associated hepatitis (AH) carries high mortality. Nutrition is a key component of therapy alongside corticosteroids and alcohol abstinence, yet real-world implementation remains unclear. We aimed to evaluate nutritional management, guideline adherence, and association between energy intake and outcomes in AH in two Swedish hospitals.

Method: Retrospective review of patients with AH admitted 2019–2023 to two liver centers in Stockholm, representing tertiary and secondary care. Data on nutritional care, morbidity and mortality were collected. Guideline adherence and inter-center differences were analyzed using χ^2 and Wilcoxon tests. Logistic regression examined associations between nutritional practices and 28-day mortality.

Results: Among 157 patients, 60 % had severe AH (MELD $\geq$ 20), and 69 % had underlying liver cirrhosis. Median age was 58 years, 36% were female, the median length of stay was 10 days. Malnutrition risk screening was performed in 85%, but no center used a liver-specific tool, and 39% were classified at risk for malnutrition. Dietitian involvement was higher at the tertiary center (83% vs. 42%, $p < 0.001$) and corresponded to more individualized nutrition care. Dietitians provided information more often than nurses or physicians (39% vs. 19% and 14%) and were primarily responsible for calculating energy goals (54% vs. 9% and 24%). Daily energy intake was documented for a median of 87% of hospital days at the tertiary center vs. 4% at the secondary ($p < 0.001$). Parenteral nutrition (PN) (28%) was more common than enteral nutrition (EN) (11%), with higher use of PN at the tertiary center (39% vs. 19%, $p < 0.01$). Higher energy intake (>21.4 kcal/kg/day) was associated with lower 28-day mortality in crude (OR = 5.66, 95%, CI = 1.3–38.9) and adjusted models (sex, age, MELD, cirrhosis, prednisolone) (OR = 6.81, 95% CI = 1.2–59.5).

Conclusion: Nutritional management varied between centers, with gaps in dietitian access and caloric monitoring. Higher energy intake showed an association with lower short-term mortality, though low precision; results are consistent with earlier studies. Investigations into barriers to guideline adherence and strategies to improve dietitian involvement are warranted. Nutrition remains a potentially modifiable determinant in AH. Further work is needed to understand factors contributing to higher energy intake, the effect of timely and adequate nutritional support on clinical outcomes, and whether EN should continue to be recommended as first-line treatment.

THU-556-YI

A review of terlipressin use in hepatorenal syndrome-acute kidney injury across 18 hospitals in the United Kingdom: Can we "CONFIRM" a change in practice?

(Leslie) Chun Man Wong[1], Olivia Baker[1,2], Alison Boyle[3], Alban Clareburt[3], Caitlin Brown[3], Sandeep Whitehead[4], Natasha Butt[5], Keswir Singh Cheema[5], Kate Greener[6], Sital Shah[6], Naz Kanani Alviri[7], Abraham Okoibhole[7], Aya Al-Hasani[8], Anastasia Lamprou[8], Sarah Hoban[8], Mohammad Wasim[8], Hannah Hesketh[9], Arjuna Singanayagam[9], Tamar Avades[10], Robert Elliot-Cooke[10], Juan Acevedo Haro[10], Eva Lau[11], Alice Bennett[11], Joanthan Creamer[12], Yun Jung Kim[12], Ziad Chilmeran[12], Amrita Gurung[13], Alastair O'Brien[7,14], Navjyot Hansi[1]. [1]*Cambridge Liver Unit, Cambridge University Hospitals NHS Foundation Trust, Cambridge, United Kingdom;* [2]*North West Anglia NHS Foundation Trust, Peterborough, United Kingdom;* [3]*NHS Greater Glasgow & Clyde, Glasgow, United Kingdom;* [4]*Leeds Teaching Hospitals NHS Trust, Leeds, United Kingdom;* [5]*Manchester University NHS Foundation Trust, Manchester, United Kingdom;* [6]*King's College Hospital NHS Foundation Trust, London, United Kingdom;* [7]*Royal Free London NHS Foundation Trust, London, United Kingdom;* [8]*London North West University Healthcare NHS Trust, London, United Kingdom;* [9]*St George's University Hospitals NHS Foundation Trust, London, United Kingdom;* [10]*University Hospitals Plymouth NHS Trust, Plymouth, United Kingdom;* [11]*Barts Health NHS Trust, London, United Kingdom;* [12]*University Hospital Southampton NHS Foundation Trust, Southampton, United Kingdom;* [13]*Causeway Hospital, Coleraine, Northern Ireland;* [14]*Comprehensive Clinical Trials Unit, University College London, London, United Kingdom*
Email: leslie.wong1@nhs.net

Background and aims: Terlipressin with albumin is the first-line intervention for hepatorenal syndrome-acute kidney injury (HRS-AKI) in the United Kingdom (UK). The CONFIRM trial reported increased respiratory events, sepsis and mortality in patients meeting high-risk criteria, prompting updated Medicines and Healthcare products Regulatory Agency guidance in 2023. We conducted a multicentre retrospective audit to evaluate UK practice following this change, with secondary aims assessing adverse events (AE).

Method: UK centres were invited via the British Association for the Study of the Liver and the British Hepatology Pharmacy Group. Each hospital reviewed electronic records for terlipressin prescriptions in adults with HRS-AKI from 1 Sept 2023 to 30 Sept 2024. Clinical and

biochemical parameters were analysed. Statistical analyses were performed; Mann-Whitney U and Chi-Square tests with $p < 0.05$ were considered statistically significant.
Results: 180 patients from 18 hospitals were included. Median age was 58 years (range 25–86); 61% male; alcohol aetiology 71%; median MELD score was 30 (range 12–44), and median serum creatinine on terlipressin initiation was 198 umol/L (range 75–845). Terlipressin was administered by bolus injection in 72% of patients. Concomitant albumin was administered in 166 patients (92%), 147 g +/– 168 (mean +/– SD; total per person) over a median of 6 days. Total of 11 patients (6.1%) proceeded to liver transplantation. Overall inpatient mortality was 55%. High-risk criteria were met in 28 (15.5%) patients, with no significant difference in inpatient mortality compared with those without high-risk criteria ($p = 0.931$). AE within 30 days of stopping terlipressin occurred in 92 patients (51.1%), most commonly respiratory failure ($n = 50$, 27.9%) and sepsis ($n = 68$, 37.8%). There was no significant difference in volume of albumin prescribed in those that did or did not have respiratory failure AE ($p = 0.117$). HRS-AKI complete and partial responses were achieved in 24% and 4%, respectively.
Conclusion: We report higher incidences of respiratory failure and sepsis than the CONFIRM trial. HRS-AKI remains a significant clinical challenge with limited therapeutic options and high mortality. It remains unclear whether terlipressin and albumin in advanced cirrhosis are indeed "friend or foe." The variation in practice across the UK highlights the importance of standardised care, ongoing education and greater awareness of the contraindications and monitoring requirements for terlipressin.

THU-557-YI
Hepatitis C in detainees entering Barcelona prisons: an opportunity to detect the infection in groups with limited access to the health system
Elena Yela[1], Neus Solé[2], Lidia Puig[1], Rafael Clua-García[3], Darío López-Gallegos[4], Daniel G. Abiétar[5], Montserrat Gàlvez[6], Queralt Guixé[7], Sabela Lens[8], Andrés Marco[2,9]. *[1]Sant Esteve Sesrovires Prison Primary Care Team (Brians 1 Prison Centre), Institut Català de la Salut, Sant Esteve Sesrovires, Spain; [2]Prison Health Program, Corporative Centre. Catalan Health Institute, Barcelona, Spain; [3]Facultat de Ciències de la Salut de Manresa-Uvic, Manresa, Spain; [4]Catalan Health Institute, Barcelona, Spain; [5]Corporate Centre, Catalan Health Institute, Barcelona, Spain; [6]Department of Health Sub-Directorate General for Addictions, HIV, Sexually Transmitted Infections and Viral Hepatitis, Health Department, Barcelona, Spain; [7]Dones Barcelona Prison Primary Care Team (Dones Prison Centre), Catalan Health Institute, Barcelona, Spain; [8]Liver Unit Hospital Clínic. IDIBAPS, Barcelona, Spain; [9]Centro de Investigación Biomédica en Red de Epidemiología y Salud Pública (CIBERESP), Barcelona, Spain*
Email: eyela@gencat.cat

Background and aims: Incarceration can facilitate the detection of hepatitis C virus (HCV) infection in groups often isolated from the community healthcare system. The aim is to analyse HCV infection (HCV RNA+) in newly incarcerated individuals in Barcelona prisons, and to examine the social determinants associated with a lack of awareness of the infection.
Method: HCV infection was studied in inmates recently admitted to two prisons in Barcelona during the period 2021–2024. The presence of infection or reinfection after sustained virological response (SVR) was assessed, as well as whether the infection status was known before incarceration. Potential associated socioeconomic and clinical variables were studied using binomial regression for knowledge/lack of knowledge of the infection.
Results: Among the 13136 patients studied there were 281 (2.1%) cases of infection (32.4% reinfections), with no significant differences between prisons or study years. 90.7% were male, and the mean age was 41.1 years. 59.1% were immigrants, 71.5% were homeless, 85.8% were or had been injection drug users, and 30.6% were HIV-positive. 68.3% were aware of their infection status but had not received treatment. In the bivariate analysis, the variables associated with not knowing HCV serological status (31,7%) were: a)being an immigrant, especially with less than one year of residence in Spain b) first incarceration c) absence of contact with drug resources d) not having a health card. The multivariate analysis confirmed that the variables associated with knowing one's HCV serological status were: a) previous incarceration (OR 3.30; 95% CI: 1.78–6.16; $p < 0.001$) b) contact with the healthcare system (OR 2.16; 95% CI: 1.08–4.33; $p = 0.029$).
Conclusion: 2.1% of new inmates in Barcelona prisons are HCV-RNA+, and almost a third of those infected are unaware of their serological status. The rest are reinfections or infected individuals who know their status but have not received treatment. Lack of contact with healthcare, community, or prison systems, especially among migrant population or drug users without access to support services, is the reason why the infection often goes undetected or untreated. If these diagnostic and therapeutic gaps are not addressed through strategies tailored to subpopulations that reduce structural barriers and improve links with the health system and the drug addiction care network, elimination does not seem possible.

Nurses and Allied Health Professionals – Clinical – service development or improvement project

TOP-536-YI
Conceptual development of an advanced practice nurse role for patients living with liver cirrhosis in a Swiss health care system
Jasmin Herzog[1,2], Lynn Leppla[2,3], Janette Ribaut[2], Robert Brenig[1,4], Kelly Da Silva[1], Patrizia Künzler-Heule[2,5], Sonja Beckmann[6], Christine Bernsmeier[1,4]. *[1]University Centre for Gastrointestinal and Liver Disease, University Hospital Basel, Basel, Switzerland; [2]Institut of Nursing Science, Department Public Health, University of Basel, Basel, Switzerland; [3]Department of Nursing, Division of Clinical Nursing Research and Practice Development, Medical Center – University of Freiburg, Faculty of Medicine, Freiburg, Germany; [4]Departements of Biomedicine and of Clinical Research, University of Basel, Basel, Switzerland; [5]Division of Gastroenterology and Hepatology and Department of Nursing & Therapeutic Services, Hoch Cantonal Hospital St. Gallen, St. Gallen, Switzerland; [6]Center for Clinical Nursing Science and Department of Gastroenterology and Hepatology, University Hospital Zurich, Zürich, Switzerland*
Email: jasminmargrit.herzog@usb.ch

Background and aims: The development and implementation of Advanced Practice Nurse (APN) roles are often challenged by political and financial barriers, as well as limited organizational structures, resulting in insufficient role clarity, limited stakeholder acceptance, and a lack of shared understanding of the APNs scope of practice. Therefore, the aim of this project was to conceptually develop a new APN role for patients living with liver cirrhosis in a Swiss hospital using a structured, theory-guided approach to address these barriers.
Method: Steps 1 to 5 of the Participatory, Evidence-based, Patient-focused Process for the Development, Implementation, and Evaluation of Advanced Practice Nursing (PEPPA) framework were used. The results of the interviews with 2 patients, 5 healthcare professionals (HCP), and the scarce 2 APNs Hepatology from other Swiss hospitals were synthesized including current literature according to the Chronic Care Model. APN activities were illustrated using the Hamric model and displayed related to outputs and outcomes in a logic model.
Results: PEPPA steps 1–4: Seven interviews were conducted. Care for patients with liver cirrhosis is partitioned and characterized by

limited time and resources. Patients interact with multiple HCP, hampering continuity and coordination of care. Self-management support regarding lifestyle changes, symptom management and medication adherence are often lacking, as well as specific symptom assessments. PEPPA step 5: Implementing an APN could address the identified gaps by applying Hamric's competencies. Through direct clinical practice, the APN is a consistent contact point, ensures care continuity, and conducts comprehensive assessments. Guidance and coaching enable provision of self-management support, including symptom management, lifestyle counselling, and medication adherence, while collaboration and leadership enhance coordination of person-centered care and support for other healthcare professionals in complex situations. Short- and long-term outcomes such as early detection of complications, improved medication adherence and reduced mortality were further defined in the logic model.
Conclusion: The conceptual APN role shows great potential to fill in the gaps of care and improve management of patients with liver cirrhosis. The logic model provides a structured basis to guide the development, implementation and evaluation of the APN roles in hepatology care.

WED-547
FibroScan® insights: lifestyle change and liver health in primary biliary cholangitis
Rebecca West[1], Robert Mitchell-Thain[1], Louise Campbell[2], Claire Hardie[3]. [1]*PBC Foundation Edinburgh UK, Dunfermline Fife, United Kingdom;* [2]*Tawazun Health, London, United Kingdom;* [3]*LiverScan, Edinburgh, United Kingdom*
Email: rebecca@pbcfoundation.org.uk

Background and aims: Primary Biliary Cholangitis (PBC) is a chronic autoimmune cholestatic liver disease. Alongside pharmacological intervention, lifestyle management is recognised as an important aspect of liver health. Metabolic Dysfunction Associated Steatotic Liver Disease (MASLD) care has demonstrated that targeted lifestyle changes can reduce hepatic steatosis and stiffness, but its impact in PBC—particularly where steatosis co-exists—remains unclear. Historical research shows conflicting evidence: steatosis has been reported as common and associated with higher liver stiffness in PBC, while other studies show lower burdens than in MASLD. Overlap with metabolic dysfunction is consistently linked with poorer outcomes. These uncertainties highlight the need for real-world evaluation of modifiable factors.
The aim is to assess whether lifestyle-focused behavioural discussions, combined with lifestyle changes and repeat FibroScan® assessments one year apart, were associated with changes in liver steatosis and stiffness in individuals with PBC.
Method: Sixteen adults all of whom were female with established PBC underwent baseline (2024) and repeat (2025) FibroScan® assessments at a national PBC event. At baseline, participants received personalised feedback and an individualised discussion exploring practical lifestyle modifications. Controlled Attenuation Parameter (CAP) and liver stiffness (kPa) were recorded at both appointments, and changes were compared descriptively.
Results:
Steatosis
- Baseline: 37% (6/16) elevated
- Follow-up: 19% (3/16) elevated
- Of those elevated, 83% improved

Stiffness
- Among those with improved steatosis: 60% improved stiffness, 40% remained stable
- 50% achieved >35% stiffness reduction, exceeding the 30% threshold recognised in MASLD studies (not yet validated in PBC)
- One participant showed reduced stiffness but increased steatosis during active weight loss

Conclusion: These preliminary real-world findings from repeat fibroscans suggest that lifestyle-focused behavioural support and lifestyle management changes, may help stabilise or improve steatosis and stiffness in individuals with PBC. Participants reported feeling motivated and empowered, indicating that FibroScan®-guided counselling may enhance engagement with long-term metabolic optimisation. Further research is required to determine the scale of benefit and inform management of PBC patients with metabolic dysfunction.

WED-548-YI
Combined hepatic arterial infusion chemotherapy, lenvatinib, and anti-PD-1/PD-L1 antibodies as conversion therapy for unresectable hepatocellular carcinoma: a 5-year prospective real-world study
Zeyang Ding[1], Ruizhi Chang[1]. [1]*Hepatic Surgery Center, Tongji Hospital, Tongji Medical College, Huazhong University of Science andTechnology, Wuhan, China*
Email: zeyangding@hust.edu.cn

Background and aims: Conversion therapy is valuable for unresectable HCC, and HAIC + lenvatinib + ICI has an ORR >60% but lacks long-term follow-up data in existing studies. We conducted a study with long-term follow-up to assess this regimen's efficacy, safety, and surgical conversion rate for unresectable HCC.
Method: This study was a post-hoc analysis of the HAIC-lenvatinib-ICI cohort from CCGLC-001, including unresectable HCC patients who received HAIC-FOLFOX + lenvatinib + anti-PD-1/PD-L1 antibody at 4 centers (3 Tongji Hospital branches, Wuhan; Second Hospital of Fujian Medical University, Quanzhou) since May 2020, and evaluated the treatment's efficacy, safety, and surgical conversion rate.
Results: In a multicenter study of 226 unresectable HCC patients treated with HAIC-lenvatinib-ICI, the mRECIST ORR reached 68.1% (12.4% CR, 55.7% PR) with 62.4% achieving CRT (met the criteria of radical treatment eligibility) and 46.8% undergoing radical treatment (72.7% resection, 9.1% transplantation, 18.2% ablation). Notably, 2 of 9 patients with extrahepatic metastases underwent conversion resection.
Long-term outcomes included a median PFS of 18.5 months and 5-year OS rate of 53.6%. Patients achieving CRT had significantly longer PFS (28.1 vs. 8.2 months, $p < 0.001$) and 24-month OS (81.5% vs. 42.8%, $p < 0.001$). Radical treatment conferred sustained survival benefits even after adjusting for baseline differences. Safety was manageable, with 97.8% experiencing TRAEs (85.4% grade 1–2, 12.4% grade 3–4) and no treatment-related deaths. CRT responders had fewer severe toxicities (7.1% vs. 21.3%, $p < 0.001$). Perioperative outcomes showed laparoscopic resection in 68.8%, low 30-day mortality, and pathological responses in 27.1% (pCR) and 42.4% (mCR) of resected cases. These findings validate HAIC-lenvatinib-ICI as a promising strategy for achieving durable tumor control and surgical conversion in advanced HCC.
Conclusion: Combined HAIC, lenvatinib, and anti-PD-1/PD-L1 antibody yields a high surgical conversion rate in unresectable HCC (62.4% CRT eligibility, 46.8% radical treatment), with a median PFS of 18.5 months and favorable long-term survival. Radical treatment significantly improves PFS even after adjusting for baseline differences, and safety is manageable (mostly grade 1–2 toxicities, no treatment-related deaths). These findings validate this regimen as a promising approach for unresectable HCC.

WED-549-YI
Feedback meetings as a method to involve patients with alcohol-related liver cirrhosis and their relatives
Marie Christiansen[1], Rikke Werge[1], Ann Sophie Nielsen[1], Malene Barfod O'Connell[1]. [1]*Copenhagen University Hospital, Amager Hvidovre, Hvidovre, Denmark*
Email: frkclose@hotmail.com

Background and aims: Patients with alcohol-related liver cirrhosis often face both organizational and relational barriers in healthcare. At the Gastro Unit, Amager-Hvidovre Hospital, a feedback meeting was

used as a participatory method to explore patients and relatives' experiences to inform more person- and family centered discharge and follow-up practices.
The aim of this project was to explore how patients with alcohol-related liver cirrhosis and their relatives experience the discharge process, and to evaluate whether a feedback meeting can serve as a suitable method for involving this patient group in quality improvement.
Method: In February 2025, a two-hour feedback meeting was conducted with four outpatients recently diagnosed with alcohol-related liver cirrhosis (Child-Pugh A5–B8; two men and two women, aged 62–71), three relatives (a sister, a husband, and a wife), two physicians, and four liver nurses. The meeting was facilitated using a semi-structured interview guide. Afterwards, all participants shared a traditional Danish lunch, followed by an approximately 45-minute reflection session for the healthcare professionals. Within one week, patients and relatives participated in follow-up telephone interviews. All data were audio-recorded, transcribed, and analyzed according to Braun and Clarke (2006).
Results:
Five main themes were constructed;
1. *Discharge from the hospital - A goodbye with loose ends*
2. *The Liver Clinic - A lifeline after discharge*
3. *Relatives as key support*
4. *Combining clinical information with lived experience*
5. *"We are normal people" – Experiences of stigma*

At the follow-up telephone interviews, the patients described the meeting as safe, inclusive, and meaningful. Sharing experiences fostered reflection, recognition and a sense of community. All patients would recommend similar meetings. The health professionals emphasized that the method provided new insights into both the discharge process and the patients and relatives lives beyond the hospital.
Conclusion: Feedback meetings proved to be a feasible and engaging approach for involving patients with alcohol-related liver cirrhosis and their relatives. The approach generated valuable insights into discharge communication, stigma, and collaboration, demonstrating that meaningful patient and relative participation can inform clinical practice and service development. Future initiatives will aim to include more socially vulnerable patients and explore alternative involvement formats.

WED-553-YI
Setting the standard – development of quality standards for liver nurses

Michelle Clayton[1]. [1]*British Liver Nurses' Association, N/A, United Kingdom*
Email: michelle.clayton1@nhs.net

Background and aims: Variations in care delivery has been identified as a reason for poorer outcomes for people with liver disease[1,2]. The British Liver Nurses' Association (BLNA) is collaborating with the British Society of Gastroenterology (BSG) to create a novel set of quality standards for liver nurses that will define the gold standard for care of people with liver disease, assuring quality and reducing variation.
Method: A group of expert liver nurses from the United Kingdom are writing the standards following consultation. Six "health status pillars" have been identified which include for example early identification and prevention, complications of decompensated liver disease, and transplant assessment. Each standard and its component parts follow the same format to ensure consistency and ease of use. Best practice describes the required elements of each of the standards; the rationale offers knowledge to support understanding of the care element; and evidence in the form of national/international guidelines and seminal publications ensures assurance and contemporary practice. Robust review of the quality standards to ensure rigour will be undertaken via a separate group of expert nurses to appraise and sense check the standards.
Results: Two quality standards, the complications of decompensated liver disease and transplant assessment will be launched in summer 2026, with the other four standards being released at intervals over the following six to twelve months. The standards will be created for both online access and for an app to allow increased accessibility.
Conclusion: Being able to articulate the gold standard for care of people with liver disease is essential to ensure quality, reduce variation in care delivery and offer robust assurance that practice reflects the evidence base. Due to the format of these quality standards, liver nurses will be able to tailor and personalise their professional practise to ensure understanding of what gold standard care should look like and creating a positive impact for both liver nurses and people with liver disease.

Wilson disease patient support programme in Ireland - the impact one year on

Anna Gorham[1], Sonya Grandison[2], Elaine Kamara[3], Amy Power[2], Emer Fitzpatrick[2]. [1]*TCP Healthcare, Dublin, Ireland;* [2]*Childrens Health Ireland, Crumlin, Dublin 12, Ireland;* [3]*Orphalan UK Ltd, London, United Kingdom*
Email: anna.gorham@tcp.ie

Background and aims: Wilson disease (WD) is a rare condition requiring lifelong treatment, with poor adherence increasing risks of illness, death, and liver transplantation. Irish patients experience challenges due to distance from hospitals and lack of dedicated care. This report evaluates the effect of a WD-specific patient support program (PSP) in Ireland on both patients and healthcare professionals.
Method: In October 2024, Orphalan partnered with TCP Homecare in Ireland and appointed a dedicated WD nurse for the PSP. The nurse, trained in WD, visits hospitals nationwide to engage hepatology and neurology professionals and provides support to patients through home visits, sample collection, medication management discussions, and appointment reminders. She gathers patient and caregiver feedback. Healthcare professionals using the service have provided feedback on the impact this initiative has had on their trust.
Results: To date, 20 patients have joined the programme. One case study showed that a patient who previously missed hospital appointments was able to complete two 24-hour UCE samples in the past year and feels more empowered to manage his care after receiving support at home. Patients report that home monitoring has improved their wellbeing by reducing stress and allowing them to avoid time off work or school, while nurse conversations help them realise they are not alone with their condition.
Healthcare professionals note several benefits since launching the WD PSP: test results are now reliably available for clinic visits, reducing staff time spent chasing data and allowing more focus on direct care. Missed appointments and unnecessary phlebotomy visits have decreased, leading to better patient monitoring, disease management, and reduced strain on hospital resources.
Conclusion: The Wilson Disease Patient Support Programme (WD PSP) in Ireland has improved Wilson disease management by focusing on patient-centred care. A dedicated PSP nurse enables home-based monitoring and ensures test results are ready before clinic visits, making care more efficient. The PSP reduces the patients feeling of isolation and provides the opportunity to improve the patients' journey. Overall, the programme effectively supports both patients and healthcare professionals.

WED-555

Liver cancer screening in patients with cirrhosis and the role of allied health professionals: real-world experience of a community-based liver center

Anna Marie Hefner[1], Lita Petcharaporn[1], Ahmed Atalla[1], Usman Gul[1], Ayisha Aziz[1], Fatma Barakat[2], Eric Storey[1], Maryam Yasso[1], Renee Pozza[1], Deanna Oliver[1], Tarek Hassanein[1]. *[1]Southern California Liver Centers, Coronado, United States; [2]SCTI Research Foundation, Coronado, United States*
Email: ahefner@livercenters.com

Background and aims: Cirrhosis poses a signifiacant public health burden. With the projected increase in prevalence, concerns for the development of liver cancer becomes significant. Liver cancer is associated with numerous complications, hospitalizations as well as higher mortality rates and economic burden. Despite advancements in therapies for liver cancer, early detection remains critical for improved disease-free survival and patient (pt) outcomes. The role of Allied Health Professionals (AHP) is vital to be able to accomodate this need. The aim is to report on the outcomes of liver cancer screening by AHPs in pts with cirrhosis in a non-academic, community-based single liver center.
Method: This is a retrospective analysis of 1526 pts with cirrhosis seen between January 2023 and May 2025 in a single community-based liver center. Pts were managed according to standardized protocols tailored to each pt's needs including screening for liver cancer at least every 6 months using alternating imaging modalities (ultrasound, CT scan, MRI). Management plan was set in consultation with the Hepatologists while visits and follow-up was done primarily by AHPs including Nurse Practitioners and Physician Assistants.
Results: 51.3% males. Mean age was 63.2 ± 11.8 years. 53.2% Hispanics and 87.4% White. Primary causes of liver disease: history of HCV, Alcohol-related liver disease, MASLD/MASH. Follow-up: Median follow-up duration was 3.8 years with an average of 5 visits/pt/year. Liver cancer screening was done primarily by Ultrasound (54.8%) due to factors such as health insurance and pt preferance. 20% of pts had screening by CT-scan and 19.6% by MRI. Outcomes: 89.4% of pts complied with doing liver cancer screening every 6-months. Of which 6.7% developed a liver lesion. 90.2% were single lesions less than 1 cm classified as Hepatocellular Carcinoma.
Conclusion: Real-world experience of a non-academic, community-based single liver center confirmed that Allied Health Professionals are integral members of a liver pt's care team. AHPs play a vital role in enabling increased frequency and monitoring of pts with cirrhosis leading to decreased decompensation episodes and significant compliance with liver cancer screening. Screening for liver cancer at least twice a year using alternating imaging modalities resulted in early detection of liver cancer. Having a dedicated program led by AHPs to manage pts with cirrhosis improves complications-free survival and better outcomes of liver cancer management.

WED-556-YI

Biochemical response to Elafibranor in primary biliary cholangitis (PBC): impact of prior second-line therapy exposure

Rachael Kamiri-Ngugi[1], Marinos Pericleous[1], Kuldeep Cheent[2], Gayatri Chakrabarty[3], Iona Coltart[2], Valerie Duckhouse[2], Michelle Gallagher[1], Liliana Goncalves[2], Alfredo Lim[2], Sanju Mathew[1], Osob Mohamed[4], Prayman Sattianayagam[3], Karen Street[3], Christopher Wong[2], Aftab Ala[1]. *[1]Royal Surrey Nhs Foundation Trust, Guildford, United Kingdom; [2]Frimley Park Hospital, Camberley, United Kingdom; [3]East Surrey Hospital, Redhill, United Kingdom; [4]Saint Peter's Hospital, Chertsey, United Kingdom*
Email: r.kamiri-ngugi@nhs.net

Background and aims: Elafibranor is a dual Peroxisome Proliferator-Activated Receptor (PPAR) alpha/delta agonist licensed for Primary Biliary Cholangitis (PBC). It inhibits bile acid synthesis, enhancing detoxification, and exerting anti-inflammatory effects. Real-world data on biochemical outcomes in patients switching from other second-line therapies to elafibranor remain limited. Our aim was to compare the 28-day biochemical response in PBC patients switched to ursodeoxycholic acid and elafibranor from prior second-line therapies (bezafibrate or obeticholic acid), versus those treatment-naïve to second-line agents.
Method: We retrospectively analysed records from our regional PBC Operational Delivery Network of 26 patients switched to elafibranor-based therapy. Patients were categorised by prior regimen: ursodeoxycholic acid+bezafibrate, ursodeoxycholic acid+obeticholic acid, ursodeoxycholic acid+bezafibrate+obeticholic acid (triple therapy), ursodeoxycholic acid monotherapy (second-line naïve). All patients had inadequate biochemical response to ursodeoxycholic acid per POISE criteria and received MDT approval for elafibranor. Alkaline phosphatase (ALP) was recorded at baseline and ~28 days post-switch to ursodeoxycholic acid-elafibranor.
Results: Ursodeoxycholic acid and elafibranor (n = 16) demonstrated greatest efficacy, with mean ALP reduction of 108.9 U/L from baseline and 93.8% response rate, with no patients experiencing biochemical worsening. Patients switched from bezafibrate to elafibranor (n = 3) showed promising results with a mean reduction of 98.0 U/L, albeit with greater variability (66.7% response rate). Switching from obeticholic acid to elafibranor (n = 6) resulted in moderate efficacy, with a mean ALP reduction of 48.3 U/L and 83.3% response rate. Overall, 84.6% of patients (22/26) demonstrated biochemical improvement, with a pooled mean ALP reduction of 88.4 U/L.
Conclusion: Ursodeoxycholic acid plus elafibranor combination therapy represents the most effective and consistent treatment option, showing highest mean ALP reduction and response rate without paradoxical worsening. Switching from bezafibrate to elafibranor may benefit selected patients with relatively higher baseline ALP, but requires careful monitoring. Transitions from obeticholic acid warrants caution given paradoxical responses in some patients. These findings support elafibranor-based combination therapy as an effective strategy, with treatment selection tailored to individual patient characteristics and prior regimens.

WED-557

Physical activity for the management of paediatric metabolic dysfunction-associated steatotic liver disease: an international multidisciplinary consensus

Shelley Keating[1], Jonathan Stine[2], Angelo Sabag[3,4], Kate Hallsworth[5,6], Shira Zelber-Sagi[7], Nathan Johnson[3], Lucille Wilson[1], Michalis Stylianou[1], Elena George[8], Ingrid Hickman[9], Kai Wheeler[1], Mohit Kehar[10], Mortada El Shabrawy[11], Way Seah Lee[12], Sander Lefere[13,14], Ruth de Bruyne[15,16], Ram Weiss[17], Ilaria Croci[18], Christopher Pugh[19,20], Daniel Cuthbertson[21,22], Nicholas Beng Hui Ng[23,24], Jacob George[25], Oyekoya Ayonrinde[26,27,28], Le Zhang[29], Ming-Hua Zheng[30,31]. *[1]School of Human Movement and Nutrition Sciences, The University of Queensland, Brisbane, Australia; [2]Penn State Health Milton S. Email: s.keating@uq.edu.au

Background and aims: Metabolic dysfunction-associated steatotic liver disease (MASLD) is the most common chronic liver disease in children and adolescents, closely linked with obesity and cardiometabolic risk. With no pharmacological therapies approved for MASLD in this population, behaviour-related lifestyle modifications are the cornerstone of management. This international consensus statement aimed to synthesise the evidence for physical activity (including structured exercise) for the management of paediatric MASLD and provide practical recommendations for clinicians, exercise professionals and families/caregivers.
Method: A systematic literature review was conducted and the 'GRADE-ADOLOPMENT' method was used to establish consensus recommendations. Consensus required >80% voting 'yes' or 'yes with changes' with changes adopted. Following open and closed consensus rounds, three research questions were established. Key considerations for evidence translation were reviewed to develop consensus on pragmatic implementation strategies.
Results: 25 collaborators contributed [11 countries, mean (SD) age 46 (11) yrs, 68% male] with expertise in hepatology, paediatrics, exercise physiology, public health and nutrition. The review netted 19 studies (15 original research; 4 systematic reviews). Preliminary data recommend 180–270 minutes/week of moderate-vigorous aerobic or combined aerobic and resistance exercise across 3–5 days/week, which can elicit modest hepatic benefit and broad cardiometabolic, cardiorespiratory and neuromuscular fitness improvements in children and adolescents with MASLD. Core recommendations are (i) adopt a whole-of-day movement approach, emphasising increases in moderate-to-vigorous physical activity, muscle strengthening activities, reduced sedentary and screen time and adequate sleep; (ii) multidisciplinary delivery involving clinicians, dietitians, and exercise professionals for a lifestyle-first approach; (iii) management should be family-centred and developmentally appropriate; and (iv) practical translation may involve school and community engagement to enhance equity and scalability.
Conclusion: Consensus established that exercise and healthy movement behaviours are safe, effective and central to paediatric MASLD management. Structured, family-centred, and multidisciplinary approaches can improve liver and cardiometabolic outcomes, with school and community settings important for sustainability, scalability and equity for access.

WED-558
Developing an evidence-based decision-support tool for culturally sensitive communication in hepatitis D care

Patrizia Künzler-Heule[1,2], Dunja Nicca[3]. *[1]HOCH Health Ostschweiz, Kantonsspital Sankt Gallen, Sankt Gallen, Switzerland; [2]University of Basel, Basel, Switzerland; [3]University of Zurich, Zürich, Switzerland*
Email: patrizia.kuenzler-heule@h-och.ch

Background and aims: Liver care nurses support patients with HBV/HDV co-infection in developing essential self-management skills, but care is frequently challenged by patients' cultural and linguistic diversity. This project aimed to develop an evidence-based decision-support tool to guide culturally sensitive communication strategies along the hepatitis D care pathway.
Method: A systematic literature review was conducted to identify communication strategies for linguistically diverse patients. Findings were discussed in a workshop with Swiss liver care nurses, focusing on their advantages and limitations across different stages of the hepatitis D care pathway. Key situations were delineated and preliminary assignments of suitable communication tools were developed. These findings are being reviewed and refined in a second workshop with international liver care nurses. In addition, semi-structured interviews with a patient representative and an expert in medical interpreting were conducted to complement the professional perspective.
Results: Identified communication strategies included the use of translators (relatives, trained healthcare professionals, and professional interpreters), digital solutions such as translation apps and artificial intelligence–based tools, as well as visual aids. Professional interpreters emerged as a key resource, particularly at early stages of care, including diagnosis, treatment decision-making, and treatment instruction, ensuring accurate communication and supporting the involvement of relatives. As care progresses, relatives were described as playing a more prominent role in ongoing communication. Translation apps were reported as especially useful for unplanned or short encounters. Visual aids were consistently described as supportive tools to reinforce verbal communication, although their availability in routine practice is limited.
Conclusion: The findings highlight the need for a structured, evidence-based approach to culturally and linguistically sensitive communication in hepatitis D care. Different strategies are required at different stages of the care pathway, with professional interpreters playing a central role in early, decision-critical situations. The ongoing refinement of these findings will inform the development of a practical decision-support tool for liver care nurses to support patient-centred self-management in culturally diverse settings.

WED-559-YI
A nurse-led tissue adhesive pathway to eliminate persistent post-paracentesis leakage: advancing hepatology nursing practice, patient comfort and value-based care

Mei Lin[1], Thinesh Edward Balasingam[1], Samantha Koh[2], Samuel Lim[2], Elizabeth Chen[2], Kevin Kim Jun Teh[2], Hiang Keat Tan[2], Jason Pik Eu Chang[2]. *[1]Nursing Division (Speciality Nursing), Singapore General Hospital, Singapore, Singapore; [2]Department of Gastroenterology and Hepatology, Singapore General Hospital, Singapore, Singapore*
Email: lin.mei@singhealth.com.sg

Background and aims: Persistent post-paracentesis leakage occurs in up to 20% of patients with cirrhosis requiring abdominal paracentesis, causing discomfort, skin irritation, increased infection

risk, and higher clinic resource utilization. Outcomes with conventional management strategies using pressure dressings, stoma bags, and/or sutures are variable and often poorly tolerated. To address these gaps, a nurse-led improvement initiative was developed to standardise post-paracentesis care using tissue adhesive as a simple and patient-centred alternative. The aim was to reduce persistent leakage to <10% within six months. Patient comfort, satisfaction, and value-based outcomes were also evaluated.

Method: A structured pathway was implemented in a tertiary restructured hospital in Singapore. Advanced hepatology nurses assessed suitability for tissue adhesive, performed the procedure, evaluated outcomes at 24 hours, and exercised independent escalation when required. Patient-reported comfort and satisfaction were assessed using structured questionnaires. Outcomes from the six-month intervention period were compared with pre-intervention leakage rates. Cost analysis reviewing changes in material and equipment use, as well as clinic resource utilisation was performed.

Results: Sixty-one patients received tissue adhesive under the nurse-led pathway. Persistent leakage rate decreased from 11–20.8% pre-intervention to 0% across all six intervention months. Patient-reported outcomes were highly favourable - 80% reported being very comfortable during application and at 24 hours, 86.7% were very satisfied, and 100% would opt for tissue adhesive in the future. Estimated cost savings over six months were SGD $4074.80, driven by reduced utilization of sutures and dressings, as well as clinic visits.

Conclusion: The nurse-led tissue adhesive pathway was safe, effective, and cost-efficient. It enhanced comfort, reduced complications, and streamlined patient care. This initiative demonstrated the impactful role of advanced hepatology nurses in pateint care, innovation, and value-based care. The pathway has since been adopted as the departmental standard, with strong potential for wider institutional and international adoption.

WED-560-YI

Improvement of patient satisfaction via implementation of a specialist nurse for patients with hepatocellular carcinoma – second interim analysis of the HCC care nurse pilot study

Larissa Pajancic[1,2], Lorenz Balcar[1,2], Abelina Kreuter[1,2], Katharina Pomej[1,2], Michael Trauner[1], Bernhard Scheiner[1,2], Matthias Pinter[1,2]. [1]*Medical University of Vienna, Department of Medicine III, Division of Gastroenterology and Hepatology, Vienna, Austria;* [2]*Vienna Liver Cancer Study Group, Division of Gastroenterology and Hepatology, Department of Medicine III, Medical University of Vienna, Vienna, Austria*
Email: larissa.pajancic@meduniwien.ac.at

Background and aims: The implementation of a hepatocellular carcinoma care nurse (HCCCN) can improve outcomes, reduce treatment-related adverse events, and can be cost-effective in patients with hepatocellular carcinoma (HCC) treated with sorafenib. Despite the rising incidence of HCC, specialist nurses are not yet widely established in Austria. This study aimed to standardise patient care by implementing a HCCCN in daily clinical practice and to evaluate its impact on quality of life, emergency admissions, length of hospitalisation, adverse events, and time on systemic treatment in patients with HCC.

Method: This single-centre, prospective pilot study included patients with HCC receiving systemic therapy at the Medical University of Vienna. Patients were randomised 2:1 to an intervention group with HCCCN support (group A) or a control group without HCCCN (group B). In addition to quality-of-life assessments, a self-developed patient satisfaction questionnaire was completed at each visit. All patients were seen by the treating physician, while patients in group A additionally received in-person and telephone follow-up by the HCCCN. The second interim analysis primarily focused on patient satisfaction.

Results: At data cut-off, 30 patients were included (group A: n = 20; group B: n = 10), most of whom were male (n = 24; 88%). The majority had advanced stage disease (BCLC stage C: n = 19; 65.5%; stage B: n = 11; 34.5%) and most were classified as Child-Pugh grade A (n = 20; 66.7%) or B (n = 10; 33.3%). Immunotherapy was administered to 17 patients and tyrosine kinase inhibitors to 13 patients. The median observation period was 9.2 months (range 1–21). In group A, a median of two in-person nurse visits (range 0–14) and one telephone contact (range 0–7) were recorded. Overall, 108 patient satisfaction questionnaires (median 3 per patient) were completed. In comparison to patients in the standard group, patients in the HCCCN group reported less difficulties with short-notice appointment scheduling (e.g. for managing side-effects) and less unannounced waiting times. Furthermore, they indicated that tracking their medical appointments was easier and they had sufficient advice on how to maintain their health status during treatment.

Conclusion: Overall, HCCCN support was associated with improved patient-reported experiences in care coordination, appointment management, and health-related guidance compared with usual care.

WED-561-YI

Improvement in Fibroscan® liver stiffness following lifestyle intervention in a real-world hepatology cohort

Amy Parry[1], Vijay Grover[1], Thomas Eddie[1], Jennifer Finn[1]. [1]*Hillingdon Hospital, Uxbridge, United Kingdom*
Email: amy.parry7@nhs.net

Background and aims: Approximately 90% of chronic liver disease is preventable; early detection with timely lifestyle intervention is key. This retrospective review aims to determine the impact upon patients who implement recommended lifestyle changes following an abnormal Fibroscan® (> 8 kPa) and a diagnosis of Metabolic Dysfunction–Associated Steatotic Liver Disease (MASLD), Alcohol Use Disorder (AUD), or combined Metabolic–Alcohol-Related Liver Disease (Met-ALD) attending an out-patient Hepatology clinic at a District General Hospital in London. A secondary aim was to evaluate the impact of socioeconomic deprivation on adherence to lifestyle intervention.

Method: Fibroscan® data from 2018–2025 were extracted from three internal devices. Collected variables included median liver stiffness (kPa), age, aetiology, body mass index (BMI), HbA1c, lipid profile, deprivation index and adherence to lifestyle recommendations. Data were analysed using statistical testing with Excel and RegressIT.

Results: We analysed 6172 Fibroscans® performed over seven years, representing 3308 individual patients (1177 MASLD, 866 Hepatitis B, 552 AUD, 84 Met-ALD and 629 other diagnoses). Among 1813 patients with MASLD, Met-ALD, or AUD, 145 (8%) had a baseline Fibroscan® > 8 kPa and repeat scan after ≥ 1 year. Liver stiffness improved by ≥ 1 kPa in 64% of patients, with 49% achieving complete reversal of fibrosis (Fibroscan® < 8 kPa). In those with improvement, 69% adhered to lifestyle intervention ($p = 0.003$) (weight loss with or without alcohol abstinence) and 43% demonstrated a reduction in BMI ($p = 0.012$). In contrast, those with a deteriorating Fibroscan®, only 11% reported positive lifestyle changes and 15% had a reduced BMI. Improvements in HbA1c and lipids were not associated with improvements in Fibroscan® (not statistically significant). Mean deprivation index scores were 5.8 for MASLD and 4.8 for AUD. Patients with MASLD in less deprived areas were more likely to adhere to lifestyle intervention and reduce BMI (14% per deprivation decile point increase), although this did not reach statistical significance.

Conclusion: This longitudinal review demonstrates that Fibroscan® liver stiffness is more likely to improve/reverse following implementation of lifestyle intervention. Improvements in glycaemic control and lipid profiles were not associated with changes in liver stiffness. The findings also suggest greater adherence to lifestyle intervention amongst patients residing in less deprived areas.

WED-562-YI

Patient reported outcomes of a nurse-led community-based post-discharge liver care program

Kristen Peake[1], Mayur Garg[1,2], Ziheng Xu[1], Diana Lewis[1], Siddharth Sood[1,2]. [1]*The Northern Hospital, Melbourne, Australia;* [2]*The University of Melbourne, Parkville, Australia*
Email: kristen.peake@nh.org.au

Background and aims: The Liver at Home (L@H) program was implemented in February 2023 to provide specialist advanced-practiced nurse support to patients in their homes following hospital discharge secondary to a liver-related condition. L@H is a 12-week program with tapering frequency of nurse encounters: 3 visits a week in weeks 1–4, and 1–2 visits between weeks 5–12. Approximately half of the visits are performed face-to-face with the remainder telehealth. L@H aims to facilitate a smoother transition to home, providing sustained care and education while reducing hospital readmissions. We evaluated patient experiences of L@H via anonymous post-program surveys.
Method: Anonymous surveys were distributed to eligible patients upon completion of the 12-week program, with a reply-paid envelope for return. Survey questions assessed patient perceptions of program effectiveness, satisfaction with care delivery, perceived impact on self-management, and support for hospital-to-community transition.
Results: Of 100 admitted patients, 45 surveys were sent to eligible participants. Reasons for non-distribution included program incompletion, patient refusal (due to illness or poor health literacy), repeat admission (n = 11), and death. The survey response rate was 44.4% (n = 20). Analysis revealed high patient satisfaction with L@H. Ninety-five percent reported gaining advanced understanding of their liver disease and feeling the program provided the necessary home support. Ninety percent felt more in control of their condition due to L@H, and all respondents (100%) reported feeling supported by program staff.
Conclusion: The patient survey results strongly suggest L@H is a well-received and beneficial care model for individuals discharged with liver-related conditions. Patients reported feeling well-supported at home and experienced an increased sense of control over their health. These positive perceptions highlight the value of at-home, nurse-led services in facilitating a smoother transition and empowering patients in chronic liver disease self-management.

WED-563

An audit to assess preventable emergency department presentations in patients with abdominal ascites secondary to cirrhosis

Kristen Peake[1], Siddharth Sood[1,2], Mayur Garg[1,2], Diana Lewis[1]. [1]*The Northern Hospital, Melbourne, Australia;* [2]*The University of Melbourne, Parkville, Australia*
Email: kristen.peake@nh.org.au

Background and aims: Ascites is a common complication of cirrhosis. Performing timely elective abdominal paracentesis in a day admission setting can prevent Emergency Department (ED) presentations, which often lead to prolonged hospital stays, higher healthcare costs, and adverse outcomes. Understanding the preventability of these ED visits is crucial for improving patient care and optimising resource allocation. We aimed to determine the proportion of ED presentations for ascites secondary to cirrhosis that were potentially preventable, and to identify the contributing factors.
Method: Patients who presented to the ED under Gastroenterology with ascites secondary to cirrhosis during the nine months (February to October) in 2024 were included. We evaluated whether their presentation was potentially preventable based on predefined criteria: patients were required to have prior involvement with our service and no concurrent medical issues requiring inpatient management. Preventability was independently assessed by a Hepatology Physician and a Senior Hepatology Clinical Nurse Consultant. In the event of disagreement, a third Hepatology Physician was consulted to determine the final classification.
Results: Forty-four patients met inclusion criteria. Of these, 19 (43%) were assessed as entirely preventable admissions based on the predefined criteria. Patients with potentially preventable admissions had a median length of stay of 4 days (interquartile range [IQR] 4 days).
Conclusion: The finding that 43% of ED presentations for abdominal ascites secondary to cirrhosis were potentially preventable highlights a critical area for targeted intervention. These patients are known to the health service, yet often experience limited access to dedicated nursing services. Increased specialised hepatology nurse support would effectively alleviate outpatient service pressures and streamline paracentesis pathways. This would allow for earlier intervention to prevent acute admission and facilitate the arrangement of timely outpatient paracentesis. Further improvements to existing processes and patient education would significantly impact the accessibility of care and prevent avoidable ED admissions. This represents a vital strategy to better support this patient population under current resource constraints.

WED-564

Areas for improved efficiency for patients with cirrhosis having elective abdominal paracentesis

Kristen Peake[1], Mayur Garg[1,2], Siddharth Sood[1,2], Diana Lewis[1]. [1]*The Northern Hospital, Melbourne, Australia;* [2]*The University of Melbourne, Parkville, Australia*
Email: kristen.peake@nh.org.au

Background and aims: Timely elective abdominal paracentesis can prevent emergency department presentations for patients with cirrhosis and refractory ascites. The current protocol at our healthcare service requires patients to first attend the Outpatient Medical Day Unit (OMDU). This is followed by a transfer to the radiology department for abdominal ultrasound marking. A resident doctor is then required to depart from their competing inpatient responsibilities to perform the abdominal paracentesis procedure in the radiology holding bay. Finally, the patient returns to the OMDU for the completion of drainage and post-procedure monitoring. In this audit, we analysed this workflow to determine areas for improved efficiency, exploring the potential benefit of Point-of-Care Ultrasound (POCUS) and implementing a nurse-led paracentesis service.
Method: Patients with cirrhosis-related ascites undergoing elective paracentesis in the OMDU over two months were included. Data included patient admission, radiology marking, drain insertion/removal, and discharge times. Analysis focused on identifying preventable delays, aiming to understand the potential impact of POCUS or future increased OMDU bed capacity.
Results: Sixteen patients were included; 87.5% (n = 14) arrived on time. Two patients (12.5%) had drain malfunctions, and three (18.75%) had inadequate ascites for paracentesis, yet all still endured admission times exceeding two hours. The mean time from admission to radiology marking was 2.26 hours (+/–SD 1.14). For the 11 patients who had paracentesis, the time from radiology marking to paracentesis was 1.74 hours (+/– 0.37). The mean time from admission to paracentesis was 3.54 hours (+/– 0.44). The overall mean time from admission to discharge was 6.91 hours (+/– 1.6).
Conclusion: The critical mean wait time from admission to paracentesis procedure is 3.54 hours, primarily attributable to delays in imaging and RMO availability. Integrating POCUS or establishing a nurse-led paracentesis service has the potential to significantly reduce unnecessary wait times, thus improving efficiency and increasing capacity for elective paracentesis. By improving OMDU efficiency, emergency department admissions related to bed availability are likely to be prevented in this patient population. These findings provide a valuable foundation for implementing a more streamlined, elective, nurse-led paracentesis process, which will enhance patient satisfaction and optimise resource utilisation within our healthcare service.

WED-569-YI

Patient-reported symptom burden and health care utilization in outpatients with advanced chronic liver disease – the prospective ATOMIC study

Martina Reiberger[1], David Bauer[2], Larissa Pajancic[3,4], Michael Schwarz[3], Nina Dominik[3], Katharina Pomej[3], Georg Kramer[3], Philipp Schwabl[3], Bernhard Scheiner[3], Michael Trauner[3], Benedikt Hofer[3], Thomas Reiberger[3]. *[1]Vienna General Hospital, Division of Gastroenterology and Hepatology, Department of Medicine III, Medical University of Vienna, Vienna, Austria; [2]Klinikum Ottakring, Vienna Healthcare Group, Vienna, Austria, Division of Gastroenterology and Hepatology, Department of Medicine III, Medical University of Vienna, Vienna, Austria, Vienna, Austria; [3]Division of Gastroenterology and Hepatology, Department of Medicine III, Medical University of Vienna, Vienna, Austria, Vienna, Austria; [4]Medical University of Vienna, Department of Medicine III, Division of Gastroenterology and Hepatology, Vienna, Austria*
Email: martina.reiberger@gmail.com

Background and aims: Patient-reported symptom burden and healthcare utilization patterns remain insufficiently investigated in (advanced) chronic liver disease (A)CLD. We aimed to assess symptom burden and health-related behaviors among stable CLD outpatients using standardized questionnaires.
Method: Patients with (A)CLD attending scheduled visits at the outpatient clinic of the Vienna General Hospital (AKH Wien) completed a 21-item symptom questionnaire assessing commonly reported liver-related symptoms, such as fatigue, sexual dysfunction, and insufficient disease- and nutrition-related information. Each item was rated on an 11-point visual analogue scale (VAS; 0–10). In addition, the questionnaire captured physical activity frequency and binary (yes/no) responses regarding alcohol use, participation in annual health check-ups, vaccination status review within the past two years, and GP visit in the past year. Continuous variables were summarized as medians with interquartile ranges. For patients with multiple visits only data from the latest visit was used to reflect current health status. Data were collected between 2021 and 2024.
Results: A total of 266 patients were prospectively included (median age: 57 [IQR 48–65] years; 64% male) with alcohol-related (n = 123, 46%) and viral (n = 32, 12.0%) liver disease as the most common etiologies. 92 (34.6%) patients had non-ACLD, 68 (26%) compensated ACLD, and 106 (39.8%) decompensated ACLD. Recent alcohol use was reported by 40 (15%). Furthermore, 94/261 (35%) had no GP visit in the past year, 129/246 (49%) did not attend annual health check-ups, and 125/247 (51%) had no vaccination status review within 2 years. Severe fatigue (pre-specified VAS≥7) was reported by 33%, low information regarding healthy nutrition (VAS<5) by 36%, and negative impact on sexual life (VAS≥7) by 26%. Symptom burden showed non-significant trends of symptom burden in dACLD compared with cACLD and non-ACLD.
Conclusion: Stable (A)CLD outpatients experience a substantial symptom burden alongside low utilization of preventive healthcare services. These findings call for systematic symptom screening, structured lifestyle counseling, care coordination, patient navigation, and systematic referral pathways with targeted interventions. A dedicated liver care nurse clinic may support the implementation of these action items by symptom triage, patient education, and timely referral to appropriate services.

WED-570-YI

The impact of a dedicated nurse practitioner in streamlining the referral pathway for patients with unresectable colorectal liver metastases in Saudi Arabia

Robyn Reis[1], Bandar Aljudaibi[1], Mohamed Shawkat[1], Dieter Clemens Broering[1]. *[1]King Faisal Specialists Hospital and Research Centre, Riyadh, Saudi Arabia*
Email: rreis3@mail.naz.edu

Background and aims: The referral and assessment process for patients with unresectable colorectal liver metastases (CRLM) for potential liver transplantation is complex and requires meticulous coordination. This study evaluates the role of a dedicated Nurse Practitioner (NP) in optimizing this pathway at a tertiary transplant center.
Method: A retrospective review of 20 consecutive patients referred for liver transplant assessment for unresectable CRLM was conducted. Data extracted included referral patterns, patient demographics, clinical characteristics, mutlidisciplinary decision decisions, and outcomes. The NP's role involved being the central point of contact, ensuring complete data collection, coordinating multidisciplinary team (MDT) meetings, and facilitating patient communication.
Results: The majority of referrals originated from the Central region (55%) in Saudi Arabia, followed by West (25%), North (10%), and South (10%) regions. Of the 20 patients assessed, 12 (60%) were accepted into the liver transplantation pathway. The primary reason for declining 7 patients (35%) was disease progression; one patient's status remained unknown. Ultimately, 4 patients (20% of the total cohort, 33% of those accepted) underwent liver transplantation. The NP's involvement standardized pre-MDT workup, reducing assessment time from a median of 45 to 28 days and ensuring 100% data completeness for discussed cases.
Conclusion: The integration of a dedicated Nurse Practitioner is instrumental in creating an efficient and patient-centered referral pathway for CRLM patients. This model improves coordination, ensures robust data-driven MDT decisions, and effectively identifies suitable candidates for liver transplantation, though disease progression remains a significant barrier to acceptance.

WED-571-YI

Impact of sedentary behaviour on metabolic profiles: insights from a romanian cohort of patients with metabolic dysfunction-associated liver disease (MASLD)

Elena Rezi[1]. *[1]Lucian Blaga University Sibiu, Sibiu, Romania*
Email: crimuntean@yahoo.com

Background and aims: Regular physical activity is essential for avoiding the effects of Metabolic Dysfunction-Associated Liver Disease (MASLD). Given Romania's high cardiovascular mortality rates, understanding activity patterns is crucial. This study aims to evaluate physical activity levels in MASLD patients using the Romanian-validated Physical Activity Index (PAI).
Method: A 24-month observational study was conducted at the Clinical Hospital of Sibiu, involving 71 patients diagnosed with MASLD via ultrasonography. Physical activity was assessed using the PAI Questionnaire. The four levels of the Physical Activity Index are based on occupational activity and weekly hours of exercise or cycling. These levels are inactive, moderately inactive, moderately active and active. Statistical correlations were analysed between PAI scores and several clinical parameters, including age, waist circumference, lipid profile, glycemia, blood pressure, BMI, and platelet count.
Results: Using Pearson's correlation coefficient (r), significant correlations were observed between Physical Activity Index and the following parameters: body mass index (r = 0.69), waist circumference (r = 0.60), triglyceride levels (r = 0.39), blood pressure (r = 0.38), glycaemic levels (r = 0.36). Interestingly, age-based analysis revealed that patients under 50 years of age were significantly less active than those over 50 years of age (p = 0.03).
Conclusion: Physical activity levels in MASLD patients are closely linked to key metabolic markers, including BMI, triglycerides, and glycaemic control. Furthermore, the findings highlight a concerning trend of higher sedentary behaviour among younger MASLD patients, suggesting a need for targeted lifestyle interventions in this demographic.

WED-572

Development of a care pathway for patients with liver cirrhosis

Laurence Seynhaeve[1], Charlotte De Vloo[1], Sofie De Meulder[1], Jef Dewyspelaere[1], Luc Harlet[1], Kymentie Ferdinande[1], Eva Puttevils[2], Jochen Decaestecker[1]. *[1]Department of Hepatology, AZ Delta Hospital, Roeselare, Belgium, Roeselare, Belgium; [2]AZ Delta, management department, Rumbeke, Belgium, Roeselare, Belgium*
Email: laurence.seynhaeve@azdelta.be

Background and aims: Patients with cirrhosis have complex, fluctuating care needs that require coordination between hospital specialists and primary care providers. Decompensated cirrhosis demands frequent in-hospital multidisciplinary management, while compensated cirrhosis is mainly managed in primary care with less intensive monitoring (6-monthly hepatology follow-up). Given the complexity and high prevalence of cirrhosis and the need for multidisciplinary collaboration, a structured care pathway is essential to reduce variability, ensure continuity, and improve patient outcomes.
Method: A care pathway for patients with liver cirrhosis was developed at AZ Delta Hospital, following a simplified version of the seven-phase model of the Network of Clinical Paths, KU Leuven.
Results: Key stakeholders, including patients, family, hepatologists, a nurse specialist, and GPs, were involved in developing a structured care pathway for cirrhosis, covering the trajectory from diagnosis to transplantation or death (excluding palliative patients and HCC under non-curative treatment). Analysis of current care identified bottlenecks such as poor follow-up after hospital discharge and limited hospital–GP communication. A communication booklet and a patient app were introduced to support self-management, monitor daily health parameters, and provide educational resources. The pathway follows key care moments such as diagnosis, hospitalization, and follow-up. The implementation in the hepatology department is ongoing, currently focusing on inpatient and post-discharge care.
Conclusion: By developing this care pathway, we aim to strengthen the coordination and overall quality of care for patients with cirrhosis. The integration of a patient-centered digital app, empowers patients to actively engage in managing their disease. Ultimately, the pathway tries to bridge the gap between hospital and primary care settings and provides a sustainable framework for continuous quality improvement.

WED-573-YI

Cutaneous manifestation and impact of chronic liver disease in resource limit setting

Sharmila Thapa[1,2], Anand Bhat[3]. *[1]Mahabaudha Medical Center, Dhangadhi, Nepal; [2]Mahabaudha Medical Center, Med, Dhangadhi, Nepal; [3]Singh Medical Clinic, Dhangadhi, Nepal*
Email: mbmc.nepal@gmail.com

Background and aims: Nepal have open borders with India and China. Cutaneous manifestations, particularly severe pruritus, skin discoloration, and visible stigmata, are highly prevalent in Chronic Liver Disease (CLD) and significantly impair Quality of Life (QoL).
Method: A cross-sectional study adult CLD patients (diagnosed via standard criteria) were consecutively follow up for a year. Exclusion criteria included acute liver failure or other primary non-hepatic causes of itch. Patient history included detailed assessment of alcohol consumption, noting specific patterns and the use of local brews. Quality of life and Itch Severity assessment done with statistical analysis.
Results: Among the 152 CLD patients were (62% male; mean age 48.5 years) which included viral hepatitis (50%), with Alcoholic Liver Disease (ALD) contributing 35%. Among ALD patients, 85% reported regular consumption average > 450 mL/day of *local brews*. Sixty-one patients (40.1%) reported clinically significant pruritus. The mean (SD) aNRS and 5D-Itch scores for the pruritic cohort were 4.3 and 13.7 respectively. Skin discoloration was frequent: jaundice (45% of total cohort) and non-icteric hyperpigmentation (21%), photoageing in all patients were prominent stigmata. Patients with pruritus demonstrated significantly lower mean scores across all non-somatic domains of the LDQOL compared to the non-pruritic group, with the most profound impact noted on Emotional Functioning ($p < 0.001$) and Sleep Quality ($p < 0.001$). Furthermore, 25% ($n = 38$) of the entire cohort screened positive for high body image distress (BIQLI-N ≥ 40), which was significantly correlated with the presence of hyperpigmentation, photoageing, fungal infections and facial spider angiomas ($p = 0.005$). Pruritus severity was significantly correlated with serum Alkaline Phosphatase levels ($r = 0.39$, $p = 0.003$).
Conclusion: Cutaneous pruritus, skin discoloration, photoageing, and associated stigmata are highly prevalent and impose a major, quantifiable psychosocial burden, including significant body image distress, on CLD patients, particularly those with a history of local alcohol intake. These findings highlight a critical gap in care and underscore the necessity of integrating standardized dermatological and psychological assessment and QoL-focused interventions, early diagnosis and treatment into national CLD management guidelines, ensuring better outcomes and reduced social stigma in low-resource settings.

WED-574

Hepatitis C electronic patient record flags: an opportunity to remove inaccuracies and re-engage lost to follow-up patients

Samuel Uveges[1], Sarah Montague[2], Stephen D Ryder[3], Edward Nicholson[3], Darren Cooper[4]. *[1]Trust Pharmacy, Nottingham, United Kingdom; [2]Nottingham University Hospitals NHS Trust, Viral Hepatitis, Nottingham, United Kingdom; [3]Nottingham University Hospitals NHS Trust, Nottingham, United Kingdom; [4]Hepatitis C Trust, London, United Kingdom*
Email: samuel.uveges@nhs.net

Background and aims: Hepatitis C Virus (HCV) positive patients at a busy teaching hospital in the Midlands (UK), have their electronic patient record (EPR) flagged to alert clinical staff of the patients HCV status. Historically, the removal of these alerts after confirmation of a sustained virological response (SVR) has been inadequate, causing staff to apply unnecessary infection prevention procedures and negatively affecting patients' hospital experience. An audit was performed to ensure only those patients with an active HCV infection were flagged thereby improving accuracy of medical records and help demonstrate true patient caseload.
Method: Hospital Data Analysts provided the hospital numbers for all patients currently marked with a hepatitis C flag. Each patient record was interrogated to establish whether they were still HCV RNA positive. If evidence could be found that demonstrated a cure, spontaneous clearance or the patient was deceased the flag was removed. The remaining hospital numbers were cross-referenced against multiple data sets from partnership organisations and other Hepatitis C Operational Delivery Networks (ODNs) to establish if a test had been conducted elsewhere in the country. Re-Engagement: All remaining patients were contacted by letter to invite them for a blood test and to opt-out of a peer visit. Those that did not opt out were then contacted by a peer from The Hepatitis C Trust.
Results: Data received in March 2024 showed that 1580 patients had an active Hepatitis C flag. Using local hospital records, 247 patients we found to have died and 632 had achieved SVR. partnership organisation data sets found a further 37 SVRs. 390 patients were found to have a current address within the Nottingham ODN, 92 of which were found to have achieved SVR. 267 patients had moved outside of the Nottingham ODN 157 were found to have achieved SVR. During re-engagement 163 letters were sent out from which we received 34 responses. 24 of the patients had achieved SVR, 1 refused further testing and 9 were found to still be HCV RNA Positive and have been referred for follow up with the CNS Team. As of 5th December 2025, a total of 1277 (80.8%) flags have been removed.
Conclusion: After detailed investigation and national collaboration, over 80% of active alerts were no longer necessary and could be

removed. Doing so prevents unnecessary protective measures being deployed by staff, anecdotally improves patient experience and gives a more accurate picture of the prevalence within the hospital.

Portal Hypertension (cirrhosis and non-cirrhosis)

TOP-486

Risk reduction in clinically significant portal hypertension with Belapectin in advanced MASH cirrhosis: results from the NAVIGATE trial

Naim Alkhouri[1], Mazen Noureddin[2], Mary E. Rinella[3], Raj Vuppalanchi[4], Eric Lawitz[5], Edward Mena[6], Khurram Jamil[7], Naga Chalasani[4]. [1]*Summit Clinical Research, Clinical Research Institute of Ohio, San Antonio, TX, United States;* [2]*Houston Methodist Hospital, Houston, TX, United States;* [3]*The University of Chicago Pritzker School of Medicine, Chicago, IL, United States;* [4]*Indiana university school of medicine, Indianapolis, United States;* [5]*The Texas Liver Institute, San Antonio, TX, United States;* [6]*California Research Institute, Pasadena, CA, United States;* [7]*Galectin Therapeutics, Norcross, GA, United States*
Email: naim.alkhouri@gmail.com

Background and aims: MASH cirrhosis with portal hypertension carries a high risk for decompensation, yet no approved therapies exist. Belapectin, a galectin-3 inhibitor, previously demonstrated at 2 mg/kg approximately 50% lower incidence of new varices (11.3% vs 22.3%, p = 0.04) in subjects who completed 18 months of therapy. This study evaluated the effect of belapectin on portal-hypertension risk using Baveno VII criteria and on fibrosis-progression risk using Agile-4.
Method: NAVIGATE (NCT04365868) randomized adults with compensated MASH cirrhosis, portal hypertension, and no baseline varices to belapectin 2 mg/kg, 4 mg/kg, or placebo every 2 weeks for 18 months. Subjects were stratified by T2DM. Of 357 randomized (119/group), 287 completed 18 months of therapy with baseline and end-of-treatment EGD and formed the per-protocol population. Baveno VII categories (CSPH, probable CSPH, no/low-risk) were defined using LSM and platelet count. Agile-4 was used to assess ≥20% worsening, a threshold associated with higher risk of liver-related events.
Results: NAVIGATE enrolled an advanced cohort with a high prevalence of CSPH at baseline. Baseline characteristics were balanced (mean age 60 years; 65% female; platelets 131 × 10^9/L; LSM 24.8 kPa; 67% T2DM). After 18 months, belapectin 2 mg/kg shifted patients toward lower-risk Baveno VII categories. In the CSPH group, rates declined from 33.3% to 25.9% with belapectin versus 34.2% to 32.9% with placebo. Importantly, The no/low-risk category increased from 42.0% to 56.8% with belapectin versus 44.7% to 51.3% with placebo. At week 78, a greater proportion of belapectin-treated subjects improved to the no/low-risk category relative to baseline compared with placebo (p = 0.0073). Agile-4 also favored belapectin: 47% more subjects experienced ≥20% progression in placebo 12/94 (16.9%) compared with belapectin 2 mg/kg 9/97 (11.5%) after 18 months. For AGILE-4 progressors (≥20%), varices developed in 16.7% of placebo patients, compared with none receiving belapectin 2 mg/kg.
Conclusion: Belapectin 2 mg/kg improved multiple validated measures of portal-hypertension risk, including Baveno VII reclassification and Agile-4 trajectories, and significantly reduced new varices. These findings support belapectin's development as a potential therapy for patients with advanced MASH cirrhosis and portal hypertension.

TOP-487-YI

Metformin added to carvedilol improves acute portal pressure response in cirrhosis – a randomized double-blind study topic: portal hypertension and complications/pharmacological therapy

Chitranshu Vashitshtha[1], Garvit Mundra[1], Rakhi Maiwall[1], Shiv Kumar Sarin[1], Vinod Arora[1], Rajan Vijayaraghavan[1], Satender Pal Singh[1], Ashok Kumar Choudhury[1], Ishank Johri[1].
[1]*Institute of liver and biliary sciences, New Delhi, India*
Email: chitranshuv@gmail.com

Background and aims: Carvedilol is a non-selective beta-blocker which reduces portal pressure by ameliorating splanchnic vasodilatation and intrahepatic vasoconstriction. However, a substantial proportion of patients fail to achieve adequate hemodynamic response. Metformin reduces intrahepatic vascular resistance through endothelial and antifibrotic mechanisms and may complement carvedilol. We aimed to evaluate whether adding metformin to carvedilol improves the acute portal pressure response compared with carvedilol alone in patients with cirrhosis.
Method: In this single-centre, randomized, double-blind, placebo-controlled trial [NCT07108075], adults with cirrhosis and portal hypertension undergoing hepatic venous pressure gradient (HVPG) measurement were randomized 1:1 to carvedilol (12.5 mg) plus metformin (1000 mg single oral dose) (group I) or carvedilol plus placebo (group II). Repeat HVPG was performed 120 minutes later. The primary outcome was acute hemodynamic response, defined as HVPG reduction of atleast 20% from baseline or absolute value below 12 mmHg. Secondary outcomes included absolute HVPG change, proportion achieving at least 10 percent reduction, and short-term safety.
Results: Seventy-two patients were randomized (36 per group). Baseline characteristics were comparable (age 48.6 ± 9.4 years, male 96%, alcohol 57%, MASLD 32%, diabetes 15%, platelet count 66 × 10 3/microliter, liver stiffness 43 kPa, spleen stiffness 78 kPa, HVPG 17.6 mmHg). Acute hemodynamic response was achieved more in group I (88.9% vs 63.9%, p = 0.013). The absolute reduction in HVPG was greater in group I (6.6 ± 4.4 mmHg vs 4.0 ± 3.3 mmHg, p = 0.005). A reduction of at least 10 percent occurred in 94.4% (group I) and 88.9% (group II) (p = 0.394). There was no significant difference between the groups in systemic hemodynamic parameters. No serious adverse events were observed.
Conclusion: Adding metformin to carvedilol significantly improves acute portal pressure reduction compared with carvedilol alone without short-term safety concerns. This dual-mechanism approach targeting portal inflow and intrahepatic resistance warrants evaluation for long-term clinical outcomes.

Background and aims: Transjugular intrahepatic portosystemic shunt (TIPS) improves survival in high-risk patients (pts) with cirrhosis and acute variceal bleeding or with recurrent/refractory ascites. Overt hepatic encephalopathy (OHE) after TIPS is reported in 30–50%. Risk factors for OHE have been mostly described in the setting of retrospective studies with elective TIPS but standard medical treatment evolved over time. We aimed to evaluate the cumulative incidence of OHE after TIPS in the 2020s in a large prospective multicenter European cohort to identify predictive factors for OHE and to assess its prognostic value after TIPS in patients with cirrhosis.
Method: This is an ancillary multicenter study within the EuroTIPS registry, which included all consecutive pts treated with TIPS in 19 centers in Europe. Pts were followed up at 1, 3, 6, 9, and 12 months, or until death or liver transplantation (LT). The primary outcome was the cumulative incidence of OHE, graded according to West Haven criteria, at 12 months, considering death and LT as competing events. Secondary outcomes were (i) predictive factors for OHE and (ii) the impact of OHE on 12-month mortality after TIPS.
Results: A total of 887 pts were included (74.0% male, median age 58 years, 71.1% alcohol-associated liver disease, 18.6% previous OHE; TIPS indication: rescue/salvage 14.1%, pre-emptive 18.6%, ascites/secondary prophylaxis 67.3%). The cumulative incidence of OHE was 28.7%, 43.9%, and 47.7% at 1, 3, and 12 months, respectively. In multivariate analysis, independent predictors of OHE were age (aHR = 1.02, 95%CI [1.01–1.03]), diabetes (aHR = 1.30, 95%CI [1.05–1.62]), any concomitant heart disease (aHR = 1.69, 95%CI [1.26–2.26]), bilirubin (aHR = 1.03, 95%CI [1.00–1.05]), and creatinine (aHR = 1.17, 95%CI [1.03–1.36]). In subgroup analyses, factors associated with OHE included previous OHE and any heart disease in rescue TIPS; MELD score in pre-emptive TIPS; and age, diabetes, any heart disease, previous OHE, and pre-TIPS ammonia levels in elective TIPS. At 12 months, 169 pts died (19.1%) and 79 (8.9%) underwent LT. Independent factors associated with death or LT were age, MELD, previous OHE, and OHE after TIPS ($p < 0.001$ at all time points).
Conclusion: OHE remains a frequent post-TIPS complication in the 2020s' and is associated with increased risk for mortality. Diabetes and any concomittant heart disease emerge as independant risk factors, suggesting that an altered brain reserve plays a role in its pathophysiology.

Email: simone.dicola@uniroma1.it

Background and aims: Nutritional status, particularly sarcopenia, may influence patients' outcomes after Transjugular Intrahepatic Portosystemic Shunt (TIPS), but the role of myosteatosis and adiposity in this setting are poorly defined. Subcutaneous adipose tissue radiodensity (RSAT) reflects adipose tissue quality and degree of inflammation. Retrospective data have shown that both muscle and adipose tissue may be modified following TIPS procedure. We aimed to evaluate body composition changes after TIPS and their prognostic value, focusing on overt hepatic encephalopathy (oHE) within 6 months.
Method: Consecutive patients with cirrhosis undergoing TIPS were prospectively enrolled in six Italian centers (2022–2025). Clinical, hemodynamic and nutritional data were collected. Body composition [skeletal muscle index (SMI), muscle attenuation (MA), visceral and subcutaneous adipose tissue (VAT, SAT), and RSAT] was assessed by CT at L3–L4 within 90 days before TIPS and at 6 months. Outcomes were recorded during 12-month follow-up.
Results: Among 102 patients (75% male; median age 61 years, IQR 54–67), baseline sarcopenia and myosteatosis were present in 54% and 81%. Median VAT and SAT were 106 and 134 mm^2; median RSAT was −92 HU (IQR −98 to −78), with 23 patients (22.5%) showing high RSAT. Three patients were excluded for early TIPS dysfunction; 84 (82%) completed 6-month follow up. SMI significantly increased (51.9 vs 48.0, $p < 0.001$); 34 patients (41%) showed ≥10% SMI increase and 15 (18%) reversed sarcopenia. VAT decreased (109.7 vs 146.9 mm^2, $p < 0.001$), SAT increased (194.7 vs 172.6 mm^2, $p < 0.001$), while RSAT remained substantially unmodified (−85.7 vs −88.1 HU, $p = 0.78$). oHE occurred in 44%. Basal SMI and MA did not differ according to oHE occurrence, whereas high RSAT was associated with an increased risk of post-TIPS oHE ($p = 0.04$), TIPS failure ($p = 0.012$), and failure to control ascites ($p = 0.006$). Sarcopenia reversal was associated with fewer bacterial infections (4% vs 26%, $p = 0.04$). At multivariable analysis, high RSAT independently predicted post-TIPS oHE after adjustment for age, MELD and prior oHE (HR 1.02, 95% CI 1.00–1.04, $p = 0.016$).
Conclusion: This first prospective multicenter study shows that TIPS improves muscle mass and adipose tissue distribution, reversing sarcopenia in 18% at 6 months. RSAT emerged as a novel prognostic marker for post-TIPS oHE, suggesting that adipose tissue quality may outperform muscle metrics for risk stratification.

Email: lucile.moga@gmail.com

Background and aims: In patients with cirrhosis, liver (LSM) and spleen stiffness measurement (SSM) by vibration-controlled transient elastography (VCTE) reflect the severity of portal hypertension (PH) and the risk of hepatic decompensation. By contrast, in patients with porto-sinusoidal vascular disorder (PSVD), LSM is generally low, whereas SSM is associated with the presence of high-risk varices. This study aimed to assess the prognostic performance of LSM and SSM by VCTE in patients with PSVD and signs of PH.
Method: This retrospective study included all patients with histologically proven PSVD and signs of PH at the time of diagnosis, who underwent ≥ 1 LSM +/− SSM by VCTE with a minimum of 1 year of subsequent follow-up. The population was divided into a monocentric derivation cohort and a multicentric validation cohort from 20 VALDIG centres. Study entry was defined as the date of the 1st VCTE. Follow-up data, including liver-related events (LRE), were recorded until the last visit or death. LRE were defined as variceal bleeding, ascites, hepatic encephalopathy, primary liver cancer, hepatopulmonary syndrome, porto-pulmonary hypertension, liver transplantation, and liver-related death. We analysed survival without LRE, considering non-liver related death as a competing event.
Results: 203 patients were included in the derivation cohort: 55% men, median age 54. All patients had ≥ 1 LSM, and 176 had ≥ 1 SSM. Median (IQR) 1st LSM and SSM values were 7.6 (6.1–11.1) kPa and 44 (29–73) kPa, respectively. 50 patients (28%) experienced ≥ 1 LRE at 5 years of the 1st VCTE. In the validation cohort (n = 383), 30% of the patients experienced ≥ 1 LRE at 5 years. In the derivation cohort, the 5-year LRE-free survival was of 94% in patients with LSM < 10 kPa and SSM ≤ 40 kPa, *vs.* 74% in those with either LSM ≥ 10 kPa or SSM > 40 kPa, *vs*. 29% in patients with LSM ≥ 10 kPa and SSM > 40 kPa. Similar results were observed in the validation cohort, with a 5-year LRE-free survival of 80%, 70%, and 29%, respectively. In the derivation cohort, 120 patients had a 2nd VCTE ≥ 2 years after the 1st, with ≥ 1 year of subsequent follow-up; the 5-year LRE-free survival after this 2nd VCTE according to the aforementioned LSM- and SSM-based categories, was 92%, 66%, and 0%, respectively.
Conclusion: LSM and SSM by VCTE predict LRE in patients with PSVD. Three categories of risk based on LSM and SSM could be useful for adapting surveillance frequency in routine care, and for identifying high-risk patients for clinical trials.

THU-415

Patient-reported quality of life in porto-sinusoidal vascular disease: insights from a qualitative study and recommendations for clinical research

Anouck Alary[1], Pierre-Emmanuel Rautou[2,3], Marco Senzolo[4], Alberto Zanetto[4], Carlotta Magnani[1], Aurélie Plessier[2,3], Virginia Hernández-Gea[5,6], Agnes Dumas[1]. *[1]INSERM, Aix Marseille Univ, IRD, ISSPAM, SESSTIM, Sciences Economiques & Sociales de la Santé & Traitement de l'Information Médicale, Equipe CALIPSO, Marseille, France; [2]Université Paris-Cité, Inserm, Centre de recherche sur l'inflammation, UMR 1149, Paris, France; [3]AP-HP, Hôpital Beaujon, Service d'Hépatologie, DMU DIGEST, Centre de Référence des Maladies Vasculaires du Foie, FILFOIE, ERN RARE-LIVER, Clichy, France; [4]University of Padova, Padua, Italy; [5]Hepatic Hemodynamic Laboratory, Liver Unit, Hospital Clínic, Clínic Barcelona, Health Care Provider of the European Reference Network on Rare Liver Disorders (ERN-RareLiver), CSUR Centro de referencia del Sistema Nacional de Salud en Enfermedad Hepática Vascular Compleja en adultos. Email: anouck.alary@inserm.fr

Background and aims: Porto-sinusoidal vascular disease (PSVD) is a rare vascular liver disorder characterized by portal hypertension (PH) in the absence of cirrhosis. Therapeutic advancements are limited in PSVD partially due to the lack of reliable surrogate end-points for clinical trials and the lack of data on patients' health-related quality of life (HRQoL). This study aimed to explore the HRQoL of patients with

PSVD and to identify relevant patient reported outcomes and measures suitable for use in future clinical research.
Method: We conducted a multicenter qualitative study in France, Spain, and Italy. A stratified purposeful sample was recruited to ensure diversity in disease stage, age, and sex. Semi-structured, in-depth interviews were conducted by experts in qualitative methods using an interview guide co-developed with members of patients' organizations. Interviews were audio-recorded, transcribed verbatim, and analyzed using inductive thematic analysis. During analysis, coding and theme development were discussed iteratively with clinicians and patients' organizations to ensure relevance and validity.
Results: Interviews were conducted with 16 patients: 8 women, 8 men; median age [interquartile range]: 48 [37–61]; 4 without signs of portal hypertension (PH), 5 with signs of PH without clinical complications, 7 with clinical complications. Anxiety was reported at all stages of the disease, although its manifestations increased with clinical evolution. In contrast, fatigue and pain became predominant symptoms in more advanced stages, particularly among patients with PH-related complications. The disease also affected reproductive health in women, work capacity in professionally active patients, and overall social functioning in those experiencing fatigue and digestive discomfort. The invisibility and rarity of PSVD further contributed to feelings of isolation. Patients with comorbidities or associated diseases described their experience as that of a "total illness" in which PSVD-related symptoms were difficult to disentangle from that of other diseases.
Conclusion: PSVD has a substantial and multidimensional impact on HRQoL. Generic HRQoL measures such as SF-36 are insufficient to capture liver-related symptoms and support the use of disease-specific tools such as the CLDQ, along with specific scales or items assessing fatigue and its unpredictability, anxiety, and the effects of the disease on reproductive health, work, and social functioning.

Email: vijayalexander@cmcvellore.ac.in

Background and aims: Pharmacologic strategies to enhance ulcer healing and prevent ulcer related bleeding after endoscopic variceal ligation (EVL) remain uncertain. Despite limited supporting evidence, sucralfate is frequently prescribed alongside proton pump inhibitors (PPIs) to reduce post-EVL ulcer burden and bleeding. We conducted a randomized controlled trial to evaluate whether adjunctive sucralfate provides incremental benefit over PPI monotherapy for post-EVL ulcer healing.
Method: In this open-label, randomized controlled trial, adults with portal hypertension and Child–Turcotte–Pugh (CTP) class A or B cirrhosis undergoing EVL as secondary prophylaxis were randomized (1:1) to receive pantoprazole 40 mg twice daily with or without sucralfate 1 g four times daily for 2 weeks. Follow-up endoscopy at 14–21 days assessed the presence, number, and dimensions of post-EVL ulcers. Secondary outcomes included ulcer-related bleeding and patient-reported post-EVL chest pain.
Results: Forty-eight patients (mean age 51.9 ± 12.3 years; alcohol-related cirrhosis 43.8%; MASLD 41.6%) were randomized to pantoprazole plus sucralfate (n = 24) or pantoprazole alone (n = 24). Baseline liver disease severity was comparable between groups (median CTP score 7 [5–9]; mean MELD score 11.8 ± 4.0 vs 13.6 ± 4.2; p = 0.13). All patients received non-selective beta-blocker therapy following endoscopy, predominantly carvedilol (40/48, 83.3%), with the remainder receiving propranolol (8/48, 16.7%). Follow-up endoscopy was completed in 44 patients with two patients lost to follow up in each arm. The number of bands applied per session was similar (median 4 [1–4] vs 4 [1–5]; p = 0.67). The prevalence of post-EVL ulcers did not differ between groups (50% vs 37.5%; p = 0.76), nor did the median number of ulcers per patient (2 [1–3] in both groups; p = 0.41). Ulcer dimensions were comparable, including maximum length (5.0 [4.0–6.0] vs 4.0 [4.0–8.0] mm; p = 0.94) and width (2.5 [2.5–5.0] vs 2.5 [2.5–5.0] mm; p = 0.65). Post-EVL chest pain occurred at similar frequencies (27.3% vs 45.5%). No patient in either group developed post-EVL ulcer bleeding during the study period. Sucralfate was well tolerated, with no treatment-related adverse events.
Conclusion: Adjunctive sucralfate does not improve endoscopic ulcer healing or post-EVL symptoms compared with PPI therapy alone. These findings do not support the routine use of sucralfate following EVL for ulcer healing or bleeding prevention.

THU-417
Histologic assessment for portal hypertension in porto-sinusoidal vascular disease

Wesam Aleyadeh[1], Sana Pirzada[1], Sawsan Fathma[1], Christopher Koh[1], David E Kleiner[1], Theo Heller[1]. *[1]National Institutes of Health, Bethesda, MD, United States*
Email: wesamaleyadeh@gmail.com

Background and aims: Porto-sinusoidal vascular disease (PSVD) encompasses diverse histologic lesions including nodular regenerative hyperplasia (NRH), portal vein muscularization, and stenosis. The discriminative value of individual histologic features for identifying portal hypertension remains incompletely characterized. We examined associations between specific histologic lesions, portal hypertension features, and laboratory markers.
Method: Retrospective analysis of 40 patients evaluated for suspected PSVD at a tertiary center between 2004 and 2025 after excluding cirrhosis, advanced fibrosis, and congenital hepatic fibrosis. Histologic features were assessed at index biopsy and included nodular regenerative hyperplasia, muscularized portal veins, portal vein stenosis, regenerative changes, and abnormal vascular repartition. Portal hypertension was defined as HVPG >5 mmHg and/or clinical signs (varices, collaterals, gastropathy). Associations with portal hypertension features and laboratory markers were examined using Fisher's exact test, Wilcoxon rank-sum test, and Spearman correlations with Benjamini-Hochberg FDR correction.
Results: The cohort comprised 40 patients: median age 45 years (IQR 35–56), 48% female, 87.5% White, mean BMI 23 kg/m^2, with common variable immunodeficiency as predominant etiology (35%). Biochemical profile was predominantly cholestatic (R-factor 1.0, IQR 0.7–1.5). NRH (60%, n = 24) predicted portal hypertension (83.3% vs 56.2%, OR 3.75, p = 0.08) and correlated with elevated HVPG (9 vs 5 mmHg, p = 0.012), transient elastography (9.1 vs 6.1 kPa, p = 0.007), FIB-4 (4.24 vs 1.85, p = 0.011), and total bilirubin (0.95 vs 0.55 mg/dL, p = 0.024). Muscularized portal veins (22.5%, n = 9) predicted HVPG ≥10: 55.6% vs 12.9%, OR 7.83, p = 0.016. Portal vein stenosis ≥50% (27.5%, n = 11) associated with elevated MELD 3.0 (7 vs 6, p = 0.006). Paradoxically, isolated regenerative changes (37.5%, n = 15) showed inverse associations: lower portal hypertension (53.3% vs 84%, OR 0.23, p = 0.065), HVPG (5 vs 9 mmHg, p = 0.012), bilirubin (0.5 vs 1.0 mg/dL, p = 0.006), and FIB-4 (2.12 vs 4.2, p = 0.043), suggesting these represent improved biochemical and clinical endpoints.
Conclusion: NRH and muscularized portal veins discriminate portal hypertension severity in PSVD on index biopsy, correlating with hemodynamic and laboratory markers. Isolated regenerative changes may be associated with less disease burden. These findings guide pathologists in identifying high-risk vascular remodeling patterns in suspected PSVD.

Background and aims: The role of salvage/rescue transjugular intrahepatic portosystemic shunt (TIPS) in patients with hepatocellular carcinoma (HCC) remains controversial. This study aimed to evaluate outcomes in patients with active HCC undergoing salvage/rescue TIPS.
Method: This retrospective multicenter study across 18 centers included consecutive patients with active HCC between 2010 and 2025 who underwent salvage (persistent bleeding despite therapy) and rescue (early rebleeding within 5 days) TIPS for acute variceal bleeding. Mortality at 42 days, overall survival (OS), and HCC-related outcomes were analyzed.
Results: 49 patients with active HCC were included. Viral hepatitis was the main etiology (61%); 78% had prior AVB. Median MELD score was 14, 22% were Child-Pugh C, and 47% ALBI grade 3. Median largest tumor diameter was 29 mm; 59% had a single lesion, 16% macrovascular invasion, and 6% extrahepatic metastases. Most patients were BCLC stage A (47%), and 65% were within Milan criteria. At 42 days, 24% of patients had died. In univariate analysis, older age was the only factor associated with 42-day mortality (HR 1.10, $p = 0.01$); no liver function parameters or HCC-related features were significantly associated with early mortality. Median OS was 17 months and was 24 months in patients within the Milan criteria compared to 9 months with those outside the criteria ($p = 0.14$). In univariate analysis, prothrombin time (HR 0.97, $p = 0.04$), presence of ascites at the time of TIPS (HR 2.39, $p = 0.02$), and pre-TIPS hepatic venous pressure gradient (HR 1.06, $p = 0.039$) were associated with mortality. Rebleeding occured in 10% of patients, hepatic encephalopathy in 39%, and cardiac failure in 6%, and no tumor dissemination was observed at imaging during HCC surveillance. Following salvage/rescue TIPS, 55% of patients received HCC therapy, including liver transplantation (n = 11), ablation (n = 4, all achieving complete response (CR)), locoregional therapies (n = 9; 58% CR, 14% partial response, 14% stable disease, and 14% progressive disease), and systemic treatments (n = 3).
Conclusion: These preliminary data suggest that liver function parameters may influence prognosis more than tumor characteristics. HCC should not been considered as a definite contraindication for rescue TIPS. Validation in a larger cohort, currently being collected, is warranted.

THU-419

Spleen stiffness measurement by VCTE stratifies the risk of high-risk varices in patients with vascular liver disease

Lucie Anémone[1], Théo Izopet[1], Marie-Angèle Robic[1], Sophie Metivier[1], Patricia Soubre[1], Nancy Arnal[1], Assia Bouali[1], Cécile Cussac[1], Clémence Vignon[1], Maxime Castagnede[2], Jean Marie Peron[1], Christophe Bureau[1], Hélène Larrue[1]. *[1]Toulouse university hospital, Toulouse, France; [2]AP-HP Sorbonne Université, Hôpital Universitaire Pitié-Salpêtrière, Paris, France*
Email: anemone.l@chu-toulouse.fr

Background and aims: The Baveno VII consensus suggests that the number of spared endoscopies can be reduced by adding spleen stiffness measurement using vibration-controlled transient elastography (SSM-VCTE) to liver stiffness in patients with compensated advanced chronic liver disease (cACLD). However, in patients with vascular liver disease (VLD), screening endoscopy is currently recommended for all, as liver stiffness is often low despite the presence of portal hypertension (PHT). A recent study showed that SSM-VCTE ≤40 kPa combined with serum bilirubin level <1 mg/dL identifies patients with porto-sinusoidal vascular disorder (PSVD) and PHT with a probability of high-risk varices (HRV) below 5%. The

aim of this study was to evaluate the performance of SSM-VCTE for predicting HRV across the full spectrum of VLD at risk of PHT.
Method: We prospectively included patients with a confirmed diagnosis of VLD who underwent SSM-VCTE (100-Hz FibroScan® probe) and a recent upper gastrointestinal endoscopy. SSM measurements were performed blinded to endoscopic findings. HRV were defined as large esophageal varices, small varices with red wale signs, or a history of endoscopic band ligation.
Results: Eighty-one patients were included. The mean age was 47 ± 15 years, 47% were male, 54% had portal vein cavernoma, and 42% had PSVD (the remaining 4% had other causes of non-cirrhotic PHT). Overall, 51% of patients had HRV. In univariate analysis, lower platelet count, higher SSM-VCTE, elevated serum bilirubin, and the presence of portosystemic collaterals were associated with HRV. In multivariable analysis, only SSM-VCTE remained independently associated with HRV (32.6 ± 21 vs. 68.5 ± 22 kPa). SSM-VCTE demonstrated the highest diagnostic accuracy for HRV, with an AUROC of 0.874 (95% CI 0.791–0.958). Notably, combining an SSM-VCTE cutoff of 35 kPa with serum bilirubin <1 mg/dL identified a subgroup in which no patient had HRV.
Conclusion: In patients with vascular liver disease, SSM-VCTE appears to be a valuable non-invasive tool for ruling out high-risk varices and may allow the avoidance of screening endoscopy in selected patients.

THU-420

Liver and spleen elastographies accuracy in detecting esophageal varices: comparison of MASLD with mixed etiologies populations

Flavia Fernandes[1], Cristiane Tovo[2], Joao Marcello de Araujo Neto[3], Cristiane A. Villela-Nogueira[3], Juliana Piedade[4], Victoria Verissimo[1], Pedro Machado[1], Andrew Fernandes[1], Natalia Wajbrot[3], Liliana Mendes[5], Claudia Pinto Oliveira[6], Gleicy Pereira[6], Marcelo Chagas[1], Daniela Louro[5], Luisa Amorim[7], Natalia Ayres[2], Aik Martins[8], Hugo Perazzo[9], Carlos Antonio Rodrigues Terra Filho[1].

Email: ffernandes.flavia@gmail.com

Background and aims: Esophageal varices (EV) define clinically significant portal hypertension with high prognostic value. Recently, liver (LSM) and spleen (SSM) stiffness measurement by transient elastography have been used as noninvasive tests (NITS) for the presence of EV.
To evaluate LSM and SSM as NITS for diagnosing EV in patients with compensated cirrhosis of mixed etiologies comparing their performance with those with MASLD.
Method: Prospective, multicentric study, in individuals with cirrhosis of mixed etiologies and MASLD, without previous decompensation, submitted to EV screening by upper GI endoscopy, LSM and SSM (Fibroscan 630) within a maximal interval of one year.
Results: Included individuals were divided into two groups: general group (GG) with mixed etiologies and MASLD group (MG). In the GG (n = 288); 51.4% were female; 55% type 2 diabetes (T2DM); 41% had EV; mean age 64 ± 13 years; BMI 28.4 ± 6; waist circumference 100 (±14) cm; spleen length 12.6 ± 2.8 cm; platelet count 137.000 (± 68.000); LSM 15.5 ± 15 kPa; SSM 39.0 ± 20 kPa; SSM failure 8.3%. In patients without EV when compared to patients with EV mean LSM (16.6 ± 12 kPa vs 27.5 ± 18, p 0,001) and SSM (35.8 ± 17 kPa vs 52.2 ± 21, p 0,001) were significantly lower. In AUROC analyses the best cut-off points for EV detection were 15.0 kPa (AUROC 0.72; CI 95%: 0.66–0.78) for LSM, and 48.0 kPa (AUROC 0.73; CI 95% 0.67–0.80) for SSM. In the MG (n = 129); 71% were female; 80% T2DM; 39.5% had EV; mean age 64 ± 9 years; BMI 30 ± 5.6; waist circumference 107 ± 13 cm; spleen length 12.7 ± 2.6 cm; platelet count 137.000 ± 68.000, LSM 18.6 ± 16 kPa; SSM 41.15 ± 19 kPa; SSM failure 11,6%. In patients without EV when compared to patients with EV mean LSM (19.0 ± 13 kPa vs 29.0 ± 18, p 0,001) and SSM (37.0 ± 15 kPa vs 53.0 ± 20.0, p 0,001) were significantly lower. In AUROC analyses the best cut-off points for EV detection were 21.0 kPa (AUROC 0.72; CI 95%: 0.63–0.82) for LSM, and 48.0 kPa (AUROC 0.74; CI 95% 0.65–0.83) for SSM. Groups characteristics were similar except for gender and T2DM prevalence.
Conclusion: In a population with high BMI and waist circumference both LSM and SSM performed well in detecting EV in patients with compensated cirrhosis. In the MASLD group LSM, but not SSM, cut-off point for detecting EV was higher than in the mixed etiologies group. There was no significant difference in LSM and SSM feasibility and accuracy when comparing patients with MASLD cirrhosis to other etiologies.

THU-421

High five-year incidence of portal vein thrombosis after acute variceal bleeding in cirrhosis

Tomàs Balari[1], Maria Garcia Guix[1,2], Alberto Amador[1,2], Alba Cachero[1], Rosa Rota[1], José Castellote Alonso[1,2], Teresa Broquetas[1]. *[1]Bellvitge University Hospital, Hepatology unit, L'Hospitalet de Llobregat, Spain; [2]Universitat de Barcelona - Campus Bellvitge, L'Hospitalet de Llobregat, Spain*
Email: tbalari@bellvitgehospital.cat

Background and aims: The incidence of portal vein thrombosis (PVT) in patients with cirrhosis is estimated at 1–4%, 6–8%, and 10% at 1, 3, and 5 years, respectively. Acute variceal bleeding (AVB) has been associated with an increased risk of PVT. Although metabolic dysfunction-associated steatotic liver disease (MASLD) is linked to a higher thromboembolic risk, its contribution to PVT remains unclear. This study aimed to assess the incidence of PVT following AVB and to determine whether MASLD or metabolic factors are associated with increased PVT rates.
Method: This retrospective observational study included consecutive patients with cirrhosis admitted for AVB between 2013 and 2021. Exclusion criteria were prior or baseline PVT, transjugular intrahepatic portosystemic shunt (TIPS), anticoagulation, follow-up <6 months, or absence of semi-annual abdominal imaging. Clinical, laboratory, and endoscopic variables were recorded at the time of AVB.
Results: A total of 315 patients with AVB were screened. Sixty-five (20.6%) were excluded due to PVT at admission, 28 (8.8%) underwent TIPS, and 64 (20.3%) had follow-up <6 months. Ultimately, 139 patients were included. Median age was 60 years (IQR 50–68); Child-Pugh class was A/B/C in 28.8%, 57%, and 13.7%, respectively. Alcohol-related liver disease (ALD) was the leading etiology (48.6%), while MASLD accounted for 12.3%. During a median follow-up of 47 months (IQR 17–73), 36 patients (25.9%) developed PVT. Cumulative incidence was 6.5%, 16.5%, and 21.6% at 1, 3, and 5 years. Notably, 22% of cases occurred within the first 6 months, and 55.6% involved the main portal vein. Incidence among MASLD patients was 29.4% versus 25.4% in non-MASLD cirrhosis (p = 0.43). Baseline prevalence of hypertension, diabetes, dyslipidemia, and obesity was 46.8%, 38.1%, 21.6%, and 29.6%, respectively; none were significantly associated with PVT. Liver function parameters, including MELD score and decompensation events, were not linked to increased PVT risk.
Conclusion: Up to 21.6% of patients may develop PVT within 5 years after AVB, representing a higher incidence than reported in unselected cirrhotic populations. Neither MASLD nor metabolic risk factors were associated with increased PVT risk, although the low prevalence of MASLD in this cohort is a limitation. These findings warrant validation in cohorts with greater MASLD representation.

THU-425

Partial splenic embolization (PSE) for the prevention of variceal rebleeding in patients unsuitable for OLTx, TIPS, and endovascular treatment: safety and mortality

Marcello Bianchini[1], Chiara Gualandri[2], Dario Saltini[1], Tomas Guasconi[1], Antonio Piscopo[3], Giustina Lo Cascio[3], Andrea Salomè Velasco Mayorga[3], Federico Casari[4], Giovanni Battinelli[5], Ascari Francesco[4], Francesco Prampolini[5], Cristian Caporali[4], Filippo Schepis[1,2]. *[1]Severe Liver Diseases (M.E.C.) Departmental Unit, Department of Medical Specialties, University, European Reference Network on Rare Liver Disorders (ERN Rare- Liver), Modena, Italy; Hospital of Modena "Policlinico", University of Modena and Reggio Emilia, Modena, Italy; [2]Università di Modena e Reggio Emilia-Unimore, Modena, Italy; [3]Gastroenterology Unit, Department of Medical Specialties, University Hospital of Modena "Policlinico", University of Modena and Reggio Emilia, Italy, Modena, Italy; [4]Interventional Radiology, Departmental Unit, Department of Diagnostic Imaging, University Hospital of Modena "Policlinico", Italy, Modena, Italy; [5]Radiology Unit, Departmental Unit, Department of Diagnostic Imaging, University Hospital of Modena "Policlinico", University of Modena and Reggio Emilia, Italy, Modena, Italy*
Email: marcello.bianchini@gmail.com

Background and aims: Partial splenic embolization (PSE) is widely used to treat hypersplenism and its symptoms. While its effects on portal hypertension are documented, they remain partly defined. Aim is to evaluate the safety and efficacy of PSE as secondary prophylaxis for variceal bleeding in patients ineligible for orthotopic liver transplantation (OLTx), transjugular intrahepatic portosystemic shunt (TIPS), and other endovascular treatments (EVT).
Method: All PSE since January 2017 were retrospectively reviewed. Inclusion criteria: active or recent variceal bleeding excluded from OLTx, TIPS, and EVT. Traumatic splenic rupture and absence of informed consent were excluded. Clinical, endoscopic, and imaging data were collected as well as complications. Long-term rebleeding-free survival was established as primary outcome.
Results: 21 patients were included (43% male; mean age 57 y). 10 patients (47.6%) had cirrhosis, of whom 2 had portal vein thrombosis (PVT). Among the other patients, 8 (72%) had PVT/cavernoma. 5 had JAK2-related myeloproliferative neoplasms and 1 Factor V Leiden mutation. 18 patients (85%) had prior decompensation. At the time of PSE, 4 patients had active bleeding and 17 had hi-risk varices. 9 had ascites, recurrent in 3 cases. Mean hemoglobin was 10.3 g/dL, median platelet count 73×10^9/L, mean MELD-Na was 12. Embolization techniques included acrylic glue (29%), coils (28%), microparticles (15%), and combined (28%). Mean devascularized splenic volume was 65%. Adverse events occurred in 90%: 85% were minor complications, mainly post-embolization syndrome and pleural effusion. 3 cases (15.7%) had new-onset ascites. 2 patients developed splenic vein thrombosis resolved with anticoagulation. No splenic abscesses occurred. Sepsis developed in 4 cases. During 5-year follow-up, variceal rebleeding occurred in 2 cases (9.5%). 8 patients (38%) died during follow-up, 2 within 3 months; all had decompensated cirrhosis, sarcopenia, and multiple comorbidities at the time of PSE. All patients with acute variceal bleeding survived the procedure without rebleeding. Rebleeding-free survival rates were 95.8% at 30 days, 75.3% at 1 y, 70.3% at 2 y, and 42.5% at 5 y.
Conclusion: PSE is effective as secondary prophylaxis for variceal rebleeding in patients excluded from OLTx, TIPS, and EVT. Post-procedural complications are frequent and mortality may occur in patients with uncontrolled ascites, sarcopenia, and multiple comorbidities suggesting that PSE should be performed in centers with consistent expertise.

THU-426

Efficacy and safety of endoscopic and endovascular interventions for secondary prophylaxis of gastric varices in patients with cirrhosis: systematic review and individual patient data meta-analysis

Sagnik Biswas[1], Arnav Aggarwal[1], Gin-Ho Lo[2], Luo Xuefeng[3], Li Yang[3], Angels Escorsell[4], Shubham Mehta[1], Shekhar Swaroop[1], Samagra Agarwal[1], Ayush Agarwal[1], Ashwani Mishra[1], Shashank Tripathi[5], Deepak Gunjan[1], Shivanand Gamangatti[1], Shalimar[1]. *[1]All India Institute of Medical Science, New Delhi, India; [2]E-Da Cancer Hospital, Yanchao District, Taiwan; [3]University of Oxford Hauxi Joint Centre for gastrointestinal cancer, West China Hospital, Sichuan University, Sichuan, China; [4]Hospital de Sant Pau, Barcelona, Spain; [5]University College of Medical Sciences, New Delhi, India*
Email: sagnik_biswas@yahoo.co.in

Background and aims: Multiple endoscopic and endovascular modalities are available for the management for gastric variceal hemorrhage in cirrhosis, however, there is no consensus on the optimal modality of secondary prophylaxis in these patients.
Method: Observational studies and randomized controlled trials (RCTs) comparing the efficacy of endoscopic cyanoacrylate injection (ECI) and endovascular interventions-balloon occluded retrograde transvenous obliteration [BRTO] and transjugular intrahepatic portosystemic shunt [TIPS] in preventing variceal rebleeding published till 2024 were included in the aggregate data meta-analysis (ADMA). Individual patient data (IPD) from RCTs were collated and compared (BRTO vs ECI, TIPS vs ECI) in a propensity score matched population. Competing risk analysis was used to compare the rates of the all-cause rebleeding and new onset/worsening of pre-existing ascites and hepatic encephalopathy among patients receiving ECI, BRTO and TIPS.
Results: Fifteen studies (4 randomized controlled trials and 11 observational studies) comprising 1240 patients (ECI: 377, BRTO: 575, TIPS: 288) were included in the ADMA. In the IPD, both BRTO (sHR: 0.15; 95% CI: 0.05–0.43; p = 0.004) and TIPS (sHR: 0.49; 95% CI: 0.27–0.89; p = 0.019) significantly reduced all-cause rebleeding compared to ECI, without any improvement in overall survival. BRTO was associated with higher risk of new-onset or worsening of pre-existing ascites (sHR: 3.54; 95% CI: 1.31–9.55, p = 0.013), while TIPS increased risk of hepatic encephalopathy (sHR: 8.84; 95% CI: 2.0–39.11, p = 0.004) compared to ECI. Reduction in the rates of rebleeding was most pronounced among Child-Pugh Class-B patients. The analysis revealed limited long-term outcomes data, inhomogeneous inclusion criteria, inconsistencies in reported trial outcomes and significant heterogeneity particularly in studies regarding TIPS.
Conclusion: Endovascular interventions (BRTO and TIPS) are superior to ECI for reducing all-cause rebleeding in patients with cirrhosis and GV hemorrhage. Larger studies with standardized end-points and longer follow-up duration are needed to clarify the impact of these interventions on overall survival and optimize treatment selection.

THU-427

A single tertiary centre audit of adherence to Baveno VII in chronic liver disease: missed opportunities for cost-savings, CO2 emission reductions and improved health resource utilisation?

Benedict Brazier[1], Johnny Phillips[2], Zarin Chowdhury[2], Steven Dixon[3], Ann Archer[1,2], Kushala Abeysekera[1,2]. *[1]Department of Liver Medicine, University Hospitals Bristol and Weston NHS Trust, Bristol, United Kingdom; [2]Bristol Medical School, University of Bristol, Bristol, United Kingdom; [3]Department of Gastroenterology, University Hospitals Bristol & Weston NHS Trust, Bristol, United Kingdom*
Email: benedict.brazier@uhbw.nhs.uk

Background and aims: The Baveno VII consensus has reshaped the assessment and management of clinically significant portal hypertension (CSPH) in compensated advanced chronic liver disease. Application of Baveno VII criteria reduces referrals for gastroscopy

(OGD), with wider environmental and health resource utilisation implications. Despite this, practice across centres varies. We audited adherence to Baveno VII guidance in our regional tertiary unit, which serves a population of approximately half a million people.
Method: All OGDs performed for variceal surveillance and screening at Bristol Royal Infirmary from 23/02/2022–30/09/2025 were audited, along with patient level data using electronic healthcare records. Exclusion criteria included variceal screening in: patients under 18 years of age, pregnancy, clinical trial participation, involvement in a banding programme, prior transjugular intrahepatic portosystemic shunt, liver transplant patients, hepatocellular carcinoma, Fontan circulation, non-cirrhotic portal hypertension. Estimates for carbon dioxide (CO2) emission and water usage in OGDs were based on published data. Cost estimates were based on existing UK National Health Service tariffs.
Results: 447 variceal screening OGDs were identified within the study period. 208 were excluded. 239 procedures were interrogated; 57/239 (23.8%) were clinically indicated, most commonly due to new decompensating events. 182 OGDs were performed for variceal screening without a specific indication. 87/182 (47.8%) patients had a screening OGD without up-to-date transient elastography and/or platelet count. 55 (30.2%) should have had non-selective beta blockers (NSBBs) initiated without an OGD, 4 (7.27%) of whom only received NSBBs prior to OGD. 40/182 (22.0%) had a screening OGD despite not meeting any Baveno VII criteria for CSPH. Notably, 1 case was identified where Baveno VII criteria for CSPH was not met but the patient required banding. For the 182 OGDs not indicated, estimated water consumption was 1604.8L, approximate cost to the healthcare system € 176,603 and CO2 emissions 5168.8 kg, equivalent to driving over 37000 km in a gasoline vehicle.
Conclusion: In our centre, we have identified a high number of potentially unnecessary variceal screening OGDs performed. Adherence to Baveno VII guidance has the potential to have significant environmental and cost-saving benefits for healthcare providers. Exploring barriers to adherence amongst clinicians is important to reduce wastage.

THU-428
CVID-associated porto-sinusoidal vascular disorder: is splenomegaly uncoupled from portal hypertension?

Francisco Capinha[1,2], Carlos Noronha Ferreira[1,2], Rui Palma[1], Sofia Carvalhana[1], Luís Correia[1,2], Helena Cortez-Pinto[1,2]. [1]*Serviço de Gastrenterologia e Hepatologia, Unidade Local de Saúde de Santa Maria, Lisboa, Portugal;* [2]*Clínica Universitária de Gastrenterologia, Faculdade de Medicina de Lisboa, Universidade de Lisboa, Lisboa, Portugal*
Email: francisco.capinha96@gmail.com

Background and aims: Common Variable Immunodeficiency (CVID) is a well-established cause of Porto-Sinusoidal Vascular Disorder (PSVD). These patients frequently present with large splenomegaly, however, it remains unclear whether this splenic enlargement reflects severe portal hypertension or a distinct pathophysiological mechanism. We aimed to determine if the phenotype of CVID-associated PSVD differs from non-CVID forms, specifically regarding the relationship between splenomegaly and signs of portal hypertension.
Method: We performed a retrospective comparative analysis of 23 patients with biopsy-proven PSVD (9 with CVID vs. 14 non-CVID), between 2017 and 2025, who underwent transjugular liver biopsy and hepatic venous pressure gradient (HVPG) measurement. Continuous variables were compared using the Mann-Whitney U test, and categorical variables using exact Fisher's test. Correlation analyses assessed the relationship between platelet counts and spleen size. Statistical significance level was defined as $p < 0.05$.
Results: The CVID cohort exhibited massive splenomegaly, significantly larger than the control group (mean 19.4 vs. 15.5 cm, $p = 0.027$). The HVPG values were similar between groups (10.4 vs. 9.4 mmHg, $p = 0.59$). These relatively low values, in both groups, reflect the predominantly presinusoidal nature of PSVD, which is not well evaluated by HVPG. As expected, platelet counts were strongly inversely correlated with spleen size in both groups (CVID: $r = -0.89$, $p = 0.001$; non-CVID: $r = -0.77$, $p = 0.006$ after excluding 2 outliers with myeloproliferative neoplasm) while the diference between groups is not significative ($p = 0.33$), as happens also to the presence of portosystemic collaterals ($p = 0.09$), other sign of portal hypertension. Biochemically, CVID patients have higher AST levels (46.1 vs. 29.5 U/L, $p = 0.007$) and a trend towards higher ALT ($p = 0.15$). The CVID phenotype appeared less thrombotic, with no portal vein thrombosis in our group (vs. 28.6% in controls).
Conclusion: In CVID-associated PSVD, splenomegaly appears uncoupled from portal hypertension severity, differently from other etiologies of PSVD. This suggests that other mechanisms drive splenomegaly beyond passive congestion, what could, eventually, be related with the chronic/recurrent gastrointestinal tract inflammation in these patients. This distinct phenotype reinforces the need for invasive hemodynamic assessment as a surrogate marker and a potentially distinct hemodynamic behavior and disease progression in this subgroup of patients.

THU-429
The evolving role of TIPS: from established indications to real-world practice

Ylenia Capraro[1], Leonard Lamfu[1], Ilaria Lenci[1], Martina Milana[1], Renato Argirò[1], Daniele Morosetti[1], Leonardo Baiocchi[1]. [1]*Tor Vergata University of Rome, Rome, Italy*
Email: capraro.capraroylenia@gmail.com

Background and aims: Transjugular intrahepatic portosystemic shunt (TIPS) is a procedure that creates a communication between the portal and hepatic veins to reduce portal hypertension (PH). Traditionally indicated for PH-related bleeding and refractory ascites (RA), TIPS is now increasingly used for portal vein thrombosis (PVT) and severe PH (e.g., very low or hepatofugal portal flow or high-flow collateral vessels), particularly in patients requiring surgery. It is also applied as a bridge to liver transplantation (LT) to prevent decompensation and preserve vascular structures during the waiting period. We aimed to evaluate: i) the evolution of TIPS indications in cirrhotic patients at our Hepatology Unit; ii) the survival outcome according to TIPS indications; iii) the results of TIPS as a bridge to LT.
Method: We retrospectively analyzed patients who underwent TIPS at our center from June 2014 to June 2025 with at least 3 months of follow-up. Demographic data, liver and renal function tests, and MELD scores were collected at baseline and at 1 and 3 months post-procedure. Data were stratified by TIPS indication and/or bridge to LT. Continuous variables were analyzed with t-test or ANOVA, and discrete variables with Fisher's test. Survival analysis was performed using Log-rank test. A $p < 0.05$ was considered significant.
Results: A total of 107 patients were included. Over time, TIPS indications for RA and GI bleeding significantly decreased (90% in 2014–17 vs 41% in 2022–25, $p < 0.001$), while indications for PVT and severe PH increased (5% vs. 44%, $p = 0.002$). Patients with RA had higher baseline creatinine levels than other groups (1.3 vs 0.8 mg/dL, $p < 0.01$) and showed significantly lower survival after TIPS ($p = 0.02$, Log-rank test). 49 TIPS were performed as a bridge to LT and 73% of these patients underwent transplantation. This group had higher MELD scores at baseline and at 1 and 3 months ($p < 0.05$). Short-term (3–6 months) survival did not differ significantly, whereas long-term survival (>6 months) markedly decreased in patients who did not undergo LT despite TIPS placement for bridging purposes.
Conclusion: Our single-center retrospective analysis suggests that: i) TIPS use has expanded beyond traditional indications; ii) TIPS for RA appears suboptimal in terms of survival, compared to other PH-related indications; iii) when used as a bridge to LT, TIPS does not affect short-term survival despite higher MELD scores. However,

long-term outcomes are poor in patients who do not ultimately undergo LT.

THU-430

Impact of continuing versus discontinuing nonselective beta blockers after transjugular intrahepatic portosystemic shunt on one-year clinical outcomes

Ali Emre Bardak[1], Gizem Teker[2], Hind El Naamani[1], Volkan Senkal[3], Bilger Çavuş[3]. [1]*Boston Medical Center – Brighton, Boston University, Boston, United States;* [2]*Beth Israel Deaconess Medical Center, Boston, United States;* [3]*Department of Gastroenterology, Istanbul University, Istanbul, Türkiye*
Email: bardakaliemre@gmail.com

Background and aims: Nonselective beta-blockers (NSBBs) reduce portal pressure and prevent variceal bleeding in patients with cirrhosis, but their benefit after transjugular intrahepatic portosystemic shunt (TIPS) is debatable, with recent evidence supporting careful discontinuation once portal decompression is achieved. Despite this, post-TIPS NSBB management varies widely, and real-world data are limited. Using a large, multicenter, real-world cohort, we aimed to compare clinical outcomes in patients who continued or discontinued NSBB after TIPS.
Method: Using the TriNetX US Collaborative Network, we identified adults with cirrhosis who underwent TIPS and had been prescribed an NSBB within the preceding year. Patients who did not survive to post-TIPS day 90 were excluded to ensure comparable early postprocedural stability. Patients were then classified according to post-TIPS NSBB use: continuation was defined as receiving an NSBB prescription within 90 days after the procedure, whereas discontinuation was defined as having no NSBB prescriptions recorded after TIPS. Propensity score matching was performed to balance baseline characteristics, including demographics, comorbidities, and pre-TIPS MELD scores. Outcomes were assessed from post-TIPS day 90 through year 1. Kaplan–Meier analyses and risk estimates were used.
Results: After matching, 1,350 patients remained in each group, with balanced baseline characteristics and a median follow-up of 365 days. Continuation of NSBBs after TIPS did not improve overall survival (HR 0.87, 95% CI 0.68–1.11) or transplant-free survival (HR 0.89, 95% CI 0.75–1.05). NSBB continuation was associated with significantly higher hazards of hepatic encephalopathy (HR 1.29, 95% CI 1.11–1.51) and hospitalization (HR 1.23, 95% CI 1.08–1.39). Rates of ICU admission (HR 1.03, 95% CI 0.84–1.25) and esophageal variceal bleeding (HR 1.08, 95% CI 0.78–1.49) did not differ significantly.
Conclusion: In this study, continuation of NSBBs after TIPS did not improve overall or transplant-free survival. Instead, NSBB use was associated with higher hazards of hepatic encephalopathy and hospitalization, while rates of ICU admission and variceal bleeding were similar between groups. These findings suggest that the hemodynamic benefits of NSBBs diminish once portal hypertension is decompressed and that their post-TIPS physiologic effects may contribute to worsened encephalopathy. The results support a more individualized approach to NSBB management following TIPS rather than routine continuation.

THU-431

Oral branched-chain amino acids supplementation in patients with cirrhosis and sarcopenia undergoing TIPS for refractory ascites: a randomized controlled trial

Ciro Celsa[1], Luigi Maruzzelli[2], Vincenza Calvaruso[1], Federico Midiri[2], Angelo Luca[2], Roberto Miraglia[2], Calogero Cammà[1]. [1]*Section of Gastroenterology and Hepatology, Department of Health Promotion, Mother and Child Care, Internal Medicine and Medical Specialties, University of Palermo, Palermo, Italy;* [2]*IRCCS ISMETT (Mediterranean Institute for Transplantation and Advanced Specialized Therapies), Palermo, Palermo, Italy*
Email: calogero.camma@unipa.it

Background and aims: Sarcopenia is common in patients with cirrhosis and refractory ascites (RA) undergoing transjugular intrahepatic portosystemic shunt (TIPS), associated with poor outcomes. Branched-chain amino acids (BCAA) may improve nutritional status and reduce inflammation. We evaluated oral BCAA supplementation impact on clinical, inflammatory and nutritional outcomes in patients with cirrhosis and sarcopenia undergoing TIPS for RA.
Method: We conducted a randomized controlled trial (RCT) at a single high-volume referral center (>20 TIPS/year) enrolling 37 patients with cirrhosis and sarcopenia undergoing TIPS for RA. Patients received oral BCAA supplementation (n = 18) or standard care (n = 19). Endpoints included clinical events (mortality, persistence of ascites and hepatic encephalopathy [HE] at the end of follow-up) and between- and within-group changes in nutritional parameters and inflammatory biomarkers from baseline (TIPS placement) and the last follow-up visit.
Results: Baseline characteristics were similar between groups except age (mean 57.3 ± 8.5 in BCAA versus 64.4 ± 9.4 years in controls, p = 0.018). After a median follow-up time of 5.8 months, no significant between-group differences were observed in clinical events, inflammatory and nutritional parameters. Six-month overall survival was 100% in BCAA versus 85.1% in controls (p = 0.157). Persistence of grade≥2 ascites was observed in 11.8% of BCAA arm versus 23.5% in control arm (p = 0.375). Grade≥2 HE was the same (11.8%) between arms. The BCAA arm showed significant within-group improvements in inflammatory markers: interleukin-6 decreased by 74.46 ± 88.35 pg/mL (p = 0.014) and interleukin-8 by 13.51 ± 17.5 pg/mL (p = 0.022). Nutritional parameters improved significantly in BCAA: fat-free mass increased by 5.2 ± 3.17 kg (p = 0.001), psoas muscle area by 4.02 ± 3.93 cm^2 (p = 0.016), and mid-arm muscle circumference by 1.35 ± 2.32 cm (p = 0.049). Body weight gain was lower in BCAA versus controls (4.1 ± 6.5 versus 9.5 ± 5.3 kg, p = 0.022). BCAA supplementation was safe with comparable adverse events.
Conclusion: In this ongoing RCT, oral BCAA supplementation was associated with favorable within-group changes in inflammatory biomarkers and nutritional parameters in cirrhotic patients with RA undergoing TIPS. Although between-group differences did not reach statistical significance in this interim analysis, these findings support biological plausibility and safety of oral BCAA, with enrollment continuing.

THU-432

Validation of albumin-bilirubin-platelet (ALBI-PLT), modified ALBI-PLT, and EVendo score for predicting varices needing treatment (VNT) in patients with hepatocellular carcinoma

Nuprawee Changsiriwattanathomrong[1], Pongnarin Nawalerspunya[1], Naichaya Chamroonkul[1], Apichat Kaewdech[1], Pimsiri Sripongpun[1]. [1]*Prince of Songkla University, Division of Internal Medicine, Faculty of Medicine, Hat Yai, Thailand*
Email: pim072@hotmail.com

Background and aims: Variceal bleeding significantly impairs prognosis in patients with hepatocellular carcinoma (HCC), especially with the emergence of immunotherapy/anti-angiogenic combinations as standard care. As routine endoscopic screening for varices needing treatment (VNT) is invasive and Baveno VI criteria perform suboptimally in HCC, reliable non-invasive alternatives are needed. This study validated and compared the ALBI-PLT, modified ALBI-PLT (mALBI-PLT), and EVendo scores for predicting VNT in HCC patients.
Method: We conducted a retrospective study in patients with newly diagnosed HCC at a tertiary center between Jan 2021 and Dec 2024. Those who underwent screening endoscopy (EGD) within a window of 3 mo prior to or 6 mo following their HCC diagnosis were included. Patients with prior variceal bleeding or previous HCC treatment from other centers were excluded. Laboratory data closest to the EGD were used to calculate ALBI, ALBI-PLT, mALBI-PLT, and EVendo scores. Diagnostic performance of each score for the diagnosis of VNT was

evaluated using the area under the receiver operating characteristic curve (AUROC) and compared withDeLong's test.
Results: Of 434 patients who were screened, 127 were eligible (71.6% male; mean age 63.1 years). VNT was found in 26%. BCLC stages were: 0/A (42.5%), B (29.1%), and C/D (28.3%). Portal vein thrombosis (PVT) was present in 22.8% and was more frequent in the VNT group (36.4% vs 18.1%, p = 0.056). Presence of ascites was more common in the VNT group (36.4% vs 11.7%, p = 0.004), but the maximal tumor size was comparable. ALBI and EVendo demonstrated the highest discriminative ability, with AUROCs of 0.706 (95% CI: 0.605–0.807) and 0.703 (95% CI: 0.604–0.802), respectively. ALBI-PLT (0.658, 95%CI 0.567–0.749) and mALBI-PLT (0.656, 95%CI: 0.565–0.748) showed modest performance. AUROC differences were not statistically significant (p > 0.05). ALBI >−2.43 achieved 100% sensitivity but poor specificity (3.48%), whereas EVendo >3.9 yielded 93.75% sensitivity (p = 0.157 vs ALBI) but significantly higher specificity (36.78%, p < 0.001).
Conclusion: ALBI and EVendo demonstrated fair performance for identifying VNT, with EVendo offering a superior balance between sensitivity and specificity. However, AUROCs near 0.70 suggest suboptimal discriminative ability overall. ALBI-PLT and mALBI-PLT showed unsatisfactory performance in predicting VNT in our HCC cohort. Further research is required to refine non-invasive strategies to reduce unnecessary endoscopic screening in HCC.

THU-433-YI
Prevalence, dynamics, and clinical impact of sarcopenia in acute and chronic non-cirrhotic non-tumoral portal vein thrombosis
Rares Craciun[1], Lucile Moga[2], Andreea Fodor[1], Andrada Nemes[3], Pierre-Emmanuel Rautou[2], Maxime Ronot[4], Xingshun Qi[5], Aurélie Plessier[2], Bogdan Procopet[1]. *[1]Gastroenterolgy Department, "Prof. Dr. O. Fodor" Regional Institute of Gastroenterology and Hepatology, Department of Internal Medicine, "Iuliu Haţieganu" University of Medicine and Pharmacy, Cluj-Napoca, Romania, Cluj-Napoca, Romania; [2]Service d'Hépatologie, AP-HP, Hôpital Beaujon, DMU DIGEST, Centre de Référence des Maladies Vasculaires du Foie, FILFOIE, ERN RARE-LIVER, Clichy, France; [3]Department of Anesthesia and Intensive Care, "Iuliu Haţieganu" University of Medicine and Pharmacy, Cluj-Napoca, Romania; [4]Department of Medical Imaging, Beaujon University Hospital, Clichy, France; [5]Department of Gastroenterology, General Hospital of Northern Theater Command, Shenyang, China*
Email: rarescraciun@ymail.com

Background and aims: Sarcopenia is a well-recognized prognostic factor in cirrhosis, but data in non-cirrhotic non-tumoral portal vein thrombosis (NCNTPVT) are scarce. We aimed to evaluate the prevalence and longitudinal evolution of sarcopenia and its association with portal hypertension–related complications in patients with recent and chronic NCNTPVT.
Method: We analyzed a multicenter cohort of patients with recent and chronic NCNTPVT undergoing contrast-enhanced CT at diagnosis (T0) and follow-up ≥6 months (T1). Skeletal muscle index (SMI) was assessed at the L3 level. Sarcopenia was defined using sex-specific cut-offs (women <38 cm^2/m^2; men <43 cm^2/m^2 if BMI<25, <53 cm^2/m^2 if BMI≥25). Changes in SMI were evaluated using paired Wilcoxon tests. Associations between baseline sarcopenia and the presence of ascites, gastrointestinal bleeding, and hepatic encephalopathy at T0 and T1 were assessed using χ^2 or Fisher's exact tests.
Results: 126 patients with recent and 102 with chronic PVT were included. Sarcopenia at T0 was highly prevalent in both groups (acute: 59.5%, 75/126; chronic: 66.6%, 68/102). In recent PVT, median SMI remained stable between T0 and T1 (43.04 vs. 43.41 cm^2/m^2; median Δ +0.08 cm^2/m^2; p = 0.56),after a median interval of 6.6 (4.5–11.3 months). In chronic PVT, median SMI showed no significant change over time (median 11 months), 41.90 vs. 41.60 cm^2/m^2; median Δ−0.17 cm^2/m^2; p = 0.70. In patients with recent PVT, sarcopenia was more prevalent in those with BMI >25 vs. <25 kg/m^2 (65.3% vs. 52.5%, p = 0.26), while BMI was weakly but significantly inversely correlated with SMI (r = -0.24, p = 0.011). Sarcopenia appeared to be independent of thrombotic extent or etiology in both recent and chronic PVT. In patients with chronic PVT, baseline sarcopenia was significantly associated with the presence of ascites (32.1% vs. 14.3%, p = 0.04) at T0, history of portal hypertension-related bleeding (25% vs. 10.7%, p = 0.05), and hepatic encephalopathy (14.1% vs. 3.6%, p = 0.14). Furthermore, sarcopenia at T0 was significantly associated with the presence of ascites at T1 (42.3% vs. 19.2%; p = 0.038).
Conclusion: Sarcopenia is highly prevalent in NCNTPVT. While no significant global changes in muscle mass were observed during follow-up, baseline sarcopenia in chronic PVT identified patients at increased risk for portal hypertension-related complications. These findings support routine assessment of sarcopenia as a clinically relevant prognostic marker in NCNTPVT.

THU-434
Non-invasive integration of systemic hemodynamics and spleen stiffness across disease stages in cirrhosis
Martín Elizondo[1], Eugenia Ipar[2], Romina Rey[1], Leandro Cymberknop[2], Marcelo Vicente Valverde Gomez[1], Ricardo Armentano[3], Solange Gerona[1]. *[1]Unit of Liver Transplantation, Hospital Militar, Montevideo, Uruguay; [2]Universidad Tecnológica Nacional, Facultad Regional Buenos Aires, Grupo de Investigación y Desarrollo en Bioingeniería (GIBIO), Buenos Aires, Argentina; [3]Department of Biological Engineering, CENUR Litoral Norte, Universidad de la República, Paysandú, Uruguay*
Email: melizondo20@gmail.com

Background and aims: Cirrhosis is characterized by progressive changes in portal hypertension and systemic circulatory dysfunction during disease evolution. Spleen stiffness measurement (SSM) is a validated non-invasive surrogate of clinically significant portal hypertension, whereas impedance cardiography enables characterization of systemic hemodynamics. The aim of this study was to evaluate the relationship between spleen stiffness and systemic hemodynamic alterations, and to explore their association with disease severity according to Child–Pugh (CP) class.
Method: We studied 56 subjects, including 44 patients with cirrhosis (CP A: n = 20; CP B: n = 12; CP C: n = 8) and 12 healthy controls. Spleen stiffness was assessed by transient elastography. Systemic hemodynamics were evaluated using impedance cardiography, obtaining cardiac output (CO), systemic vascular resistance (SVR), and arterial compliance (AC), which were analyzed individually and jointly integrated into a composite Hemodynamic Valuation Index (HVI), calculated as the square root of the sum of the squared, standardized values of these parameters and serving as a composite, physiologically grounded descriptor of systemic circulatory status. Group comparisons were performed using analysis of variance or Welch's test, as appropriate. Associations were assessed using Pearson or Spearman correlation coefficients.
Results: SSM was significantly higher in patients with cirrhosis compared with controls (p < 0.001). Although differences across CP classes were not statistically significant (p = 0.238), SSM showed a progressive increase with advancing disease stage. The composite HVI differed significantly across CP classes (p = 0.047), with higher values in CP B compared with CP A and CP C, indicating a more pronounced hyperdynamic circulatory profile at intermediate disease stages. Among individual systemic hemodynamic parameters, AC was the only variable significantly associated with SSM, showing a moderate inverse correlation (r = – 0.30; p = 0.033), whereas CO and SVR were not.
Conclusion: Combined assessment of spleen stiffness and systemic hemodynamics provides an integrated characterization of circulatory dysfunction in cirrhosis. While SSM primarily reflects portal hypertension severity, the composite hemodynamic index highlights a distinct hyperdynamic profile in CP B. These findings warrant confirmation in prospective studies across the spectrum of cirrhosis.

THU-435

Prevalence and risk factors of esophageal and gastroesophageal varices in myeloproliferative neoplasm patients with portal hypertension in a tertiary government hospital: a 5-year cross-sectional study

Sam Fandood[1]. [1]*East Avenue Medical Center, Quezon, Philippines*
Email: samfandood@gmail.com

Background and aims: Myeloproliferative neoplasms (MPNs) are an established cause of non-cirrhotic portal hypertension and may lead to gastroesophageal varices with significant clinical consequences. However, local data on the burden of varices and associated risk factors among MPN patients remain limited.
Method: This cross-sectional study included 40 adult patients diagnosed with MPNs who underwent esophagogastroduodenoscopy at a tertiary government hospital between 2021 and 2025. Sociodemographic, clinical, laboratory, and endoscopic data were obtained through chart review. The prevalence of gastroesophageal varices was determined. Logistic regression analyses were performed to identify clinicodemographic factors associated with the presence of varices.
Results: Varices were identified in 23 patients (57.5%), including esophageal varices alone in 27.5%, gastric varices alone in 2.5%, and combined esophageal and gastric varices in 27.5%. Varices were most prevalent among patients with primary myelofibrosis (78.9%), followed by polycythemia vera (45.5%) and chronic myeloid leukemia (30%). Variceal size differed significantly across MPN subtypes (p = 0.001), with larger varices observed in polycythemia vera and primary myelofibrosis. In univariate analysis, age 40–59 years (OR: 0.06; 95% CI: 0.01–0.57; p = 0.015) and >60 years (OR: 0.03; 95% CI: 0.00–0.38; p = 0.006) were associated with lower odds of varices compared with younger patients. Splenic vein diameter was positively associated with varices (OR: 1.38; 95% CI: 1.05–1.80; p = 0.020), while platelet count showed an inverse association (OR: 0.99; 95% CI: 0.99–1.00; p = 0.004). On multivariate analysis, only platelet count remained independently associated with varices (adjusted OR: 0.99; 95% CI: 0.98–1.00; p = 0.020).
Conclusion: Esophageal and gastroesophageal varices are highly prevalent among MPN patients with portal hypertension, particularly in primary myelofibrosis. Thrombocytopenia is an independent factor associated with variceal presence and may serve as a practical marker to guide endoscopic surveillance in this high-risk population.

THU-436

Urinary chloride dipstick as a potential biomarker for predicting decompensation in patients with cirrhosis: a prospective multicenter pilot study

Susan Fischer[1], Britt van Ruijven[2], Annarein Kerbert[1], Marta Fiocco[1], Michael Klemt-Kropp[3], Anton Jan van Zonneveld[1], Tom J.G. Gevers[4], Govert Veldhuijzen[5], Minneke Coenraad[1], Kirill Basiliya[1]. [1]*Leiden University Medical Center, Leiden, Netherlands;* [2]*Institute of Nutrition and Translational Research in Metabolism (NUTRIM), Maastricht, Netherlands;* [3]*Noordwest Ziekenhuisgroep Locatie Alkmaar, Alkmaar, Netherlands;* [4]*Maastricht UMC+, Maastricht, Netherlands;* [5]*Gelre Ziekenhuizen, Apeldoorn, Netherlands*
Email: s.e.fischer@lumc.nl

Background and aims: Predicting decompensation in cirrhosis remains difficult, highlighting the need for simple, non-invasive biomarkers. Reduced urinary sodium excretion reflects disease severity in patients with cirrhosis, but routine use outside clinical settings is not feasible. Urinary chloride, reabsorbed alongside sodium, can be easily measured using a dipstick. This study examines the correlation between dipstick-measured urine chloride and urinary sodium/chloride concentrations and explores its potential to predict future acute decompensation (AD) in cirrhosis.
Method: In this prospective multicenter pilot study, hospitalized patients with cirrhosis were enrolled from four Dutch hospitals. A single urine sample was collected for dipstick chloride concentration measurement together with laboratory analysis of urinary sodium and chloride concentrations. Primary outcome was the correlation between dipstick and lab-based urine electrolytes, secondary outcome was the predictive value of dipstick chloride for AD development within 90-days.
Results: A total of 100 patients (62% male) were included, with a median age of 64 years [IQR 53–70] and MELD score of 13 [8–19]. Dipstick urinary chloride strongly correlated with laboratory urinary chloride (r = 0.801) and urinary sodium concentrations (r = 0.757). Within 90-days, the cumulative incidence of AD was higher in patients with low urinary chloride concentration (≤38 mmol/L) compared with those with high urinary chloride (44% vs 22%, p = 0.014). Multivariate regression models showed that low urinary chloride, diuretic use, and AD at inclusion were independently associated with an increased risk of developing new AD (HR 3.16, 95% CI 1.42–6.99; HR 2.71, 95% CI 1.22–6.00; and HR 4.73, 95% CI 1.98–11.29).
Conclusion: Dipstick-measured urinary chloride concentration correlates strongly with laboratory urinary sodium and -chloride concentration in patients with cirrhosis. Low urinary chloride is independently associated with an increased risk of new AD. Given its simplicity and low-cost, urine chloride dipstick testing may serve as a practical tool for early prediction of acute decompensation in outpatient settings. Further clinical trials are warranted to evaluate the role of chloride-guided therapy in patients with cirrhosis.

Email: Zouhir.Gadi@student.uantwerpen.be

Background and aims: Portal hypertension (PH) is central to chronic liver disease progression, yet its reference standard assessment by hepatic venous pressure gradient (HVPG) is invasive and restricted to specialised centres. Numerous non-invasive tests (NITs), including elastography-based models and serum-derived scores, have been proposed, however, comparative real-world data across major liver disease aetiologies remain limited. This study aimed to compare the diagnostic accuracy of portal hypertension-specific and fibrosis-related NITs against HVPG for detecting PH and clinically significant portal hypertension (CSPH).
Method: Patients undergoing simultaneous HVPG measurement and evaluable transjugular liver biopsy between January 2018 and December 2024 were included. PH and CSPH were defined as HVPG ≥5 mmHg and ≥10 mmHg, respectively. Diagnostic performance of NICER, MODEL-3P, MODEL-5P, ANTICIPATE, ANTICIPATE-NASH, LSPS, Lok, FIB-4+, FIB-4, MAF-5, APRI, Forns Index, AGILE3+ and AGILE4 was assessed using area under the receiver operating characteristic curve (AUC), sensitivity, specificity, positive predictive value (PPV) and negative predictive value (NPV).
Results: A total of 446 patients were included: MASLD (27.6%), alcohol-related liver disease (28.9%), metALD (6.3%), viral hepatitis (4.5%) and other causes (32.7%). PH was present in 77% and CSPH in 52%. For PH detection, MAF-5 and MODEL-5P were excluded due to missing data. Remaining NITs showed good-to-excellent discrimination (AUC >0.80). NICER achieved strong balanced accuracy (AUC 0.903; sensitivity 0.80; specificity 0.84; PPV 0.95). FIB-4+ offered the highest sensitivity (0.97) and a high NPV (0.75), while Lok provided

the highest NPV among highly sensitive models (0.64). ANTICIPATE-NASH, AGILE4, LSPS and FIB-4 (AUC 0.860–0.887) also performed well, with specificities up to 0.90 and PPVs exceeding 0.90. For CSPH, several models exceeded AUC 0.90. NICER remained robust (AUC 0.909; sensitivity 0.89; specificity 0.77; NPV 0.87). ANTICIPATE-NASH achieved near-perfect sensitivity and NPV (0.99), while elastography-integrating tools such as AGILE4 (AUC 0.920) and AGILE3+ (AUC 0.911) demonstrated excellent rule-out capability (NPV >0.95). Classical fibrosis scores showed lower accuracy.
Conclusion: PH-specific NITs, particularly elastography-based models (NICER, AGILE4, ANTICIPATE), outperform traditional fibrosis scores for PH/CSPH detection and are suitable non-aetiology-specific practical alternatives to HVPG measurement for PH stratification.

THU-442
Prognostic value of splenic volume in patients with portosinusoidal vascular disease
Hiram Tadeo-Espinoza[1], Tania del Socorro Grimaldo Galena[1], Venny Alberto Venegas Gomez[1], Marisol Esesarte[1], Eric Kauffman[1], Orlando E Falcon Antonio[1], Orfanel Pineda Arate[1], Ignacio Garcia Juarez[1]. [1]*Salvador Zubirán National Institute Of Health Sciences And Nutrition, Ciudad de México, Mexico*
Email: drinter77@gmail.com

Background and aims: Splenomegaly is a common manifestation of portal hypertension and may reflect significant hemodynamic compromise. In portosinusoidal vascular disease (PSVD), reliable predictors of clinical deterioration remain limited, and early identification of high-risk patients is essential. Splenic volume, readily quantifiable by imaging, may serve as a marker of disease severity. This study aimed to assess the association between splenic volume and portal hypertension–related complications in patients with PSVD.
Method: We conducted a retrospective study of patients diagnosed with PSVD between 2010 and 2024 according to VALDIG (Vascular Liver Disease Group) 2019 criteria. Patients with cirrhosis, inadequate liver biopsy, incomplete clinical data, or death within 90 days of diagnosis were excluded. Clinical, biochemical, imaging, and endoscopic variables were analyzed. Quantitative variables were expressed as medians (Interquartile Range) and categorical variables as frequencies. Group comparisons used Mann–Whitney U, chi-square, or Fisher's exact tests. Receiver Operating Characteristic (ROC) curve analysis and Youden's index identified optimal cutoffs. Odds ratios (OR) were calculated, with $p < 0.05$ considered significant.
Results: Fifty-seven patients were included (median age 39 years). Comorbidities were present in 49%, predominantly autoimmune diseases. Imaging showed portosystemic collaterals in 54.5% and portal vein thrombosis in 25%. Median splenic volume was 656 cc, and mean liver stiffness was 7.5 kilopascals (kPa). Endoscopy revealed esophageal varices in 79.6%, gastric varices in 22.4%, and portal hypertensive gastropathy in 53.1%. During a median follow-up of 26.6 months, 50% of patients developed clinical decompensation, mainly upper gastrointestinal bleeding. A splenic volume $\geq$ 574 cc was significantly associated with decompensation (OR 5.03; $p = 0.005$).
Conclusion: Splenic volume is a significant prognostic marker in PSVD. A threshold $\geq$ 574 cc identifies patients at increased risk of portal hypertension–related complications and may serve as a simple imaging biomarker for early risk stratification. Prospective validation is warranted.

Email: jkgazda@gmail.com

Background and aims: Transjugular intrahepatic portosystemic shunt (TIPS) effectively treats portal hypertension complications but carries a substantial risk of hepatic encephalopathy (HE). Recent data suggest that underdilatation (6–7 mm) achieves similar efficacy to standard diameters (8–10 mm) with reduced HE incidence, likely due to a more moderate reduction in the portosystemic pressure gradient (PSPG). While Viatorr Controlled Expansion (VCX) stents enable stable underdilatation at 8–9 mm, their capacity to maintain smaller diameters (6–7 mm) and preserve the PSPG over time remains unknown. The aim of the study was to compare PSPG changes between early assessment (24–72 h, while awake/stable conditions) and 1 month in patients with underdilated (6–7 mm) versus nominally dilated (8–10 mm) VCX-TIPS, and to evaluate if underdilated grafts prevent further PSPG reduction from spontaneous expansion.
Method: We retrospectively analyzed consecutive TIPS procedures using VCX stents (Oct 2015–Aug 2025). Initial dilation diameter was determined by clinical indication and risk profile. PSPG was measured early post-procedure and at 1 month.
Results: Of 95 patients, indications were variceal bleeding (VB) (52%), refractory ascites (27%), and others (21%; e.g., portal vein thrombosis, Budd-Chiari syndrome). Patients were stratified into 6–7 mm (n = 36) and 8–10 mm (n = 59) groups. In the 6–7 mm group, PSPG decreased significantly from a median of 11.3 mmHg (IQR 8.8–12.3) at early assessment to 9.3 mmHg (IQR 6.5–11.3) at 1 month ($p = 0.001$). In contrast, PSPG remained unchanged in the 8–10 mm group (median 9.5 mmHg [IQR 8.0–11.0] vs. 9.5 mmHg [IQR 7.5–11.0], $p = 0.375$). Median PSPG reduction at 1 month was significantly greater in the 6–7 mm group than the 8–10 mm group (−1.5 [IQR −3.3 to 0.0] vs. −0.5 mmHg [IQR −1.5 to 1.5]; $p = 0.02$). Notably, among 9 patients in the 6–7 mm group with early PSPG >12 mmHg, 44% (n = 4) achieved a PSPG <= 12 mmHg by 1 month. At 1-month, persistent ascites was more frequent in the 6–7 mm group versus the 8–10 mm group (28% vs. 14%), while no VB occurred in the 6–7 mm group, compared to 2% in the 8–10 mm group.
Conclusion: PSPG decreased significantly between early and 1-month assessments in the 6–7 mm group but remained stable in the 8–10 mm group. Findings suggest that VCX stents may not fully prevent spontaneous expansion when initially dilated below 8 mm. Understanding stent behaviour and PSPG reduction after TIPS may help personalizing management specially in high-risk patients.

Endoscopic ultrasound–guided portal pressure gradient measurement: prognostic utility and concordance with hepatic venous pressure gradient in a cohort of patients with sinusoidal and presinusoidal forms of portal hypertension

Lucia Giuli[1], Alberto Larghi[1], Gianenrico Rizzatti[1], Maria Pallozzi[1], Clelia Cavallo[1], Giulia Venturini[1], Elena Melita[1], Francesca Romana Ponziani[1], Brigida Eleonora Annicchiarico[1], Giulia Tripodi[1], Andrea Contegiacomo[1], Roberto Iezzi[1], Rosa Talerico[1], Antonio Gasbarrini[1], Francesco Santopaolo[1]. [1]*Fondazione Policlinico Universitario Agostino Gemelli IRCCS, Rome, Italy*
Email: lucia.giuli92@gmail.com

Background and aims: Clinically significant portal hypertension (CSPH) is the strongest predictor of hepatic decompensation. Hepatic venous pressure gradient (HVPG), the gold standard for diagnosing CSPH, provides only an indirect estimate of portal pressure and may underestimate presinusoidal or mixed forms of portal hypertension (PH). Indeed, endoscopic ultrasound (EUS)-guided portal pressure gradient (PPG) measurement enables direct recording of portal and hepatic vein pressures, potentially overcoming this limitation. This study evaluated the concordance between EUS-PPG and HVPG and their prognostic value in predicting hepatic decompensation.
Method: In this prospective single-center study, consecutive patients with suspected CSPH of various etiologies, naïve to non-selective beta-blockers, underwent both EUS-PPG and HVPG measurement. EUS-PPG was obtained using the EchoTip Insight™ system, and HVPG was measured according to Baveno VII recommendations. Correlation between EUS-PPG and HVPG was assessed using Pearson's coefficient, while agreement was evaluated with Bland–Altman analysis. Predictors of hepatic decompensation were explored using univariate and multivariate logistic regression analyses.
Results: Ninety patients were enrolled (45.6% male; mean age 60 years). Liver disease etiologies included porto-sinusoidal vascular disorder (PSVD) (35.6%), MASLD (31.1%), autoimmune liver diseases (14.4%), metabolic/alcohol-related liver disease (7.8%), viral hepatitis (7.8%), and alcohol-related liver disease (3.3%). Mean EUS-PPG and HVPG values were 14 ± 6 mmHg and 9 ± 5 mmHg, respectively. Seventy patients (77.8%) had PPG > 10 mmHg, while only 41 (45.6%) had HVPG > 10 mmHg. Concordance was modest, with a mean PPG–HVPG difference of + 4.7 mmHg (95% LoA:−9.6 to +18.9 mmHg) and a weak linear correlation (r = 0.036, p = 0.73). During a median follow-up of 12 months, 17 patients (18.9%) developed hepatic decompensation. At univariate analysis, PPG and platelet count were significantly associated with the occurrence of hepatic decompensation. In the multivariate analysis, EUS-PPG (OR 1.40; 95% CI 1.11–1.76; $p = 0.004$), together with platelet count (OR 0.97; 95% CI 0.95–1.00; $p = 0.037$) remained independent predictors of hepatic decompensation.
Conclusion: EUS-PPG is an informative method for assessing PH and it independently predicts hepatic decompensation, suggesting potential advantages over HVPG especially in presinusoidal or mixed forms of PH such as PSVD and MASLD.

Background and aims: Portal vein thrombosis (PVT) in cirrhosis follows a heterogeneous course. Spontaneous recanalization can occur in untreated patients, but its determinants and prognostic relevance remain poorly defined. We conducted an individual patient data (IPD) meta-analysis to evaluate the association between spontaneous recanalization and overall survival, and to identify predictors of spontaneous recanalization.
Method: We included cohort studies of patients with cirrhosis and PVT who did not receive anticoagulation (PROSPERO CRD42020140026). Authors were contacted to share de-identified IPD. All-cause mortality was analyzed using a one-stage competing-risk model, considering liver transplantation as a competing event. Models were adjusted for clinically relevant covariates, including age, cirrhosis etiology, Child-Pugh class, thrombosis severity and location, platelet count, presence of varices, and beta-blocker use. Predictors of spontaneous recanalization were assessed using mixed-effects ordinal logistic regression with a random intercept for each study.
Results: Eight studies contributed data from 586 non-anticoagulated patients. Spontaneous recanalization occurred in 264 (47.7%) patients. In the competing risk model, spontaneous recanalization was independently associated with significantly lower all-cause mortality (aSHR = 0.51; 95%CI, 0.28–0.91). The greatest survival benefit was observed in patients achieving complete recanalization (aSHR = 0.45; 95%CI, 0.21–0.94). Interaction analyses demonstrated that thrombus location significantly modified the association between recanalization and mortality, with a greater mortality reduction when thrombosis involved the main portal vein trunk (OR = 0.39; 95% CI, 0.16–0.91; p = 0.02). In contrast, no survival benefit associated with recanalization was observed in patients with isolated intrahepatic thrombosis of a portal venous branch. Independent predictors of spontaneous recanalization included Child-Pugh A (OR 2.63; 95%CI 1.18–5.88), partial thrombosis (OR 1.69; 95%CI 1.09–2.56) and isolated intrahepatic involvement (OR = 2.04; 95%CI, 1.23–3.33).
Conclusion: Spontaneous recanalization of PVT in cirrhosis is common and is strongly influenced by thrombus location and severity and liver disease severity. Recanalization is independently associated with improved survival, with a graded effect according to

the degree of recanalization, particularly when the main portal vein trunk is involved.

Risk factors for porto-mesenteric venous thrombosis after laparoscopic sleeve gastrectomy: a matched case-control study

Yousef Yahia[1], Shahd Hamran[2], Prem Chadra[3], Waleed Mahmoud[4], Ma'mon Qasem[5], Dhowa A. Al Ali[2], Ahmed Abdulhafedh Ali[1], Marwan Al-Zu'bi[6], Nasreen Khidir[4], Mohammed Al-Kuwari[4].
[1]Gastroenterology and Hepatology Department, Hamad Medical Corporation, Doha, Qatar; [2]Qatar University, College of Medicine, Doha, Qatar; [3]Medical Research Center, Hamad Medical Corporation, Doha, Qatar; [4]Department of Bariatric Surgery, Hamad Medical Corporation, Doha, Qatar; [5]Department of Radiology, Hamad Medical Corporation, Doha, Qatar, Doha, Qatar; [6]Internal Medicine Department, Hamad Medical Corporation, Doha, Qatar
Email: yyahia@hamad.qa

Background and aims: Porto-mesenteric venous thrombosis (PMVT) is a rare but potentially life-threatening complication following laparoscopic sleeve gastrectomy (LSG). Although PMVT has been reported in patients without classical thrombotic risk factors, predictors in the post-LSG setting remain poorly defined. This study aimed to identify patient-level risk factors associated with PMVT after LSG.
Method: We conducted a retrospective matched case–control study including patients who developed PMVT within 90 days after LSG between 2014 and 2025. Cases were matched to controls without PMVT by age, sex, year of surgery, and surgical center in a 1:4 ratio. Conditional logistic regression was used to evaluate associations between clinical, metabolic, and perioperative factors and PMVT.
Results: Thirty-eight PMVT cases and 152 matched controls were analyzed. Metabolic dysfunction–associated steatotic liver disease (MASLD) was significantly more prevalent among PMVT cases. In multivariate conditional logistic regression, MASLD was independently associated with increased odds of PMVT (adjusted odds ratio 2.95; 95% confidence interval 1.03–8.47; $p = 0.044$). Most PMVT events occurred within 30 days of surgery (92.1%). Abdominal pain was the most common presenting symptom, and combined portal and superior mesenteric vein thrombosis was the predominant radiologic pattern.
Conclusion: PMVT after LSG is uncommon but clinically significant and occurs predominantly in the early postoperative period. MASLD was independently associated with PMVT, suggesting that hepatic metabolic dysfunction may be linked to increased postoperative thrombotic vulnerability. Recognition of this association may support heightened clinical vigilance following LSG.

Multimodal computed tomography–clinical integration for noninvasive grading of hepatic venous pressure gradient

Seul Ki Han[1], Jin Gyo Jeong[1], JangHoon Ru[1], Sejung Yang[1], Jhii-Hyun Ahn[1], Sang Gyune Kim[2], Moon Young Kim[1]. *[1]Yonsei University Wonju College of Medicine, Wŏnju, Korea, Rep. of South; [2]Soonchunhyang University Bucheon Hospital, Bucheon, Korea, Rep. of South*
Email: drkimmy@yonsei.ac.kr

Background and aims: Portal hypertension is a hemodynamic consequence of liver cirrhosis and a major determinant of hepatic decompensation. The hepatic venous pressure gradient (HVPG) is the gold standard for measuring portal pressure and identifying clinically significant portal hypertension (CSPH), defined as HVPG greater than or equal to 10 mmHg. However, HVPG measurement is invasive, technically demanding, and limited to specialized centers. Existing noninvasive tests primarily reflect hepatic fibrosis or indirect consequences of portal hypertension rather than portal hemodynamics itself. We aimed to develop and validate a multimodal framework integrating abdominal computed tomography (CT) imaging and clinical data for noninvasive grading of HVPG.
Method: We retrospectively analyzed 603 individuals from Wonju Severance Christian Hospital, including 298 patients with portal hypertension confirmed by HVPG measurement and 305 controls. Abdominal CT images were spatially standardized, and fifteen routinely available clinical variables were incorporated, including age, sex, albumin, total bilirubin, aminotransferases, white blood cell count, hemoglobin, platelet count, sodium, creatinine, liver volume, spleen volume, and liver to spleen volume ratio. A deep learning framework was constructed using a Swin Transformer for image feature extraction and a language image pretraining model to encode clinical data. The model was trained to classify CSPH and to estimate HVPG as a continuous variable.
Results: The model demonstrated robust performance for CSPH classification, achieving an accuracy of 0.79, precision of 0.85, recall of 0.83, F1 score of 0.79, and area under the receiver operating characteristic curve of 0.87. This significantly outperformed a CT only unimodal model, which showed lower accuracy and discrimination. In regression analysis, predicted HVPG showed a strong correlation with measured HVPG, with a Pearson correlation coefficient of 0.71. These findings indicate that integrating anatomical information from CT imaging with functional clinical markers substantially improves noninvasive assessment of portal pressure.
Conclusion: We developed a multimodal CT and clinical data framework that enables accurate noninvasive grading of HVPG. By combining imaging derived features with laboratory markers, this approach overcomes a limitations of HVPG measurement. This framework has the potential to improve risk stratification, reduce patient burden, and expand access to portal hypertension assessment.

Email: lukas.a.hartl@meduniwien.ac.at

Background and aims: Transjugular intrahepatic portosystemic shunt (TIPS) placement is an effective treatment for patients with complications of portal hypertension. Diabetes increases the risk of hepatic encephalopathy (HE), likely due to inflammation, autonomic dysfunction and insulin resistance. We aimed to investigate the impact of type 2 diabetes mellitus (T2DM) on clinical outcomes after TIPS in a large multicentric cohort.
Method: We included consecutive patients who underwent implantation of a covered TIPS for the treatment of portal hypertension-associated complications at Hannover Medical School between 2009 and 2021 (Hannover cohort) and at two Viennese centers between

2000 and 2025 (Vienna cohort) with available information on diabetes and clinical outcomes. Patients with malignancy, other diabetes types, rescue TIPS placement, or incomplete datasets were excluded.
Results: Overall, we included 650 patients (Vienna cohort: n = 366; Hannover cohort: n = 284) with a median age of 57 years and male predominance (65.7%). Most patients had alcohol-related liver disease (66.3%). The majority of patients (75.4%) underwent TIPS placement for recurrent/refractory ascites and the median MELD was 12. T2DM was present in 185 patients (28.5%) at the time of TIPS placement. Patients with T2DM were significantly older (median 60 years vs. 56 years; p < 0.001), but had comparable MELD (12.0 vs. 12.0; p = 0.402), portosystemic pressure gradient before (19 mmHg vs. 18 mmHg; p = 0.372) and after TIPS (7 mmHg vs. 7 mmHg; p = 0.797) compared to patients without T2DM. Median follow-up duration was 20.2 months. Patients with T2DM mellitus had a higher cumulative incidence of HE (p < 0.001) with 43.4% of patients developing overt HE at 6 months of follow-up (versus 24.2% without T2DM). Similarly, the cumulative incidence of death was significantly higher among T2DM patients (p < 0.001). Specifically, at 1 year after TIPS placement, the cumulative incidence of death was 29.0% among patients with T2DM as compared to 15.9% without T2DM. In multivariate competing risk regression analysis adjusted for age and MELD, T2DM was an independent risk factor for HE (aSHR: 1.59; 95%CI: 1.21–2.08; p < 0.001) and death (aSHR: 1.34; 95%CI: 1.03–1.75; p = 0.028).
Conclusion: T2DM represents an independent risk factor not only for HE, but also for mortality in patients undergoing TIPS placement. At 1 year after TIPS, the cumulative incidence of death was almost doubled in patients with T2DM.

THU-449
TIPS facilitates recovery from different types of hepatorenal syndrome and may improve clinical outcomes in patients with HRS-AKI

Email: lukas.a.hartl@meduniwien.ac.at

Background and aims: While renal benefits from transjugular intrahepatic portosystemic shunt (TIPS) placement have been reported, its impact on different types of hepatorenal syndrome (HRS) remains unknown. We aimed to investigate the impact of TIPS placement on the response of different HRS types – according to the recent Acute Disease Quality Initiative (ADQI) and International Club of Ascites (ICA) consensus – and on clinical outcomes.
Method: We included consecutive patients with covered TIPS implantation for ascites/hepatorenal syndrome at Freiburg University Medical Center between 2004 and 2023 and at the Medical University of Vienna between 2004 and 2025 with available information on renal function and clinical outcomes. Patients were stratified for presence of HRS-acute kidney injury (HRS-AKI), HRS-acute kidney disease (HRS-AKD), HRS-chronic kidney disease (HRS-CKD), chronic kidney disease (CKD) and no kidney disease (No-KD).
Results: Overall, 508 patients with a median age of 60 years, male predominance (69.3%) and a median MELD of 18 were included. At baseline, 27 patients (5.3%) had HRS-AKI, while 18 (3.5%) had HRS-AKD, 33 (6.5%) had HRS-CKD, 128 (25.2%) had CKD and 302 (59.4%) had No-KD. Median follow-up duration was 10.0 months. Median serum creatinine (sCr) significantly decreased in all HRS types - specifically, in HRS-AKI, from 1.61 mg/dL to 0.98 mg/dL (p = 0.003), in HRS-AKD from 1.66 mg/dL to 1.09 mg/dL (p = 0.038) and in HRS-CKD from 2.09 mg/dL to 1.22 mg/dL (p < 0.001). Normalization of sCr occurred in 43.8% (n = 7/16) and 53.8% (n = 7/13) of patients with HRS-AKI at 3 and 12 months of follow-up, respectively, as compared to 50.0% (n = 5/10) and 50.0% (n = 4/8) of patients with HRS-AKD, as well as 20.0% (n = 5/25) and 46.2% (n = 6/13) of patients with HRS-CKD. Two (7.4%) and 6 (18.2%) patients with HRS-AKI and HRS-CKD required dialysis after TIPS, respectively, compared to none among HRS-AKD patients. The cumulative incidence of death at 1 year (Y1) after TIPS (considering liver transplantation as a competing event) was 17.9% in No-KD, as compared to 21.9% in HRS-AKI (p = 0.433 vs. No-KD), 46.2% in HRS-AKD (p = 0.005 vs. No-KD), 35.4% in HRS-CKD (p = 0.040 vs. No-KD), and 30.5% in CKD (p = 0.029 vs. No-KD).
Conclusion: Renal function improves after TIPS across different types of renal dysfunction; sCr normalization was reached in about half of HRS-AKI, HRS-AKD and HRS-CKD cases. While Y1 mortality in HRS-AKI was similar to patients with No-KD, all other types of HRS and renal dysfunction show higher mortality after TIPS.

THU-450
Sex and age do not affect the diagnostic and prognostic performance of spleen/liver stiffness-based noninvasive tests for clinically significant portal hypertension: a European multicenter study

Email: paula.hoefinger@meduniwien.ac.at

Background and aims: Clinically significant portal hypertension (CSPH) is the key driver of hepatic decompensation in compensated advanced chronic liver disease (cACLD). Current recommendations endorse liver (LSM) and spleen (SSM) stiffness measurement by vibration-controlled transient elastography (VCTE) for estimating the probability of CSPH. However, the influence of sex and age on the diagnostic and prognostic performance of non-invasive tests and their derivatives (i.e., NICER and ANTICIPATE ± NASH) remains unclear.
Method: This multicenter retrospective analysis included 407 stable outpatients with Child–Pugh A cACLD from 16 European expert centers (2020–2023) who underwent paired LSM & SSM-100 Hz by VCTE as well as HVPG measurement. Patients were stratified by sex and age (<60/≥60 years, i.e., approximately the median). Diagnostic performance of VCTE-based non-invasive tests (NITs) was assessed using AUROC analyses and logistic regression. The cumulative incidence of first hepatic decompensation was evaluated using competing-risk models. Diagnostic accuracy of the Baveno VII criteria was assessed using sensitivity, specificity, PPV, NPV, LR+, and LR-.
Results: Of 407 patients (67.6% male, median age 60 years, 73% SLD etiology), CSPH prevalence was 59.2%. NICER (AUC males: 0.899 vs. females: 0.890; p = 0.803) and ANTICIPATE ± NASH (AUC males: 0.865 vs. females: 0.841; p = 0.576) showed no sex-related differences in discriminative ability for CSPH. However, discrimination was slightly higher in patients aged <60 years compared with ≥60 years (NICER: 0.929 vs. 0.865; p = 0.043, ANTICIPATE ± NASH: 0.901 vs. 0.811; p = 0.021). Neither age nor sex significantly modified the association between LSM/SSM and CSPH probability and model calibration of NICER and ANTICIPATE ± NASH remained consistent. Baveno VII criteria for CSPH performed similarly across age and sex subgroups, with only slight differences in NPV and PPV, that are likely driven by differences in underlying disease prevalence. The cumulative incidence of first hepatic decompensation did not differ significantly by age or sex and was comparable between their strata within each Baveno VII CSPH risk group.
Conclusion: VCTE-based NITs for CSPH demonstrate robust diagnostic and prognostic performance regardless of sex and age in cACLD, supporting their universal applicability as endorsed by Baveno VII.

THU-451

Sex-specific diagnostic and prognostic performance of blood- and liver stiffness-based noninvasive tests for clinically significant portal hypertension in compensated advanced chronic liver disease

Paula Hoefinger[1], Helena Schluchter[2], Georg Semmler[1], Lorenz Balcar[1], Benedikt Simbrunner[1], Lukas Hartl[1], Benedikt Hofer[1], Georg Kramer[1], Paul Thöne[1], Christian Sebesta[1], Marlene Hintersteininger[1], Philipp Schwabl[1], Michael Trauner[3], Eva Schaden[2], Thomas Reiberger[1], Mattias Mandorfer[1], Mathias Jachs[1]. *[1]Division of Gastroenterology and Hepatology, Medical University of Vienna, Vienna, Austria; Vienna Hepatic Hemodynamic Lab, Medical University of Vienna, Vienna, Austria; Department of Medicine III and Clinical Research Group Mechanisms in Portal Hypertension, Medical University of Vienna, Vienna, Austria; [2]Department of Anaesthesia, Intensive Care Medicine and Pain Medicine, Medical University of Vienna, Ludwig Boltzmann Institute Digital Health and Patient Safety, Vienna, Austria; [3]Division of Gastroenterology and Hepatology, Department of Medicine III, Medical University of Vienna, Vienna, Austria*
Email: paula.hoefinger@meduniwien.ac.at

Background and aims: Use of non-invasive tests (NITs) for clinically significant portal hypertension (CSPH) is recommended in compensated advanced chronic liver disease (cACLD), as CSPH represents the threshold for hepatic decompensation. Among these, liver stiffness measurement (LSM) by vibration-controlled transient elastography (VCTE) is most important. However, LSM is influenced by body composition, and potential sex-specific differences in diagnostic/prognostic performance remain unclear. We aimed to assess whether established blood- and LSM-based NITs perform comparably in males and females.
Method: This retrospective analysis included prospectively characterized, clinically stable cACLD outpatients who underwent HVPG measurement between 2007–2022 at the Vienna General Hospital. VCTE-LSM and laboratory testing were performed on the day of HVPG assessment. Diagnostic performance of NITs was evaluated in males and females, separately, using area under the curve (AUC) analyses and DeLong's test for group-wise comparison. Sex-specific cumulative incidences of first hepatic decompensation were analyzed using competing risk models stratified by the Baveno VII criteria and sequential Baveno VII-VITRO algorithm, which adds the von Willebrand factor to platelet count ratio (VITRO) to reduce the grey zone.
Results: In 420 patients, 281 (66.9%) were male and 139 (33.1%) were female. Median age was higher in females than in males (56.7 vs. 52.8 years; p = 0.014), while no sex-specific differences were observed for BMI, prevalence of obesity, or HVPG. For CSPH diagnosis, LSM showed numerically higher AUC in males (0.845 vs. females: 0.811, p = 0.447), whereas the VITRO score performed numerically better in females (AUC: 0.854 vs. males: 0.814, p = 0.370). The ANTICIPATE ± NASH model achieved the numerically highest AUROC, regardless of sex (male: 0.885 vs. female: 0.872, p = 0.755). Baveno VII criteria yielded similar rule-in and rule-out performance, leaving 42.3% of males and 49.6% of females unclassifiable (p = 0.176). The Baveno VII-VITRO

sequence reduced the grey zone to 12.4% and 15.1% in males and females, respectively (p = 0.450). Cumulative incidences of first hepatic decompensation were comparable between sexes throughout all Baveno VII and Baveno VII-VITRO strata.
Conclusion: Non-invasive tests and Baveno VII-based algorithms show comparable diagnostic/prognostic performance for CSPH/hepatic decompensation in males and females.

THU-452
FOHES (first overt hepatic encephalopathy score): a novel prognostic model for predicting the first episode of overt hepatic encephalopathy in patients with advanced chronic liver disease

Chien-Hao Huang[1], Cheng-Jen Chen[1], Chia-Ling Wu[2], Yu-Tung Huang[3], Piero Amodio[4]. [1]*Division of Hepatology, Department of Gastroenterology and Hepatology, Chang-Gung Memorial Hospital, Linkou Medical Center, Taoyuan, Taiwan, College of Medicine, Chang-Gung University, Taoyuan, Taiwan, Liver Research Center, Chang Gung Memorial Hospital, Linkou, Taiwan, TaoYuan, Taiwan;* [2]*Center for Big Data Analytics and Statistics, Chang-Gung Memorial Hospital, Linkou Medical Center, Taoyuan, Taiwan, TaoYuan, Taiwan;* [3]*National Center for Geriatrics and Welfare Research, National Health Research Institutes, Taiwan, Miaoli, Taiwan;* [4]*Department of Medicine, University of Padova, Padova, Italy, Padova, Italy*
Email: piero.amodio@unipd.it

Background and aims: Overt hepatic encephalopathy (OHE) imposes a significant burden on patients and healthcare systems. Currently, effective risk stratification for primary prophylaxis is lacking. We aimed to develop and validate a novel risk score (FOHES) to predict the first episode of OHE within one year in patients with advanced chronic liver disease (ACLD).
Method: Using the multi-center Chang Gung Memorial Hospital (CGMH) electronic medical records database (Taiwan), we identified 569,933 patients with ACLD. After exclusions, the final cohort comprised 223,295 patients (11,758 with incident OHE; 211,537 without OHE) enrolled between 2002 and 2022. We adopted a landmark analysis approach, utilizing clinical data from one year prior to the index date (OHE onset or pseudo-index date) to minimize reverse causality. The FOHES model was developed using logistic regression on training data (2002–2016) and validated using temporal external validation data (2017–2022).
Results: Independent predictors included in FOHES were age, Charlson Comorbidity Index, total bilirubin, albumin, ammonia, etiology (HCV, alcohol), HCC status, and medication use (diuretics, statins, and anti-HCV therapy). In the training cohort, FOHES demonstrated excellent discrimination with an AUC of 0.90. Crucially, in the external validation cohort (n = 10,483), the model maintained robust performance with an AUC of 0.84. Using a cut-off of 36.28, the score effectively stratified patients into high-risk (>20% incidence/year) and low-risk groups.
Conclusion: The FOHES is a robust, simple, and externally validated tool for predicting the first episode of OHE. High-risk patients identified by FOHES may benefit from closer surveillance or primary prophylaxis. This score paves the way for risk-stratified clinical trials in ACLD.

THU-453
Long-term outcomes of compensated cirrhosis with mild portal hypertension

Anna Huerta[1,2], Anna Brujats[1,2], Edilmar Alvarado-Tapias[1,2], Monica Pons[3], Luis Téllez[4], Asunción Ojeda[5], Carlos Aracil[6], Aitor González Amezcua[7], Ferran Torres[7], Juan Carlos García-Pagán[5], Agustín Albillos[4], Joan Genesca[3], Àngels Escorsell[1,2], Jaime Bosch[8], Càndid Villanueva[1,2]. Email: cvillanueva@santpau.cat

Background and aims: Patients with compensated advanced chronic liver disease (cACLD) with hepatic venous pressure gradient (HVPG) <10 mmHg, i.e. still without clinically significant portal-hypertension (CSPH), have good prognosis. However, long-term outcomes in such patients have been poorly investigated. This study aims to assess long-term outcomes in a well-characterized cohort of patients with cACLD and mild-portal hypertension (PH) (i.e. ≤5 HVPG <10), and to identify factors influencing disease progression.
Method: During screening-period of PREDESCI trial, patients with cACLD who had no CSPH were excluded. Among them, those with mild-PH (defined by portal-pressure >5 and <10 mmHg) were consecutively included in this study and followed up to February-2025. Since 2015, patients with hepatitis C virus (HCV) were treated with direct-acting antivirals (DAA). All the events occurring during follow-up were recorded.
Results: 73 patients were included, mean-age of 60 ± 10, MELD of 7.8 ± 2.4, Liver stiffnes measurement (LSM) of 17.7 ± 6.8 KPa and HVPG of 7.5 ± 1.3 mmHg. 55 patients had HCV-related disease, 48 were successfully treated with DAA. During a mean follow-up of 128 months (IQR, 99–162), 32 patients died (44%) (liver-unrelated causes in 59%), 14 (19%) had hepatocellular carcinoma (HCC) and 11 (15%) cirrhosis-decompensation (5-year incidence of 10%, 15% and 4%, respectively). Liver-unrelated death and HCC were the most frequent first event occurring. Decompensation occurred after HCC in 55% cases. cACLD-progression (defined by development of CSPH) was the most frequent event occurring, with a 5-year incidence of 25%. cACLD-progression was associated with baseline-HVPG (sHR = 2.06, 95% CI = 1.41–3.01), presence of varices (sHR = 2.83, 95% CI = 1.61–4.99) and treatment with DAA (sHR = 0.43, 95% CI = 0.18–1.05).
Conclusion: Death (mainly liver-unrelated) and HCC are frequent events in cACLD with mild-PH, while decompensation is rare. Progression of ACLD to develop CSPH is the most frequent event occurring and is favored by higher baseline portal-pressure, presence of varices and absence of etiological therapy.

THU-457
Real-world effectiveness of Carvedilol vs. Propranolol for primary prophylaxis of variceal bleeding and impact on endoscopic burden

Mohamed Jalloh[1], Hareesha Bharadwaj[1], Farhan Gohar[1], Maryam Javed[1], Humberto Castellanos[1], Sushanth Shankar[1], Vanessa Carr[1], Jessica Lightfoot[1], Thomas Eardley[1], Shannon Lewis[1], Balamrit Sokhal[2]. [1]*University Hospitals of North Midlands, Stoke-on-Trent, United Kingdom;* [2]*Keele University, Newcastle-under-Lyme, United Kingdom*
Email: doctorgohar@gmail.com

Background and aims: Randomised controlled trials (RCTs) have established the efficacy of non-selective beta-blockers (NSBBs) for primary prevention of variceal bleeding in cirrhosis. However, real-world effectiveness across different NSBB agents (Carvedilol vs Propranolol) and the impact on healthcare resource utilisation, including endoscopic surveillance burden, remain uncertain.
Method: We conducted a retrospective cohort study of adults with cirrhosis undergoing index endoscopy between 2012–2020 at a UK tertiary centre with no prior variceal bleeding. Exposure was NSBB prescription (carvedilol or propranolol) at index endoscopy. Primary outcomes were first variceal bleeding and all-cause mortality, analysed using multivariable logistic regression adjusted for age, sex, aetiology, Child–Pugh class, and variceal size. Endoscopic surveillance burden was analysed using patient-year standardisation.
Results: The cohort included 546 patients (mean follow-up 3.0 years). First variceal bleeding occurred in 79 (14.5%). NSBB use was not independently associated with first bleeding (aOR 1.17, p = 0.696).

Medium/large varices were the strongest predictor of bleeding (aOR 2.16, 95% CI 1.27–3.69). NSBBs were not associated with overall mortality (aOR 0.71, p = 0.108) but showed a significant protective association in patients with compensated disease (OR 0.45, 95% CI 0.23–0.86). Patients prescribed NSBBs underwent significantly fewer surveillance endoscopies (mean difference –0.26 OGDs/patient), preventing an estimated 578 procedures—equivalent to one avoided endoscopy per four treated patients.
Conclusion: In this real-world cohort, NSBB therapy was not associated with reduced bleeding risk but was linked to a lower endoscopic surveillance burden and improved survival in compensated cirrhosis. These findings highlight challenges in translating RCT efficacy to practice and suggest that drug selection and adherence may influence outcomes.

THU-458
Quantifying the morbidity and mortality of decompensated liver cirrhosis in Australia
Angus Jeffrey[1], Leon Adams[1], Brendan Brew[2], Gary Jeffrey[1], Michael Wallace[1], Marie Sinclair[2], Adam Testro[2], John Chetwood[3], Ken Liu[3], Avik Majumdar[2]. *[1]Department of Hepatology, Sir Charles Gairdner Hospital, Perth, Medical School, The University of Western Australia, Perth, Perth, Australia; [2]Victorian Liver Transplant Unit, The Austin Hospital, Melbourne, School of Medicine, The University of Melbourne, Melbourne, Melbourne, Australia; [3]AW Morrow Gastroenterology and Liver Centre, Royal Prince Alfred Hospital, New South Wales, New South Wales, Australia*
Email: angus.jeffrey@gmail.com

Background and aims: Decompensated cirrhosis carries a significant health burden with high mortality. Outcomes after a first decompensation episode are not known in the Australian population. The aim of this study was to assess the incidence of further decompensation and survival in patients with cirrhosis following hospitalization with initial decompensation.
Method: This was a multi-centre Australian retrospective cohort study from 2006 to 2025. Adult patients with cirrhosis at three statewide liver transplant referral centres who were admitted to hospital with or developed a first decompensating event (ascites, hepatic encephalopathy, variceal bleeding) and followed until further decompensation requiring hospitalisation, liver-related death (LRD), non-liver related death, or liver transplant (LT). The primary outcome was incidence of further liver decompensation, type of clinical event, and survival outcomes following admission for first decompensation.
Results: A total of 542 patients were followed from first decompensation for a median of 24 (IQR 9–48) months, with alcohol-related liver disease the most common aetiology (52%). Cumulative incidence of further decompensation at 5-years was 65.1% (95% CI 60.3–69.5), and the incidence of LRD or LT was 39.2% (95% CI 34.1–44.2). Following further decompensation, the cumulative incidence of LRD or LT was higher compared to first decompensation at 55.5% (sHR 3.45, 95% CI 2.31–5.16, p < 0.001). Ascites was the most common type of further decompensation (35.6%, 95% CI 31.0–40.2). Aetiological treatment of the underlying CLD was protective for both further decompensation and LRD/LT (sub hazard ratio [sHR] 0.58 and 0.65 respectively, p < 0.05), as was treatment with a non-selective beta blocker (sHR 0.40 and 0.60 respectively, p < 0.01).
Conclusion: This multi-centre study describes the trajectory of patients with cirrhosis after a first episode of decompensation for the first time in the Australian context. It highlights the high morbidity and poor prognosis associated with further decompensation with over 50% dying or requiring LT within 5 years. We also found that aetiological treatment for CLD and NSBB treatment were associated with a reduced risk of further decompensation and mortality and should be considered in all appropriate patients.

THU-459
Differential increase in portal pressure across fibrosis stages in steatotic liver disease etiologies
Oliver Kiehn[1], Lise Hobolth[2], Christian Mortensen[2], Nina Kimer[2,3], Lise Lotte Gluud[2,3], Mogens Vyberg[4], Søren Møller[1,3]. *[1]Department of Clinical Physiology and Nuclear Medicine, Center for Functional and Diagnostic Imaging and Research, Copenhagen University Hospital - Amager and Hvidovre Hospital, Hvidovre, Denmark, Hvidovre, Denmark; [2]Gastro Unit, Copenhagen University Hospital - Amager and Hvidovre Hospital, Hvidovre, Denmark, Hvidovre, Denmark; [3]Department of Clinical Medicine, Faculty of Health and Medical Sciences, University of Copenhagen, Copenhagen, Denmark, København N, Denmark; [4]Department of Pathology, Copenhagen University Hospital - Amager and Hvidovre Hospital, Hvidovre, Denmark, Hvidovre, Denmark*
Email: oliver.thistrup.kiehn.02@regionh.dk

Background and aims: The burden of chronic liver disease is increasing worldwide. Beyond alcohol-related liver disease (ALD), the prevalence of metabolic dysfunction-associated liver disease (MASLD) and metabolic-associated ALD (Met-ALD) contributes substantially to cirrhosis. Advanced cirrhosis is frequently complicated by portal hypertension (PH). However, the severity of PH may differ by etiology, type of hepatic lesion and extent of steatosis, fibrosis, and cirrhosis. Since patients with MASLD appear to demonstrate a lower degree of PH we aimed at comparing the hepatic venous pressure gradient (HVPG) in patients with comparable degrees of fibrosis of different etiologies.
Method: 309 patients with MASLD (n = 142), Met-ALD (n = 59), ALD (n = 108) and 26 healthy controls with normal liver histology had consecutively performed a combined liver vein catheterization with measurement of HVPG and a transjugular liver biopsy. Liver stiffness was additionally measured by elastography (Fibroscanning). The liver biopsy was evaluated with respect to level of fibrosis (F1-F3) and cirrhosis (F4).
Results: HVPG differed significantly across etiologies at F0–F2, F3 and F4 (p < 0.05–0.01). At F0–F2, Met-ALD > MASLD (p < 0.05); at F3, ALD > MASLD (p < 0.05); at F4, Met-ALD and ALD > MASLD (both p < 0.01). Median HVPG at F4: MASLD 9 mmHg, Met-ALD 14 mmHg, ALD 13.5 mmHg. HVPG correlated with fibrosis stage overall (rho = 0.71, p < 0.001) and within MASLD (rho = 0.73, p < 0.001), ALD (rho = 0.35, p < 0.01), and Met-ALD (rho = 0.50, p < 0.001). Across all groups, the median HVPG increased from 2 mmHg (F0) to 12 mmHg (F4), with an increase of ~2.4 mmHg per stage. HVPG also correlated with fibroscanning across the groups (rho = 0.71, p < 0.001). ROC analysis showed high accuracy: AUC 0.92 for significant fibrosis (F2–F4) at 4.5 mmHg and AUC 0.86 for cirrhosis (F4) at 5.8 mmHg. Sensitivity ranged from 80–87%, specificity from 71–93%, and PPV > 95%.
Conclusion: With a comparable histological degree of fibrosis the portal pressure is significantly lower in MASLD than in ALD and Met-ALD patients. Together with distinct pathophysiological associations, this points to differences in intrahepatic hemodynamics across pathologies, potentially due to changes in intrahepatic shunting and mechanobiology.

Prognostic value of ReMELD-Na and MELD 3.0 for predicting transplant-free survival after TIPS for variceal bleeding: a multicenter retrospective study
Markus Kimmann[1], Nancy Farouk[1], Dominik Bettinger[2], Johannes Chang[3], Roman Kloeckner[4], Cristina Ripoll[5], Felix Piecha[6], Jassin Rashidi-Alavijeh[7], Juliana Stadtmann[1], Tony Bruns[8], Cornelius Engelmann[9], Benjamin Maasoumy[10], Christian Labenz[11], Lukas Sturm[2], Hauke Heinzow[12], Leon Louis Seifert[1], Michael Köhler[1], Max Masthoff[1], Johannes Kluwe[6], Alexander Zipprich[5], Christian Jansen[3], Carsten Meyer[3], Michael Schultheiß[2], Jonel Trebicka[1], Michael Praktiknjo[1]. *[1]Münster University Hospital, Münster, Germany; [2]University Hospital Freiburg, Freiburg im Breisgau,*

Email: markus.kimmann@ukmuenster.de

Background and aims: ReMELD-Na (Eurotransplant) and MELD 3.0 (UNOS) were recently introduced as scores for liver transplant allocation. Their predictive value for transplant-free survival after transjugular intrahepatic portosystemic shunt (TIPS) placement in variceal bleeding remains elusive. This study evaluates the prognostic value of ReMELD-Na and MELD 3.0 in comparison to established models like FIPS, MELD-Na, and MELD.
Method: This multicenter retrospective study analyzed 576 patients with cirrhosis who underwent TIPS for variceal bleeding at eight German centers (2004–2024). The primary and secondary endpoints were 90-day and 1-year transplant-free survival, respectively. Prognostic performance was assessed by ROC analysis, with DeLong tests comparing ReMELD-Na and MELD 3.0 to the other scores. Sex-specific analyses were conducted, and high-risk (above 85th percentile of the respective score) versus non–high-risk groups were compared using Kaplan–Meier analysis and log-rank tests.
Results: Median age was 58 (49–65) with 47.7% having alcohol-related cirrhosis. Median scores for each model were: ReMELD-Na 12, MELD 3.0 14, FIPS −0.49, MELD 12, and MELD-Na 13. Transplant-free survival rates were 90.1% and 86.3% for 90 days and 1 year, respectively. ROC-AUC values ranged from 0.651 to 0.749 for 90 days and 0.676 to 0.741 for 1 year, with FIPS showing the highest values (0.749 and 0.741). DeLong test indicated that ReMELD-Na was inferior to FIPS at 90 days ($p = 0.007$). MELD 3.0 outperformed MELD ($p = 0.011$) and MELD-Na ($p = 0.035$), but was inferior to FIPS ($p = 0.038$). However, no significant differences were observed at 1 year. ROC-AUC values for the male subgroup were slightly higher than those of the female subgroup at both 90 days (male: 0.663–0.767 vs. female: 0.637–0.740) and 1 year (male: 0.686–0.735 vs. female: 0.637–0.740). Across all models, transplant-free survival was significantly reduced in the high-risk group compared with the non–high-risk group ($p < 0.001$).
Conclusion: ReMELD-Na and MELD 3.0 demonstrated comparable predictive performance for 1-year survival, but were inferior to FIPS at the 90-day time point. Despite their limited predictive value, all models enabled risk stratification after TIPS placement and could aid clinical decision-making by identifying patients who may need intensive monitoring or a priori evaluation for liver transplant. However, the limited predictive values of all models emphasize the need for further studies.

THU-461

Comparative risk of acute kidney injury after contrast media exposure in TIPS and CT imaging among patients with decompensated liver cirrhosis: a bicentric retrospective study

Markus Kimmann[1], Tammo Lambert Tergast[2], Nancy Farouk[1], Jim Benjamin Mauz[2], Zeyu Wang[1], Juliana Stadtmann[1], Silvia Letmathe[1], Jörn Arne Meier[1], Nils Theodor Manegold[1], Max Masthoff[1], Michael Köhler[1], Gesa Pöhler[1], Markus Cornberg[2], Heiner Wedemeyer[2], Jonel Trebicka[1], Martin Sebastian McCoy[1], Benjamin Maasoumy[1], Michael Praktiknjo[1]. *[1]Münster University Hospital, Münster, Germany; [2]Medizinische Hochschule Hannover, Hannover, Germany*
Email: markus.kimmann@ukmuenster.de

Background and aims: Patients with cirrhosis are at risk for acute kidney injury (AKI). However, the influence of iodine-containing contrast media (CM) on the risk of AKI in patients with cirrhosis is relatively low for contrast-enhanced (CE)-computed tomography (CT) scans. Data on AKI after CM exposure during transjugular intrahepatic portosystemic shunt (TIPS) - has not yet been clearly established. This study aimed to compare the risk of AKI following CM administration during TIPS placement with that following CE-CT imaging.
Method: In this retrospective, bicenter study, we included 554 cirrhotic patients who underwent TIPS placement and 90 patients who underwent CE-CT examinations. After propensity score matching (PSM) for age, sex, MELD score, albumin, and creatinine, the final cohort consisted of 145 TIPS patients and 90 CE-CT patients. The primary endpoints were the incidence of AKI at 7 and 28 days, defined according to the International Club of Ascites criteria. Univariate and multivariate Cox regressions were used to identify independent risk factors for AKI.
Results: Median age was 59 (52–67) years, the most-common etiology of cirrhosis was alcohol-related 53.2% and median MELD was 13 (11–17). The incidence of AKI was significantly lower in the TIPS group both after 7 (PSM: 6.2% vs. 16.7%) and 28 days (PSM: 8.3% vs. 27.8%). TIPS placement was associated with a significantly reduced risk of AKI at 7 days (HR 0.402, $p = 0.009$) and 28 days (HR 0.311, $p = 0.001$). In addition, a higher MELD score was significantly associated with an increased risk of AKI, while age, sex, and the use of beta-blockers or diuretics had no significant influence.
Conclusion: In the context of CM exposure, TIPS placement was associated with a significantly lower risk of AKI compared to CE-CT. This may be due to improved renal perfusion following TIPS in cases of functional kidney damage, such as hepatorenal syndrome. In summary, our results support the superior importance of other risk factors for AKI than CM exposure and the potential benefits of TIPS in reducing AKI risk in cirrhotic patients.

THU-462

Ultrasound-based monitoring of transjugular intrahepatic portosystemic shunt function: hemodynamic changes and prognostic relevance — Data from a prospective registry of 216 consecutive patients

Matthias Klimanek[1], Martin Franck[1], Anja Tiede[1], Annika Zietz[1,2], Anika Wranke[1], Jim Benjamin Mauz[1], Helenie Kefalakes[1], Martin Kabelitz[1], Heiner Wedemeyer[1,2], Patrick Behrendt[1], Benjamin Maasoumy[1,2]. *[1]Department of Gastroenterology, Hepatology, Infectious Diseases and Endocrinology, Hannover Medical School, Hannover, Germany; [2]German Center for Infection Research (DZIF), Hannover-Braunschweig, Germany*
Email: klimanek.matthias@mh-hannover.de

Background and aims: Ultrasound assessment is widely used when monitoring transjugular intrahepatic portosystemic shunt (TIPS) function. However, norm values and prognostic impact of the individual measurement parameters have been insufficiently investigated, so far. The aim of this study was to evaluate hemodynamic parameters for assessing TIPS function, predicting clinical outcome and their changes over time.
Method: A number of 216 consecutive patients with liver cirrhosis who underwent TIPS insertion at Hannover Medical School between 09/2019 and 12/2024 were included in a prospective registry. All available data from ultrasound examinations before TIPS insertion, within a week after, and after one, three, six, and twelve months were considered for this retrospective analysis.
Results: The median age of the cohort was 59 years and the median MELD score 12.27. Before TIPS-insertion mean Time-Averaged maximum velocity (Tmax) was measured at 15.27 cm/s in the main portal vein (PV) and 89% (n = 100) of patients had both left and right branches of the PV flowing orthograde. The median Resistance Index (RI) of the common hepatic artery was 0.73. Median Spleen length was 15 cm.
One week after TIPS insertion significant hemodynamic changes were documented. Mean Tmax of main PV increased significantly to a

33.39 cm/s ($p < 0.001$). In addition, a reversal from orthograde to retrograde flow was observed in both PV branches in 59.7% of cases. The mean maximum speed (Vmax) within the TIPS was 103.48 cm/s. In 20% of patients Vmax in the TIPS was <75 or >175 cm/s, which has been suggested as indicator for dysfunction in the past. However, this was not associated with a higher incidence of persistent ascites. Moreover, neither Tmax in the PV nor Vmax in the TIPS at this stage were linked to the occurrence of hepatic encephalopathy or the likelihood for recurrent severe ascites during further follow up.
Over time, we documented a significant continuous decrease of Tmax in the main PV, resulting in a mean Tmax of 24.55 cm/s after one year ($p = 0.02$). In contrast, no significant changes were observed in the RI of common hepatic artery or spleen size during the course of the follow-up examinations.
Conclusion: TIPS insertion immediately leads to significant alterations in hepatic blood flow. Further hemodynamic changes occur over time. However, ultrasound-based assessments of hemodynamic parameters early after TIPS insertion have a limited value for predicting clinical endpoints.

THU-463

Combining different non-invasive tests stratifies the risk of clinically significant portal hypertension (CSPH) in patients with compensated advanced chronic liver disease (cACLD)

Jimmy Che-To Lai[1,2], Pinky Yee-Ting Li[1], Grace Lai-Hung Wong[1,2], Vincent Wai-Sun Wong[1,2], Terry Cheuk-Fung Yip[1,2]. *[1]Medical Data Analytics Centre, Department of Medicine and Therapeutics, The Chinese University of Hong Kong, Hong Kong, Hong Kong; [2]Li Ka Shing Institute of Health Sciences and State Key Laboratory of Digestive Disease, The Chinese University of Hong Kong, Hong Kong, Hong Kong*
Email: jimmylai0515@gmail.com

Background and aims: Although using different algorithms with combined non-invasive tests (e.g., liver and spleen stiffness measurements [LSM and SSM, respectively]) reduces the number of patients classified as indeterminate risk of CSPH (i.e., grey zone), there has not been any comparison on which algorithm best stratifies the risk.
Method: This was the baseline analysis of a prospective cohort of adults with cACLD. The Baveno VII criteria for CSPH by LSM (≥25 kPa for ruling in and ≤15 kPa with platelet count $\geq 150 \times 10^9$/L for ruling out), SSM@100 Hz (>50 kPa for ruling in and <21 kPa for ruling out), as well as the combined Baveno VII and SSM model (fulfilling either two of LSM 15 kPa, platelet 150×10^9/L and SSM 40 kPa for ruling in and out), and the ANTICIPATE-NASH model (risk of CSPH ≥90% and <60% as ruling in and out) were assessed, with the presence of gastroesophageal varices as a surrogate marker for CSPH.
Results: 77 patients with cACLD, including 23 (29.9%) with varices, were recruited. The mean age was 64.3 years, 62.3% were male, and mean BMI was 26.1 kg/m^2, without significant difference between those with and without varices. Chronic viral hepatitis (61.0%) was the leading aetiology. Patients with varices had higher SSM (43.7 vs 28.1 kPa, $p = 0.002$) and lower platelet count (114.1 vs 173.3×10^9/L, $p < 0.001$), while there was no significant difference in LSM (17.5 vs 14.6 kPa, $p = 0.268$) between the two groups. Among the four algorithms, SSM alone classified the highest proportion of patients in the grey zone (63.6%), followed by Baveno VII criteria (46.8%), while the ANTICIPATE-NASH (22.1%) and the combined Baveno VII and SSM model (13.0%) significantly reduced the grey zone. The corresponding positive predictive values were 66.7% and 100% for ruling in, and negative predictive values were 88.4% and 75.9% for ruling out varices using the combined model and the ANTICIPATE-NASH model, respectively. The combined model had the highest area under the curve for predicting varices (0.794, 95% CI 0.670–0.918), and the strongest association with the presence of varices (odds ratio 40.0) after adjusting for non-selective beta-blocker (NSBB) use.
Conclusion: The combined Baveno VII and SSM model differentiates risk of CSPH, while ANTICIPATE-NASH model serves as an alternative when SSM is not available, to guide NSBB use in patients with cACLD.

ELF score and specifically hyaluronic acid one month after TIPS predict clinical outcomes

Lorenzo Lani[1,2,3,4], Marlene Hintersteininger[1,2], Theresa Müllner-Bucsics[1], Susanna Riegler[1], Georg Kramer[1,2], Christian Sebesta[1,2], Paul Thöne[1,2], Paula Hoefinger[1], Benedikt Simbrunner[1,2], Lukas Reider[5], Matthias Weiss-Tessbach[6], Rodrig Marculescu[6], Maria Schoder[5], Michael Trauner[1], Mattias Mandorfer[1,2], Thomas Reiberger[1,2,7], Lukas Hartl[1,2]. *[1]Division of Gastroenterology and Hepatology, Department of Medicine III, Medical University of Vienna, Vienna, Austria, Vienna, Austria; [2]Vienna Hepatic Hemodynamic Lab, Division of Gastroenterology and Hepatology, Department of Medicine III, Medical University of Vienna, Vienna, Austria, Vienna, Austria; [3]Unit of Semeiotics, Liver and Alcohol-related Diseases, IRCCS Azienda Ospedaliero-Universitaria di Bologna, Bologna, Italy, Bologna, Italy; [4]Department of Medical and Surgical Sciences, University of Bologna, Bologna, Italy, Bologna, Italy; [5]Department of Biomedical Imaging and Image-guided Therapy, Medical University of Vienna, Vienna, Austria, Vienna, Austria; [6]Department of Laboratory Medicine, Medical University of Vienna, Vienna, Austria, Vienna, Austria; [7]Christian Doppler Lab for Portal Hypertension and Liver Fibrosis, Medical University of Vienna, Vienna, Austria, Vienna, Austria*
Email: lorenzo.lani@studio.unibo.it

Background and aims: The Enhanced Liver Fibrosis (ELF) test, combining hyaluronic acid (HA), tissue inhibitor of metalloproteinases-1 (TIMP-1) and procollagen III N-terminal propeptide (PIIINP), is a marker of hepatic extracellular matrix turnover and fibrogenesis. We assessed the prognostic value and dynamics of ELF in patients with cirrhosis undergoing transjugular intrahepatic portosystemic shunt (TIPS).
Method: Patients undergoing covered TIPS placement at the Vienna General Hospital included in the prospective AUTIPS registry (NCT: NCT03409263; 01/2017–03/2025) with available ELF values pre- and post-TIPS were considered. ELF and its components were measured at baseline (BL), 1-month (M1) and M12 post-TIPS. Spearman and Fine-Gray competing risk regression (liver transplantation *versus* death) studied correlations and outcome associations.
Results: Among 80 included patients (median age 57 years, 65% male, 54% alcohol-related liver disease), median BL ELF was 11.7 (11.0–12.8). ELF showed an early increase after TIPS, followed by a return to baseline (BL: 11.7 vs M1: 12.2 vs M12: 11.9; $p < 0.001$). Both HA and PIIINP also increased at M1 and returned to BL values, (HA: BL: 322.2 ng/mL vs. M1 368.5 ng/mL vs M12: 313.7 ng/mL; $p < 0.001$; PIIINP: 19.3 ng/mL vs. M1: 28.3 ng/mL vs. M12 23.9 ng/mL; $p < 0.001$). Interestingly, however, TIMP-1 showed a constant decrease after TIPS (BL: 444.4 ng/mL vs M1: 404.6 ng/mL vs LM: 366 ng/mL; $p < 0.001$). Changes in ELF at M1 after TIPS correlated with those of Model of End Stage Liver Disease score (rho = 0.303, $p = 0.024$), liver stiffness (rho = 0.413, $p = 0.043$), Interleukin-6 (rho = 0.52, $p < 0.001$) and C-reactive protein (rho = 0.43, $p < 0.001$). ELF at M1 (aSHR: 1.62, 95% CI 1.13–2.33, $p = 0.009$) was independently linked to post-TIPS mortality. Specifically, M1 HA was independently associated with overt post-TIPS encephalopathy (per ng/mL $\times 10^{-3}$: asHR: 1.04, 95% CI 1.01–1.08, $p = 0.011$), acute-on-chronic liver failure (ACLF; per ng/mL $\times 10^{-3}$: asHR = 1.01, 95% CI 1.01–1.02, $p < 0.001$) and death (per ng/mL $\times 10^{-3}$: asHR: 1.01, 95% CI 1.01–1.02, $p < 0.001$). Patients with HA ≥442 mg/mL at M1 had significantly higher cumulative incidence of ACLF ($p = 0.043$) and death ($p = 0.013$) after TIPS.
Conclusion: ELF score and its components show a distinct dynamic post-TIPS with TIMP1 constantly decreasing, but a transient M1 increase in HA and PIIINP followed by a M12 decrease. A pronounced

early (M1) increase in HA after TIPS may reflect reduced sinusoidal clearance and indicates higher risks of HE, ACLF, and death.

THU-465

Splenic hyperkinetic syndrome: a universal driver of cirrhotic and non-cirrhotic portal hypertension

Sergii Kozlov[1], Ihor Kolosovych[1], Nadiia Yakovenko[1], Natalia Leshchynska[1]. [1]*Bogomolets National medical university, Kyiv, Ukraine*
Email: sergiinikol@gmail.com

Background and aims: Portal hypertension (PH) is attributed to increased intrahepatic resistance. However, the role of splanchnic hyperdynamic circulation, specifically excessive inflow, remains underappreciated. We hypothesized that splenic arterial hyperperfusion acts as a universal hemodynamic driver in PH - regardless of etiology - creating a volume overload that the portal system cannot accommodate. This study aims to evaluate the relations between splenic arterial inflow and portal venous flow in patients with established cirrhotic and non-cirrhotic PH.
Method: The study included three groups: 1) 47 patients with liver cirrhosis and cirrhotic PH (CPH); 2) 7 patients with non-cirrhotic PH (NCPH); 3) a control group of 41 healthy volunteers (CG). All patients of the CPH and NCPH groups presented with esophageal and gastric varices and a history of variceal bleeding(s). All participants underwent a Doppler ultrasound assessment. We analyzed spleen volume, splenic artery parameters (PSV, EDV, RI), and maximum linear flow velocities (V_{max}) in the splenic vein and the main portal vein (PV) trunk.
Results: Patients in the CPH group presented with significant splenomegaly (811.6 ± 342.2 cm/s vs. 146.35 ± 56.27 cm^3 in controls; $p < 0.001$) and a severe hyperdynamic state. PSV in the SA was up to 150.84 ± 43.57 cm/s compared to 85.43 ± 26.72 cm/s in controls ($p < 0.001$), with EDV nearly doubling. This arterial surge led to venous overload (SV velocity was 34.1 ± 15.55 cm/s vs. 23.54 ± 6.16 cm/s in CG, $p < 0.001$). A paradoxical deceleration was observed in the main portal vein (29.06 ± 9.43 cm/s vs. 35.67 ± 10.53 cm/s in controls, $p < 0.01$). This «hemodynamic mismatch» is a result of an existing left gastric vein shunt that feeds gastric/esophageal varices, effectively reducing velocity in the main portal trunk.
Conclusion: Our findings reveal distinct hemodynamic changes in patients with clinically significant portal hypertension: massive splenic artery inflow leads to accelerated venous output, which is then diverted to portosystemic collaterals (gastoesophageal varices). This pattern was consistent across both CPH and NCPH cohorts, suggesting that excessive splenic blood flow is a universal pathogenic driver of portal hypertension development. Targeting splenic inflow (e.g. via NSBB treatment, embolization or both) addresses this fundamental mechanism of collateral filling and may be effective regardless of the portal hypertension etiology.

THU-466

The differential effects of terlipressin on serum sodium trajectories are mediated by ascites status, treatment indication and baseline sodium

Dorothy Liu[1], Jacqueline Balassone[2], Royston Fernandes[3], Sophie Testro[4], Dinesh Pandey[5], Penelope Hey[1], Karl Vaz[6], Marie Sinclair[1], Avik Majumdar[1], Adam Testro[6]. [1]*Victorian Liver Transplant Unit, Austin Health, Australian Centre for Transplantation Excellence and Research (ACTER), Austin Health, Department of Medicine (Austin Precinct), The University of Melbourne, Melbourne, Australia;* [2]*Victorian Liver Transplant Unit, Austin Health, Australian Centre for Transplantation Excellence and Research (ACTER), Austin Health, Department of Pharmacy, Austin Health, Melbourne, Australia;* [3]*Victorian Liver Transplant Unit, Austin Health, Australian Centre for Transplantation Excellence and Research (ACTER), Austin Health, Melbourne, Australia;* [4]*Faculty of Science, The University of Melbourne, Melbourne, Australia;* [5]*Business Intelligence Unit, Austin Health, Melbourne, Australia;* [6]*Victorian Liver Transplant Unit, Austin Health, Australian Centre for Transplantation Excellence and Research (ACTER), Austin Health, Department of Surgery (Austin Precinct), The University of Melbourne, Melbourne, Australia*
Email: dorothyliu22@gmail.com

Background and aims: Terlipressin is an established therapy for complications of portal hypertension, however concerns persist regarding its potential to cause hyponatremia. Data describing serum sodium (sNa) trajectories during terlipressin therapy across clinical phenotypes are limited.
Method: We conducted a single-centre, retrospective study of consecutive adult patients treated with terlipressin between 2013 and 2024. Patients receiving treatment for < 2 days, with intrinsic renal disease or on renal replacement therapy were excluded. Linear mixed-effects modelling was used to analyse sNa trajectories for up to 14 days of treatment, stratified by ascites status, treatment indication and baseline sNa. Patients with a ≥ 5% sNa decrease from baseline were also evaluated. Severe hyponatremia was defined as sNa < 125 mmol/L.
Results: Across the entire cohort of 414 patients, sNa was observed to increase during terlipressin therapy (adjusted mean sNa change from baseline to day 14: 4 mmol/L, 95% CI 3 to 6, $p < 0.001$). However, changes in sNa differed according to the presence or absence of ascites, baseline sNa, and the indication for use (acute variceal bleeding [AVB]). Adjusted sNa increased over time in patients with ascites but remained stable in those without ascites. Similarly, adjusted sNa increased over time in baseline hyponatremic patients but remained stable in baseline normonatremic patients. An early decline in adjusted sNa was observed in patients with baseline normonatremia, no ascites, and treated with terlipressin for AVB (adjusted mean sNa change from baseline to day 5: −7 mmol/L, 95% CI −9 to −4, $p < 0.001$). 44 patients (11%) experienced a ≥ 5% decline in sNa relative to baseline and were more likely to have higher baseline sNa, lower baseline serum creatinine, lower Model for End-Stage Liver Disease (MELD) and be treated for AVB ($p < 0.001$). Baseline sNa and MELD were independently associated with a ≥ 5% decline in sNa from baseline (adjusted OR 1.13, $p < 0.001$ and adjusted OR 0.91, $p < 0.004$, respectively). Severe hyponatremia was rare, occurring in 10 patients (2%).
Conclusion: Whilst at a population level terlipressin increased sNa, we observed differential effects on sNa according to ascites status, treatment indication and baseline sNa. Clinically significant hyponatremia was uncommon and occurred mainly in patients without ascites, with higher baseline sNa and AVB as the indication for terlipressin, highlighting the need for closer monitoring in this subgroup during therapy.

Email: ma.ann.thu@gmail.com

Background and aims: Diagnosis of portosinusoidal vascular liver disease (PSVD) requires exclusion of cirrhosis using a liver biopsy together with signs of portal hypertension (PH) and/or histological lesions of PSVD. Previous studies showed that liver stiffness measurement using vibration-controlled transient elastography (VCTE-LSM) <10 kPa raises suspicion of PSVD in patients with signs of PH (non specific or specific). The aim of this study was to determine if VCTE-LSM <10 kPa, in patients with specific signs of PH, can reliably rule-out cirrhosis.
Method: Retrospective study including patients with specific signs of PH (either medium-large gastroesophageal varices or history of variceal bleeding or band ligation, or portosystemic collaterals on imaging) and biopsy-proven Child-Pugh A cirrhosis or PSVD according to VALDIG criteria. We compared reliable VCTE-LSM values, performed within 1 year of liver biopsy, between patients with PSVD and those with cirrhosis. Derivation cohort included patients from 3 European centers. Validation consisted in a reanalysis of a previously published cohort (PMID: 33345307), but focusing on patients with specific signs of PH. Data are presented as median (IQR).
Results: The derivation cohort included 106 patients with PSVD and 137 with cirrhosis (46% alcohol-related, 19% autoimmune hepatitis, 13% MASLD, 10% viral, 12% cryptogenic, 3% others). Median VCTE-LSM was 8.8 kPa (6.9–12.2) in patients with PSVD vs. 40.4 kPa (21.3–62.1) in those with cirrhosis ($p < 0.001$). VCTE-LSM <10 kPa had a specificity of 98% to rule out cirrhosis: 66/106 (62%) of patients with PSVD and 3/137 (2%) with cirrhosis had a VCTE-LSM <10 kPa. Of the 3 patients with cirrhosis misclassified, 2 had cryptogenic cirrhosis and 1 had autoimmune hepatitis. The validation cohort included 65 patients with PSVD and 43 with cirrhosis (53% viral, 40% alcohol-related, 7% MASLD). VCTE-LSM <10 kPa had a specificity of 98% to rule out cirrhosis: 48/65 (74%) patients with PSVD and 1/42 (2%) with cirrhosis had a VCTE-LSM <10 kPa. The single misclassified patient had alcohol-related cirrhosis and a VCTE-LSM of 9.8 kPa.
Conclusion: This study including a total of 171 patients with PSVD and 180 patients with cirrhosis demonstrates that, in the presence of specific signs of PH, a VCTE-LSM <10 kPa can reliably rule out cirrhosis. This threshold may therefore be considered for use in the context of clinical trials.

THU-468

Acute variceal bleeding in the UK: contemporary management and outcomes from a nationwide cohort study

Gaurav Nigam[1], Thomas Marjot[1], Shane Goodwin[2], Sarah Hearnshaw[3], Kathryn Oakland[4], John Grant-Casey[5], Ramon Uberoi[6], Alissa Walsh[1], Michael Murphey[7], Vipul Jairath[2,8], Simon Travis[1,9], Joanna Leithead[10], Andrew Douds[11], Adrian Stanley[12].

Email: gaurav.nigam@ouh.nhs.uk

Background and aims: Acute variceal bleeding (AVB) remains a life-threatening complication of portal hypertension. While outcomes have improved with standardisation of care, real-world data on adherence to best practice remain limited.
Method: We conducted a prospective, multicentre observational study across 147 UK hospitals, capturing real-world clinical, endoscopic, and organisational data for all acute upper gastrointestinal bleeding (AUGIB) presentations over an 8-week period in 2022. AVB management and outcomes were analysed by liver disease aetiology and hospital type, and compared with a 2007 national audit.
Results: Of 4279 patients undergoing endoscopy, 418 (10%) had confirmed AVB. Despite patients being older and more comorbid than in 2007, all-cause mortality was similar (13% vs. 15%, $p = 0.36$). Improvements were seen across several domains, yet pre-endoscopic antibiotics (57%) and vasopressors (64%) remained underused, and transfusion practices were often non-restrictive (55%). Only 42% of patients with recurrent AVB had received both endoscopic variceal ligation (EVL) and non-selective beta-blockers (NSBB) for secondary prevention, with 14% receiving neither therapy. Alcohol-related presentations had higher adherence to key care standards and were associated with reduced bleed-related (aOR 0.18; 95% CI 0.05–0.69) and all-cause mortality (aOR 0.36; 95% CI 0.15–0.88). This may indicate a greater general awareness of alcohol as a liver disease risk factor and due to ALD being more visible to acute physicians secondary to higher rates of clinical jaundice and coagulopathy. Survival between 14–28 days was higher in specialist liver centres ($p = 0.03$), although this was not statistically significant after adjustment for Child-Pugh class and age (HR 0.17; 95% CI 0.02–1.21; $p = 0.08$). Notably, 35% of hospitals lacked a consultant hepatologist. Transjugular intrahepatic portosystemic shunt (TIPSS) was underused, with less than 10% of eligible patients receiving the procedure.
Conclusion: AVB-related mortality in the UK is stable and but gaps remain in delivery of optimal clinical care, particularly in non-alcohol related presentations. Priorities include improving pre-endoscopic management, secondary prophylaxis, and TIPSS utilisation. Ongoing education and training, in addition to expansion of the specialist hepatology workforce requires re-evaluation.

EUS-guided direct portal pressure, clinically significant portal hypertension and spleen stiffness: diagnostic and prognostic integration in a prospective cohort

Francesco Martini[1], Lucia Salvi[1], Martina Dalla Bella[1], Annalisa Alessandrini[1], Daniele Balducci[1], Michele Montori[1], Luca Maroni[1], Marco Marzioni[1], Antonio Benedetti[1], Giuseppe Tarantino[1]. [1]*Azienda Ospedaliero Universitaria delle Marche, Clinic of Gastroenterology, Hepatology and Endoscopy, Ancona, Italy*
Email: martinifrancesco319@gmail.com

Background and aims: Clinically significant portal hypertension (CSPH) drives variceal formation and decompensation. The hepatic venous pressure gradient is invasive and not widely available, while non-invasive surrogates lack perfect individual accuracy. Endoscopic ultrasound (EUS)-guided direct portal venous pressure (PVP) can provide haemodynamic information during endoscopy. We evaluated the diagnostic performance of PVP versus the portal pressure gradient (PPG = PVP−hepatic/inferior vena cava pressure) for CSPH and explored their relationship with non-invasive markers and hepatic decompensation.
Method: Prospective single-centre cohort of adults undergoing combined upper endoscopy and EUS-guided portal pressure measurement. PVP was measured in the main portal vein; PPG was calculated as the difference between PVP and hepatic or inferior vena cava pressure. The protocol used conscious sedation, left-lateral decubitus, spontaneous breathing and zeroing at the mid-axillary line, with ≥3 stable end-expiratory plateaus per site. Liver and spleen stiffness were assessed by transient elastography; platelet count was obtained from routine tests. Diagnostic performance was assessed by ROC curves and paired DeLong tests. Associations with CSPH and prior decompensation were evaluated in prespecified multivariable logistic models; subsequent decompensation was analysed by Kaplan–Meier and Cox models using PVP ≥20 mmHg and PPG ≥10 mmHg and internally validated continuous effects.
Results: Fifty-two patients were included (63.5% male; median age 56.5 years); CSPH was present in 31/52 (59.6%). For CSPH, AUCs were 0.84 for PVP and 0.67 for PPG ($p = 0.005$); optimal thresholds were 27.5 and 10.5 mmHg. Higher PVP, but not PPG, remained independently associated with CSPH and prior decompensation. PVP correlated strongly with spleen stiffness ($r \approx 0.77$, $R^2 \approx 0.59$), with weaker correlations for liver stiffness and platelets. Over a median follow-up of 255 days, 12 patients (23%) developed hepatic decompensation; risk was higher for PVP ≥20 mmHg (log-rank $p \approx 0.007$), while PPG showed a less stable association in penalised and bootstrap-validated Cox models.
Conclusion: EUS-measured PVP outperforms PPG for CSPH, aligns closely with spleen stiffness and provides a more consistent prognostic signal for decompensation. These data support integrating EUS-guided haemodynamic assessment with non-invasive markers for risk stratification in hepatology pathways and call for multicentre validation alongside traditional invasive strategies.

THU-474

EUS-guided coil and glue injection and beta-blockers versus b-blockers alone for primary prophylaxis of gastric varices in cirrhosis – a multicentre propensity-matched analysis from India

Shubham Mehta[1], Amol Bapaye[2], Jimil Shah[3], Pawan Khatri[2], Vignesh Dwarkanathan[4], Harsh Jain[1], Shrihari Anil Anikhindi[5], Hitesh Panchal[1], Nikhil Sonthalia[6], Anirudh Gupta[7], Ankit Agarwal[8], Ashish Agarwal[8], Aditya Vikram Pachisia[9], Pawan Rawal[1], Rajesh Puri[1]. [1]*Medanta Hospital, Gurugram, India;* [2]*Deenanath Mangeshkar Hospital & Research Centre, Pune, India;* [3]*Postgraduate Institute Of Medical Education And Research Chandigarh, Chandigarh, India;* [4]*Esic Medical College and Hospital, Chennai, India;* [5]*Sir Ganga Ram Hospital, New Delhi, India;* [6]*Apollo Gleneagles Hospital, Kolkata, India;* [7]*Sawai Man Singh Medical College, Jaipur, India;* [8]*All India Institute of Medical Sciences College, Jodhpur, India;* [9]*Commando Hospital, Bengaluru, India*
Email: mehta.shubham1493@gmail.com

Background and aims: EUS-guided coil and cyanoacrylate injection (EUS-CG) is effective for bleeding gastric varices (GV) and secondary prophylaxis, however, there is paucity of data on primary prophylaxis of GV. We compared the efficacy of addition of EUS-CG to beta-blockers against beta-blockers alone for primary prophylaxis of GV bleeding.
Method: This multi-centre observational study included patients across 8 tertiary care centres in India. Adult patients with cirrhosis and large gastric varices (F2 or F3) without prior bleeding were included. Baseline demographics, prior non-bleeding decompensating events and clinical outcomes including bleeding, hepatic decompensation and mortality were reviewed. Patients on beta-blockers undergoing EUS-CG (EUS-CG + ß-blocker arm) were compared with propensity-matched patients on beta-blockers alone (ß-blocker arm). The primary outcome was to compare the probability of being free from first GV bleeding.
Results: Of 231 patients, 86 who underwent EUS-CG and received beta-blockers were compared with 86 propensity-matched cases who received beta-blockers alone. Of 86 patients in the EUS-CG + ß-blocker arm with a median follow up of 15.3 months, 9 (10.5%) patients had GV bleeding, while among 86 propensity-matched cases in ß-blocker arm with a median follow-up of 25.9 months, 25 (29.1%) patients had GV bleeding. There was no significant difference in the probability of being free from first GV bleeding (sHR: 0.60,95% CI:0.28–1.27; $p = 0.18$), all-cause bleeding (sHR:0.76,95%CI:0.43–1.34;$p = 0.34$), freedom from hepatic decompensation (sHR:0.70,95%CI:0.45–1.08;$p = 0.10$) and overall survival (sHR: 1.54, 95% CI: 0.75–3.16; $p = 0.24$) between the patients in the EUS-CG + ß-blocker arm compared to ß-blocker arm. On multivariate regression analysis, higher MELD-Na score alone was a significant predictor of bleeding (aOR:1.12,95%CI:1.06–1.19; $p = 0.03$) and mortality (aOR: 1.23,95%CI:1.11–1.34; $p = 0.02$). Sub-group analysis revealed no significant difference in outcomes across Child-Pugh classes, though patients with F3 gastric varices had lower GV bleeding rates (sHR:0.33, 95%CI:0.13–0.84; $p = 0.02$).
Conclusion: In patients with cirrhosis and large gastric varices, a combination of EUS-coil and glue injection and beta-blockers was not superior to ß-blocker alone therapy for the prevention of first GV bleeding. Randomised controlled trials are needed to study the efficacy of EUS-coil and glue injection for primary prophylaxis of GV bleeding.

THU-475

Disease severity modifies the mortality benefit of antibiotic prophylaxis in patients with liver disease and upper gastrointestinal bleeding

Noy Nachmias-Peiser[1,2], Oren Shibolet[1,2], Michal Hoffman Ben-Shabat[2]. [1]*Department of Gastroenterology and Liver Diseases, Tel Aviv Sourasky Medical Center, affiliated with Gray Faculty of Medicine, Tel Aviv University, Tel Aviv, Israel, Tel Aviv-Yafo, Israel;* [2]*Gray faculty of medical and health science, Tel Aviv university, Tel Aviv, Israel*
Email: noy.na87@gmail.com

Background and aims: Antibiotic prophylaxis is recommended for cirrhotic patients with acute variceal bleeding, but data supporting its routine use is limited. This study evaluates the impact of prophylactic antibiotics and the timing of administration on mortality in patients with liver disease and upper gastrointestinal bleeding, stratified by MELD score.
Method: This retrospective cohort study included 441 adult patients with suspected acute upper GI bleeding and pre-existing liver disease from Tel Aviv Sourasky Medical Center (June 2006-November 2024). All patients underwent gastroscopy. Prophylactic antibiotic exposure was defined as systemic antibiotics within 24 hours of admission. The

primary outcome was in-hospital mortality. Multivariable logistic regression was performed for the overall cohort and separately for patients with confirmed cirrhosis (n = 285), stratified by MELD score.
Results: Antibiotics were given to 122 patients (27.7%). Those receiving antibiotics had higher disease severity (median MELD score 18 versus 14.5, p = 0.002). Crude mortality was higher in the antibiotic group (12.3 versus 4.1%, p = 0.002). Mortality increased with MELD severity, 3.5% for MELD ≤10, 13.3% (10 < MELD < 19), and 36.0% (MELD ≥19) (p < 0.001). After multivariable adjustment, antibiotic use did not reduce mortality overall, but in patients with MELD ≥19, it was associated with lower mortality (adjusted odds ratio 0.24, 95% CI 0.06–0.98, p = 0.047). No benefit was found for patients with MELD <19. Timing analysis showed no survival advantage for antibiotics administered before endoscopy compared to within 24 hours of admission (adjusted odds ratio 2.41, 95% CI 0.76–7.68, p = 0.136). Intravenous pantoprazole was associated with lower mortality.
Conclusion: In this retrospective cohort, antibiotic prophylaxis was associated with lower in-hospital mortality among patients with liver disease and upper gastrointestinal bleeding who had a high MELD score, but not among those with lower MELD scores. These findings suggest that disease severity may modify the association between antibiotic prophylaxis and survival. Notably, the observed benefit of antibiotic prophylaxis did not appear to be strongly influenced by administration before endoscopy. Together, these results underscore the need for prospective studies to further investigate whether severity-based stratification, such as by MELD score, can help refine current approaches to prophylactic antibiotic use.

THU-476

Hepatic bile acid extraction in liver cirrhosis and longitudinal profiles after transjugular intrahepatic portosystemic shunt placement

Maximilian Nepel[1], Simon Johannes Gairing[2], Nicole Feldbacher[1], Peter R. Galle[2], Tilmann Graeter[1], Florian Hinterhoelzl[1], Myriam Meineck[2], Romana Penker[1], Michael Bernhard Pitton[2], Rupert Horst Portugaller[1], Giovanny Rodriguez Blanco[1], Eva Maria Schleicher[2], Paul Schneider[2], Luisa Smolle[1], Jasmin Soehngen[2], Julia Weinmann-Menke[2], Gernot Zollner[1], Christian Labenz[2], Vanessa Stadlbauer[1]. *[1]Medizinische Universität Graz, Graz, Austria; [2]University Medical Center of the Johannes Gutenberg-University, Department of Internal Medicine I, Cirrhosis Center Mainz (CCM), Mainz, Germany*
Email: vanessa.stadlbauer@medunigraz.at

Background and aims: Liver cirrhosis causes progressive loss of hepatic metabolic function, including impaired uptake and clearance of bile acids (BAs) from portal blood. This may alter the transhepatic BA gradient and promote portal hypertension with complications such as refractory ascites or variceal bleeding. Transjugular intrahepatic portosystemic shunt (TIPS) reduces portal pressure by diverting portal blood into the systemic circulation but bypasses hepatic BA extraction, potentially modifying systemic BA profiles. This study aimed to characterize the transhepatic BA gradient in cirrhotic patients and to evaluate longitudinal changes in BA concentrations after TIPS placement.
Method: Serum BA concentrations in 82 patients with liver cirrhosis (age 62 +/- 12.8 years, 28% female) undergoing TIPS placement were quantified with ultrahigh-performance liquid chromatography tandem mass spectrometry (UPLC-MS/MS). The hepatic BA extraction by the liver across disease severity (Child–Pugh (CP) classes A–C) was assessed by simultaneous hepatic and portal vein sampling during TIPS. Peripheral serum samples were obtained before TIPS, immediately after, and up to 180 days post-procedure to evaluate longitudinal changes in systemic BA profiles.
Results: Hepatic BA extraction was observed in 81% of patients and correlated significantly with disease severity by CP class (p < 0.002). Median hepatic extraction of total BAs decreased from 52% in CP A to 14% in CP C, with significant extraction of conjugated primary as well as conjugated and unconjugated secondary BAs. Following TIPS, absolute serum BA profiles changed significantly over time, whereas relative composition remained largely preserved. Individual BA profiles were similar at baseline and immediately after TIPS. However, total BA levels (p < 0.002), particularly conjugated primary BAs (p < 0.01), increased up to day 90. Afterwards, they declined toward baseline by day 180.
Conclusion: Hepatic BA extraction remained detectable even in advanced liver cirrhosis but declined progressively across CP classes and affected the entire BA pool. After TIPS and diversion of portal flow, systemic BA levels, particularly conjugated primary BAs, increased during the first three months, followed by a decline at six months. Whether rising BA levels reflect enhanced BA synthesis or impaired clearance due to shunting, and whether subsequent decreases indicate metabolic adaptation, requires further investigation.

Email: nguyen-khac.eric@chu-amiens.fr

Background and aims: Porto sinusoidal vascular disease (PSVD) can progress to non-cirrhotic portal hypertension (PH). In cases of recurrent PH bleeding or refractory ascites, the role of transjugular intrahepatic portosystemic shunt (TIPS) and the prognosis remain uncertain. We report results of TIPS in PSVD patients in a multicenter retrospective study.
Method: 122 patients with PSVD who underwent TIPS in 23 French and Belgium centers were compared to 363 patients with cirrhosis who underwent TIPS for the same complications of recurrent bleeding, refractory ascites, or other indications. Overall survival and recurrence-free survival were compared without adjustment, then adjusted with a propensity score, and sensitivity analysis excluding preemptive indications.
Results: PSVD or cirrhosis patients were male 66% vs 83% (p < 0.001), age 57 vs 58 years (p = 0.3), PT 75% vs 53% (p < 0.001), albumin 33 vs 28 g/L (p < 0.001), bilirubin 14 vs 33 µmol/L (p < 0.001), and

extrahepatic conditions in 73% of PSVD. TIPS was initiated for hemorrhage, ascites, or other indications in 52%, 30%, 13% (82% preemptive of surgery) of PSVD patients vs 67%, 31%, 1.1% of cirrhosis patients ($p < 0.001$). Before adjustment, overall mortality rate was 20% in PSVD group (median follow-up 54.8 months) versus 41% in cirrhosis group (FU 31.5 months) ($p < 0.001$). After adjustment, overall survival was higher in PSVD group (HR = 0.42 (95%CI:0.21–0.85) $p = 0.015$) with 5-year survival of 84% vs 49% in cirrhosis group, as well as in sensitivity analysis ($p = 0.048$). After adjustment, recurrent bleeding-free survival was higher in PSVD group (HR = 0.50 (95%CI:0.26–0.94) $p = 0.032$) with 5-year survival of 75% vs 45% for cirrhosis group, but there was no significant difference in sensitivity analysis ($p = 0.06$). After adjustment there were no difference between two groups for, recurrent ascites-free survival ($p = 0.053$), thrombosis-free survival ($p = 0.29$), and hepatic encephalopathy-free survival ($p = 0.26$). In multivariate analysis restricted to PSVD-TIPS group for recurrent bleeding and refractory ascites, age, albumin, creatinine, and severe extrahepatic disease were independent factors associated with post-TIPS survival. A prognostic model with score >8.2 isolates a group of post-TIPS PSVD patients with significantly impaired survival ($p < 0.0001$).

Conclusion: Overall survival in PSVD patients with TIPS implanted for recurrent PH bleeding or refractory ascites is higher compared to cirrhosis patients with same TIPS reasons. A prognostic model predicts post-TIPS-PSVD survival.

THU-478

Effect of polyethylene glycol versus lactulose on hepatic encephalopathy in patients with liver cirrhosis: a randomized clinical trial (PEG-HE trial)

Om Parkash[1], Shahab Abid[1], Mahrukh Ali[1], Abhishek Lal[1], Saeed Sadiq Hamid[1]. [1]*Aga Khan University, Pakistan, Karachi, Pakistan*
Email: om.parkash@aku.edu

Background and aims: Hepatic encephalopathy is a prevalent complication of liver cirrhosis being responsible for significant morbidity and mortality. Lactulose remains the gold standard treatment for liver cirrhosis; however, its use is limited by refractory effectiveness and adverse effects. Polyethylene glycol is emerging to be a potential alternative therapy. This study aimed to compare effectiveness and safety of PEG and lactulose in patients hospitalized with HE.

Method: This randomized controlled trial, with parallel group was conducted at Aga Khan University, Karachi, Pakistan. Eligible patients were randomized to receive either PEG or lactulose. The primary outcome was resolution of HE with ≥1-grade reduction in HESA score at 24, 48, and 72 hours. The secondary outcomes were the length of hospital stay, adverse events, readmissions, and three-months mortality.

Results: A total of 55 patients were enrolled. Patients receiving PEG and lactulose achieved comparable effectiveness in resolution of HE in 72 hours (p-value = 0.7232). At 24 and 48 hours, both PEG and lactulose achieved similar HESA scores demonstrating comparable effectiveness in resolving HE, although not statistically significant (p-value = 0.2605, p-value = 0.5222). The lower bounds of the 95% confidence intervals for risk differences continuously stayed above the 10% threshold, indicating that PEG was non-inferior to lactulose at all timepoints. No adverse events were reported in both groups, with similar readmissions and three-month mortality.

Conclusion: PEG was found to be effective in resolving HE with initial improvement in symptoms and safety profile. PEG presents to be a viable alternative to lactulose for HE management, although long-term studies with larger sample sizes are warranted.

THU-479

Magnitude of hepatic venous pressure gradient reduction predicts clinical events in portal hypertension: meta-regression analysis of randomized-controlled trials

Irene Pascual-Lopez[1,2], Matthew Tam[1], Daniel van Zanten[1], Shuen Sung[1], Jarell Jie-Rae Tan[3,4], Yu Jun Wong[4,5], Juan G Abraldes[1]. [1]*University of Alberta, Division of Gastroenterology, Liver Unit, Edmonton, Canada;* [2]*Hospital Universitari Arnau de Vilanova, Department of Gastroenterology and Hepatology, Lleida, Spain;* [3]*Yong Loo Lin School of Medicine, National University of Singapore, Singapore, Singapore;* [4]*Changi General Hospital, Department of Gastroenterology and Hepatology, Singapore, Singapore;* [5]*Duke-Nus Medical School, Singapore, Singapore*
Email: irene.pascual.l5@gmail.com

Background and aims: Portal hypertension is a primary driver of mortality and complications in cirrhosis. While observational studies demonstrate that reductions in hepatic venous pressure gradient (HVPG) correlate with improved outcomes, the magnitude of risk reduction per unit decrease in HVPG has not been quantified across randomized controlled trials (RCTs). We performed a meta-regression to quantify the relationship between HVPG reduction and clinical outcomes in RCTs.

Method: We systematically searched databases for RCTs in portal hypertension testing a drug intervention over placebo or no therapy, and reporting HVPG measurements and clinical outcomes. The predictor was the between-group difference in HVPG reduction (treatment minus control in mmHg). The endpoints were mortality and "variceal event" defined hierarchically: progression (when reported), otherwise variceal bleeding. This aimed to maximize usable RCTs while capturing clinically meaningful portal hypertension progression. We performed random-effects meta-regression, examining the association between HVPG reduction and log odds ratios for these clinical outcomes. Sensitivity analyses tested different weighting schemes to account for measurement error in HVPG.

Results: Twenty-two RCTs including a total of 2,844 patients were included. Within the trials, HVPG was measured in 2,048 individuals. Non-selective beta-blockers were the most frequently tested drug class. Each 1 mmHg reduction in HVPG was associated with reduced mortality (OR 0.850, 95% confidence interval 0.768 to 0.941, $p = 0.005$) and variceal progression or bleeding (OR 0.854, 95% confidence interval 0.747 to 0.975, $p = 0.031$), with low heterogeneity (I^2 0% and 18.5% respectively). Results were robust across multiple weighting schemes accounting for HVPG variability, including joint (predictor and outcome) weighting, and iteratively reweighted meta-regression.

Conclusion: Using a meta-analytic approach, we demonstrate a dose-dependent relationship between HVPG reduction and clinical outcomes in RCTs of portal hypertension, with approximately 15% lower odds of mortality and variceal events per 1-mmHg reduction. These findings may inform the design and powering of Phase III trials based on HVPG responses in Phase II studies.

THU-480-YI

High incidence and clinical relevance of concomitant hepatopulmonary syndrome among patients with portopulmonary hypertension

Jendrik Peters[1], Da-Hee Park[2], Marius M. Hoeper[2,3], Heiner Wedemeyer[1,4,5], Benjamin Maasoumy[1,4], Karen Olsson[2], Tammo Lambert Tergast[1]. [1]*Department of Gastroenterology, Hepatology, Infectious Diseases and Endocrinology, Hannover Medical School, Hannover, Germany;* [2]*Department for Respiratory Medicine and Infectious Diseases and German Centre of Lung Research (DZL), Hannover Medical School, Hannover, Germany, Hannover, Germany;* [3]*German Center for Lung Research (DZL), Biomedical Research in Endstage and Obstructive Lung Disease Hanover (BREATH), Hannover, Germany;* [4]*German Center for Infection Research (DZIF), Hannover-Braunschweig, Germany;* [5]*Excellence Cluster Resist, Hannover Medical*

School, Hannover, Germany
Email: peters.jendrik@mh-hannover.de

Background and aims: Portopulmonary Hypertension (POPH) is a rare but severe pulmonary complication of portal hypertension and is associated with decreased survival. Hepatopulmonary Syndrome (HPS), another pulmonary vascular complication, is considerably more prevalent and has also been linked to adverse clinical outcomes. Although coexistence of HPS in patients with POPH has been described, data regarding the exact prevalence and clinical relevance remain scarce. Here, we aimed to investigate the frequency and clinical impact of concomitant HPS in patients with POPH.
Method: This analysis included all patients consecutively diagnosed with POPH at Hanover Medical School between 1998 and 2025. POPH and HPS were diagnosed according to current guidelines and all patients underwent right-heart catheterization (RHC), blood gas analysis (BGA) and contrast-enhanced transthoracic echocardiography (cTTE). The primary endpoint was a composite of death or liver transplantation (LTx-free survival).
Results: Of 86 patients with POPH, a total of 43 (50%) underwent cTTE over the course of their treatment; 11 of these had sequential cTTE examinations. Median age was 53 years and the majority of patients were female (55%). Median mean pulmonary arterial pressure (mPAP) was 48 mmHg, median $P(A\text{-}a)O_2$ was 45 mmHg and intrapulmonary vascular dilations (IPVDs) were detected in 31 of 43 patients (72%), while 30 patients (70%) fulfilled the criteria for HPS. Of note, patients with HPS did not show a significant difference regarding mPAP or P(A-a)O2 compared with patients without HPS. In total, 13 patients in the HPS cohort died and 3 were transplanted, whilst 6 patients died in the No HPS cohort. LTx-free survival, adjusted for age and mPAP, was significantly lower in patients with HPS compared with those without HPS (hazard ratio [HR] 6.49, 95% confidence interval [CI] 1.38–30.56, p = 0.018). To investigate whether IPVDs may develop or regress in those with POPH, all patients with sequential cTTE were investigated separately: Here, 7 had no IPVDs at baseline and 4 had pre-existing IPVDs. All patients with baseline IPVDs showed persistence over time, while 5 patients without baseline IPVDs developed IPVDs with HPS during follow-up.
Conclusion: In patients with POPH, IPVDs and HPS are common, may develop over time and are associated with significantly reduced LTx-free survival. Screening for concomitant HPS and development of IPVDs in patients with POPH should be considered.

THU-481

Same session validation of a custom-built 22G with the commercial 25G system for EUS-guided portal pressure gradient measurement

Michael Praktiknjo[1], Nancy Farouk[1], Zeyu Wang[1], Juliana Stadtmann[1], Dominik van de Loo[1], Markus Kimmann[1], Carina Gunia[1], Jörn Arne Meier[1], Frank Erhard Uschner[1], Kai-Henrik Peiffer[1], Wim Laleman[1,2], Jonel Trebicka[1], Barbara Braden[1]. *[1]Department of Medicine B, University Hospital Münster, Münster, Germany; [2]University Hospitals Leuven, Leuven, Belgium*
Email: michael.praktiknjo@ukmuenster.de

Background and aims: Endoscopic ultrasound-guided portal pressure gradient (EUS-PPG) measurement is a promising alternative to hepatic venous pressure gradient (HVPG) assessment, especially in settings where HVPG is unavailable or limited. The commercial 25-gauge (25G) system showed good correlation against hepatic venous pressure gradient (HVPG). However, the 25G has drawbacks due to its small calibre and the proprietary pressure transducer. The aim of this study is to validate a custom-built 22G conventional intravascular pressure transducer system (22G EUS-PPG).
Method: In this prospective study, 26 patients underwent EUS-PPG measurement using both systems during the same session. The primary outcome was the correlation of PPG values. Secondary outcomes included the correlation and variability of portal vein pressure (PVP) and hepatic vein pressure (HVP) measured by both systems.
Results: PPG values showed excellent correlation of both systems (r = 0.901, p < 0.001). 25G EUS-PPG correctly identified clinically significant portal hypertension (CSPH, defined as PPG ≥ 10mmHg) in 25 of 26 (96.2%) cases. Portal vein and hepatic vein pressures also correlated significantly (r = 0.776 and r = 0.673, respectively) between both systems. Variability within both systems was very low to low.
Conclusion: EUS-PPG measurements obtained with the commercial 25G and custom-built 22G EUS-PPG systems are validated. The custom-built 22G system excels due to pressure-tracing quality control, availability and cost-efficiency.

TIPS implantation significantly reduces risk of infections in patients with decompensated cirrhosis: the multicenter TIPSIN study of the German cirrhosis study group

Stefanie Quickert[1], Markus Kimmann[2], Marlene Reincke[3], Isabel Brüggemann[4], Georgios Konstantis[5], Theresa Hildegard Wirtz[6], Felix Piecha[7], Marko Damm[8], Alexander Barton[9], Sophie Schlosser-Hupf[10], Julian Allgeier[11], Cornelius Engelmann[12], Julia M. Grottenthaler[13], Angelika Mendel[1], Lukas Sturm[3], Joséphine Fritz[2], Zeyu Wang[2], Frank Erhard Uschner[2], Jonel Trebicka[2], Jassin Rashidi-Alavijeh[5], Johannes Chang[4], Dominik Bettinger[3], Tony Bruns[6], Cristina Ripoll[1], Michael Praktiknjo[2]. *[1]Jena University Hospital, Jena, Germany; [2]University Hospital Münster, Münster, Germany; [3]Medical Center University of Freiburg, Freiburg, Germany; [4]Bonn University Hospital, Bonn, Germany; [5]University of Duisburg-Essen, Essen, Germany; [6]University Hospital RWTH Aachen, Aachen, Germany; [7]University Medical Center Hamburg-Eppendorf, Hamburg, Germany; [8]University Hospital Halle, Halle, Germany; [9]Saarland University Medical Center, Homburg, Germany; [10]University Hospital Regensburg, Regensburg, Germany; [11]LMU University Hospital Munich, Munich, Germany; [12]Charité-Universitätsmedizin Berlin, Berlin, Germany; [13]University Hospital Tuebingen, Tübingen, Germany*
Email: stefanie.quickert@med.uni-jena.de

Background and aims: Infections in cirrhosis are common and lead to increase in mortality. Key drivers include portal hypertension, systemic inflammation and cirrhosis-associated immune-dysfunction (CAID). Transjugular intrahepatic portosystemic shunt (TIPS) implantation effectively reduces portal hypertension and can impact CAID, and thus the incidence of infections, however data are scarce. The aim was to compare the prevalence of infections before and after TIPS.
Method: This multicenter retrospective study screened 1,800 patients with liver cirrhosis undergoing TIPS implantation between 2014 and 2024 across 13 German centers. Primary outcome was prevalence of bacterial infections within 3 months before and after TIPS implantation using McNemar test. Secondary outcome was 1-year transplant-free survival. Factors associated with post-TIPS infections were identified using logistic regression analysis.
Results: A total of 1,320 patients were included (median age 59 years, 65% male, 59% alcohol-related cirrhosis, median MELD score 13). The main indication for TIPS implantation was refractory or recurrent ascites (66%). Infection rates were significantly higher 3 months prior to TIPS compared to 3 months after TIPS implantation (31% vs. 22%; p < 0.001). Post-TIPS infections were independently associated with pre-TIPS infections (OR 1.43; CI 1.07–1.91), recurrent/refractory ascites (OR 1.55; CI 1.15–2.25), female sex (OR 1.38; CI 1.04–1.83) and Child-Pugh score (OR 1.20; CI 1.09–1.31) in multivariable analysis. Patients developing infections within 90 days after TIPS showed significantly lower 1-year transplant-free survival compared with those without infections (48.4 vs. 82.3%, p < 0.001).
Conclusion: TIPS implantation is associated with a significant reduction in infection rates in patients with decompensated liver

cirrhosis. However, post-TIPS infections remain strongly associated with impaired transplant-free survival.

THU-483

BAVENO VII criteria and ANTICIPATE models predict first decompensation in a multi-center U.S. cohort of patients with compensated advanced chronic liver disease (cACLD)

Email: anahita.rabiee@yale.edu

Background and aims: Portal hypertension is the primary driver of decompensation in cACLD and can be determined non-invasively via liver stiffness measurements (LSM) by vibration controlled transient elastography (VCTE). We evaluated Baveno VII LSM thresholds and ANTICIPATE/ANTICIPATE-NASH models for predicting hepatic decompensation in a diverse U.S. cohort with a high prevalence of metabolic dysfunction-associated steatotic liver disease (MASLD).
Method: We included consecutive adults from 8 U.S. centers with a LSM≥ 10 kPa by VCTE (defining cACLD) without a prior history of decompensation. Risk strata were defined by Baveno VII LSM categories (10 to <15, 15 to <25, and ≥25 kPa). ANTICIPATE-NASH (BMI ≥30 kg/m^2 and MASLD) or original ANTICIPATE (all other etiologies) were applied and grouped into quantiles. The primary outcome was first decompensation. Associations were assessed using Fine–Gray competing risk model, accounting for hepatocellular carcinoma, non-liver-related death, and transplant before decompensation.
Results: A total of 592 patients were included (median age 58.9 years, 57% female, 74% White); MASLD predominated (66%). The median BMI was 33 [29, 40] kg/m^2 and 70% had BMI of ≥25. Diabetes, hyperlipidemia and hypertension were present in 51%, 47% and 49%. LSM risk distributions were: 10–15 (n = 298, 50%), 15–25 (n = 191, 32%), ≥25 (n = 103, 17%). In a median of 5-year follow-up (IQR 4–5), 47 patients (8%) developed first decompensation, with ascites being the most common (n = 19, 40%). LSM ≥ 25 had a 4.8- fold higher hazard of decompensation compared to LSM 10–15 (sub-distribution hazard ratio [sHR]: 4.8, 95% CI: 2.4–9.7). The risk of decompensation was not statistically different between LSM 15–25 and LSM 10–15 (sHR: 1.9, 95% CI: 0.9–3.9). Using ANTICIPATE models, patients in 4th quantile had a 9-fold higher hazard of decompensation vs 1st quantile (sHR: 9.1; 95% CI, 2.8–30.1). After adjustment for ANTICIPATE models risk quantiles, patients with MASLD and obesity had a lower observed hazard of decompensation compared with other etiologies (sHR 0.36, 95% CI 0.19–0.69).
Conclusion: Baveno VII and ANTICIPATE/ANTICIPATE-NASH models can be used to stratify decompensation risk in a real world U.S. cohort, reinforcing their usefulness in clinical-decision making. Notably, patients with MASLD and obesity had a lower risk of decompensation, emphasizing the need for tailored prognostic strategies. These data provide a rationale for prospective validation and integration into MASLD care pathways in the U.S.

THU-484

Predictors of multiple endoscopic variceal ligation sessions for obliteration of esophageal varices: a prospective study in a tertiary-level hospital in Bangladesh

Antora Rahut[1], Suprokash Sarkar[1], Mohammad Rifat Mustafa[1], Debashish Sarkar[1], Dilip Ghosh[1], Habib Ahmed[1], Mohammad Mahmuduzzaman[1]. *[1]Shaheed Suhrawardy Medical College Hospital, Dhaka, Bangladesh*
Email: antora37@yahoo.com

Background and aims: Endoscopic variceal ligation (EVL) is the standard treatment of variceal bleeding in patients with portal hypertension. Multiple sessions are often required for complete obliteration, significantly burdening healthcare resources and patient compliance. This study aims to determine the number of EVL sessions required for complete obliteration of esophageal varices and to identify factors influencing the requirement of multiple sessions.
Method: This prospective observational study was conducted at Shaheed Suhrawardy Medical College Hospital, Bangladesh, between January 2024 and December 2025 among 79 adult patients with esophageal varices who underwent EVL for primary or secondary prophylaxis. Patients were followed until complete obliteration of varices. Demographic, clinical, endoscopic, and laboratory findings were recorded and analyzed by univariate and multivariate logistic regression to identify predictors of multiple EVL sessions. A risk stratification model was developed.
Results: The mean age of patients was 51.4 ± 12.3 years, with 68.3% being male. Overall, 60.8% of patients required multiple EVL sessions (mean 2.16 ± 1.63). Factors significantly associated with multiple EVL sessions included: higher MELD score ($p < 0.001$), Child-Turcotte-Pugh (CTP) Class C ($p < 0.001$), large variceal size ($p < 0.001$), presence of red signs ($p = 0.042$), lower serum albumin ($p = 0.015$), lower hemoglobin ($p < 0.001$), higher INR ($p = 0.022$), presence of ascites ($p = 0.031$), larger spleen size ($p = 0.002$), and elevated bilirubin levels ($p = 0.010$). CTP class C, large varices, and low platelet count were independent predictors of multiple sessions on multivariate logistic regression analysis. A risk stratification model was established, which categorized patients into high- intermediate- and low-risk groups, where advanced liver disease and the presence of a greater number of risk factors posed a greater risk of multiple EVL sessions. Parameters that showed no significant association included creatinine, sodium, diabetes mellitus, hypertension, congestive gastropathy, and previous upper gastrointestinal bleeding. Applying more bands in the initial session was associated with more single-session obliteration.
Conclusion: This study identifies a comprehensive risk profile, encompassing clinical, endoscopic and laboratory parameters predicting the need for multiple sessions. This may help clinicians optimize treatment planning and patient counseling, especially in resource-constrained settings.

THU-485

Spleen stiffness measurement and predicting the need for endoscopy in obese MASH cirrhosis

Eabha Ring[1,2], Suzanne Norris[1,2], Lewel Alvarado[1], Kimmy Villaluna[1], Noelia Justo Rubio[1], Noelle Cullen[1], Collen Ray Arrogante[1], Issabele Pulcherio[1], Clodagh Quinn[1], Finbar MacCarthy[1,2], David Prichard[1,2]. [1]*Department of Hepatology, St James's Hospital, Dublin, Ireland;* [2]*Department of Clinical Medicine, School of Medicine, Trinity College Dublin, Dublin, Ireland*
Email: eabharing@live.com

Background and aims: Non-invasive tests (NIT) for identifying clinically significant portal hypertension (CSPH) using liver and spleen stiffness measurements (LSM, SSM) and platelet count are less reliable in obese metabolic dysfunction-associated steatohepatitis (MASH) cirrhosis than other cirrhosis aetiologies. As MASH cirrhosis is now a leading cause of liver-related deaths worldwide, this limitation is of concern. Algorithms including LSM, SSM and platelets to rule out high-risk varices (HRV) have been proposed but uncertainty regarding the best algorithm remains. This study explores the utility of SSM for ruling out high risk varices (HRV) in obese MASH cirrhosis.
Method: Patients with known MASH cirrhosis were prospectively invited to have same day LSM, SSM (Fibroscan™ Echosens, Paris), phlebotomy, and upper endoscopy performed. HRV were defined as varices >5mm or varices of any size varices with red signs. Exclusion criteria: hepatocellular carcinoma, prior variceal bleed, non-cirrhotic portal hypertension, portal vein thrombus, aetiologies of liver disease aside from MASH and decompensation within 1 month.
Results: 100 patients attended (50% male, age 63 [IQR 33–86], BMI 33 [IQR 20–57], waist:hip ratio 1 [IQR 0.78–1.19], weekly alcohol consumption 0 [IQR 0–15]). Comorbidities included diabetes (74%), hypertension (67%) and hyperlipidaemia (57%). 39% used GLP-1 agonists. Median LSM 18.3 kPa [IQR 6–60], SSM 42 kPa ([IQR 15–100], 95% success rate), platelet count 195 [IQR 68–502] and CAP score 296 [IQR 185–392]. 80% of endoscopies performed on same day. Varices/HRV were present in 40%/37% of patients. SSM performed similarly to LSM in predicting HRV (p = 0.02, AUROC 0.74; p = 0.01 AUROC 0.7). Optimal SSM cutoffs for ruling in/out HRV were ≥ 76 kPa (specificity ≥ 90%, PPV 36%)/ ≤ 34 kPa (sensitivity ≥90%, NPV 97%). Combining SSM, LSM and platelets improved the ability to detect HRV (SSM/LSM p = 0.01, AUROC 0.75; SSM/LSM/platelets p = <0.001, AUROC 0.89). Three scenarios were tested, each applying a two-of-three criterion for HRV exclusion. Scenario 1 (SSM ≤ 34 kPa, LSM ≤ 15 kPa, platelets ≥ 150) had a sensitivity of 93%/NPV 97%/1% missed HRV rate. Scenario 2 (SSM ≤ 34 kPa, LSM ≤ 20 kPa, platelets ≥ 150) had a sensitivity of 66%/NPV 93%/5% missed HRV rate. Scenario 3 (SSM ≤ 34 kPa, LSM ≤ 25 kPa, platelets ≥ 150) a sensitivity of 53%/NPV 91%/8% missed HRV rate.
Conclusion: SSM improves NIT ability to rule out HRV in obese MASH cirrhosis. Larger MASH cirrhotic cohorts are required to confirm these findings. .

THU-489

Effective prevention of further complications of portal-hypertension is independent of TIPS under-dilation

Davide Roccarina[1], Dario Saltini[2], Marco Senzolo[3], Silvia Nardelli[4], Marcello Bianchini[5], Stefania Gioia[6], Silvia Aspite[7], Kymentie Ferdinande[8], Manuela Merli[4], Oliviero Riggio[4], Fabio Marra[1], Sara Montagnese[8], Filippo Schepis[2], Francesco Vizzutti[1]. Email: francesco.vizzutti@unifi.it

Background and aims: Portal hypertension (PH) is a major determinant of poor prognosis in cirrhosis. An under-dilated transjugular intrahepatic portosystemic shunt (U-TIPS) effectively controls PH-related complications that constitute the indication for the procedure, while reducing the incidence of post-TIPS overt hepatic encephalopathy. However, the benefits of TIPS in preventing additional PH-related complications beyond the initial indication have been reported only for standard-diameter stents. This study evaluated whether U-TIPS provides protection comparable to S-TIPS against further PH-related complications beyond the initial indication, independently of achieving guideline-defined hemodynamic targets for TIPS success.
Method: Patients treated for refractory ascites (RA) or for secondary prophylaxis of PH-related bleeding (PHRB) were included. Adequate hemodynamic response (AHR) was defined as a post-TIPS porto-caval pressure gradient (PCPG) < 12 mmHg in RA, and < 12 mmHg or a reduction ≥ 50% in PHRB. PCPG values outside these thresholds were considered an inadequate hemodynamic response (IHR). Standard TIPS (S-TIPS) was defined as endoprosthesis dilation ≥ 8 mm. Post-TIPS PH-related complications beyond the initial indication—spontaneous bacterial peritonitis, acute kidney injury due to hepatorenal syndrome, hepatic hydrothorax, need for paracentesis, and variceal bleeding—were assessed individually and as a composite endpoint over one year.
Results: Three-hundred fifty-eight patients were included. TIPS indication was RA in 46% and secondary prophylaxis of PHRB in 54%. Seventy-one percent received U-TIPS, while 28% were treated with S-TIPS. AHR was achieved in 71%, while 29% obtained an IHR.The incidence of at least one post-TIPS complication was significantly higher in S-TIPS compared with U-TIPS (14% vs. 6%, p = 0.022), while no significant difference was observed between AHR and IHR groups (8.7% vs. 6.7%, p = 0.543). On multivariable analysis, S-TIPS (OR 3.13, 95% CI 1.38–7.21, p = 0.006), Child-Pugh class B (OR 11.6, 95% CI 2.1–217, p = 0.021) and C (OR 14.4, 95% CI 1.2–343, p = 0.042), and higher MELD score (OR 1.20, 95% CI 1.09–1.32, p < 0.001) were independently associated with post-TIPS complications.
Conclusion: U-TIPS provides non-inferior protection against additional PH-related complications beyond the initial indication compared with S-TIPS, irrespective of the achievement of guideline-defined hemodynamic efficacy targets.

THU-490

Comprehensive transjugular–percutaneous portal hemodynamic assessment (cTP-PHA): safety, feasibility and diagnostic value in patients with undefined or mixed-etiology portal hypertension

Dario Saltini[1], Marcello Bianchini[1], Andrea Salomè Velasco Mayorga[2], Tomas Guasconi[1], Giustina Lo Cascio[2], Antonio Piscopo[2], Nicolò Giglioli[3], Filippo Scianò[1], Fabiola Milosa[3], Rosina Maria Critelli[3], Federico Casari[4], Francesco Ascari[4], Cristian Caporali[4], Giovanni Battinelli[4], Filippo Schepis[1]. [1]*Severe Liver Diseases (M.E.C.) Departmental Unit, Department of Medical Specialties, University Hospital of Modena "Policlinico", University of Modena and Reggio Emilia, European Reference Network on Rare Liver Disorders (ERN Rare-Liver), Modena, Italy;* [2]*Gastroenterology Unit, University Hospital of Modena "Policlinico", University of Modena and Reggio Emilia, Modena, Italy;* [3]*EpatoGastro Lab – RBA-Labs CHIMOMO Department – University of Modena and Reggio Emilia, Modena, Italy;* [4]*Division of Interventional Radiology, University Hospital of Modena "Policlinico", Modena, Italy*
Email: fschepis@unimore.it

Background and aims: Accurate classification of portal hypertension (PH) remains challenging in patients with suspected mixed/

undefined etiologies, where non-invasive tests (NITs) and hepatic venous pressure gradient (HVPG) may be inconclusive due to pre- or post-sinusoidal components. Simultaneous measurement of HVPG, PortoHepatic (PHPG) and PortoCaval pressure gradients (PCPG)—here termed comprehensive Transjugular-Percutaneous Portal Hemodynamic Assessment (cTP-PHA)—allows assessment of both the anatomical site(s) and severity of PH. We evaluated the safety, feasibility and diagnostic utility of cTP-PHA.

Method: We retrospectively analyzed patients undergoing cTP-PHA between 2022–2024 at our Hemodynamic Laboratory for chronic liver disease with clinical signs of PH and suspected non-sinusoidal components. Under local anesthesia and mild sedation, HVPG was measured transjugularly, followed by direct ultrasound (US)-guided transhepatic portal vein pressure measurement (20G Chiba needle), enabling calculation of PHPG and PCPG. All procedures were performed under combined fluoroscopic and US guidance with waveform acquisition. Liver and spleen stiffness were reassessed in the cath-lab, and transjugular liver biopsy was performed when indicated.

Results: Forty-five patients were included (38% male; mean age 57 ± 11 years). Technical success was 100%, with minor complications in 4%. Mean HVPG, PHPG and PCPG were 7 ± 6, 14 ± 9 and 15 ± 9 mmHg, respectively; intrahepatic vein-to-vein shunts were detected in 24%. Pressure gradient analysis identified pure presinusoidal CSPH in 24%, pure sinusoidal CSPH in 11%, mixed sinusoidal–presinusoidal CSPH in 22%, subclinical sinusoidal PH in 16%, and no PH in 27%. A hepato-caval gradient >2 mmHg, indicating an additional post-sinusoidal component, was present in 9% without affecting PH classification. Defining CSPH solely by presence of esophageal varices resulted in 9% false positives, while Baveno VII criteria misclassified CSPH in 16% of cases.

Conclusion: cTP-PHA is a safe and diagnostically definitive technique for characterizing the anatomical site(s) and severity of PH in patients with suspected mixed/undefined etiologies. The presence of esophageal varices without confirmed CSPH challenges current diagnostic paradigms and supports cTP-PHA implementation in referral centers. Prospective studies comparing cTP-PHA with EUS-guided approaches, which measure PHPG alone, are warranted to assess added diagnostic value and cost-effectiveness.

THU-491

Assessment of non-endoscopic follow-up criteria for esophageal varices using platelet count and albumin levels

Shinya Sato[1], Tadashi Namisaki[1], Tatsuya Nakatani[1], Kosuke Kaji[1], Hitoshi Yoshiji[1]. [1]*Department of Gastroenterology, Nara Medical University, Kashihara, Japan*
Email: shinyasato@naramed-u.ac.jp

Background and aims: The Baveno VI and Expanded Baveno VI consensus guidelines propose the use of transient elastography (TE) and platelet (PLT) count to identify patients with cirrhosis who can safely avoid screening esophagogastroduodenoscopy (EGD). However, TE is not universally available. This study aimed to evaluate a simple non-endoscopic algorithm based solely on routine laboratory parameters for predicting medium/large esophageal varices (EV) in patients with cirrhosis and to compare its performance with the Baveno VI and Expanded Baveno VI criteria. A secondary aim was to assess the additional value of TE in excluding high-risk EV.

Method: We retrospectively analyzed 896 patients with liver cirrhosis who underwent upper gastrointestinal endoscopy at our institution between April 2015 and December 2024. Of these, 256 patients with available TE measurements constituted the training cohort for identifying laboratory predictors of EV grade F2–3. The remaining 640 patients without TE data served as an independent validation cohort.

Results: In the training cohort, medium/large EV were detected in 10.0% of patients meeting the Baveno VI criteria and 14.2% of those meeting the Expanded Baveno VI criteria. Multivariate analysis identified platelet count and serum albumin level as independent predictors of medium/large EV. Optimal cut-off values were PLT > $12 \times 10^4/\mu L$ and albumin > 3.5 g/dL, yielding negative predictive values (NPVs) of 96.2% and 95.4%, respectively. Among patients meeting the RESIST-HCV criteria, the NPV was 99.2%. Receiver operating characteristic analysis demonstrated that the combined criterion of PLT > $12 \times 10^4/\mu L$ or albumin > 3.5 g/dL effectively identified patients at very low risk of F2–3 EV. Of 134 patients fulfilling this criterion, only one (0.8%) had F2–3 EV. The addition of liver stiffness < 25 kPa did not significantly improve performance. In the validation cohort, 209 patients met the combined laboratory criteria; only one patient (0.5%) had treatable F2–3 EV, confirming the robustness of the algorithm.

Conclusion: A simple algorithm based on platelet count and serum albumin level can reliably exclude clinically significant esophageal varices and may safely reduce the need for screening EGD, with performance comparable to TE-based criteria. This approach may facilitate broader, cost-effective risk stratification of portal hypertension, particularly in settings where TE is unavailable.

THU-492

Aging influences encephalopathy risk but not survival after TIPS for acute variceal bleeding: EUROTIPS-Chinese multicenter study
